HIGHLIGHTS

- MOC often carry genetic events indicating a targeted therapy and should be entered in basket trials of such agents.
- A distinct subset of MOC are estrogen receptor positive (~11%), suggesting hormonal therapy as an option.
- Mismatch repair deficiency is present in <1% of MOC; the role of checkpoint inhibitors is uncertain.
- Rarity of homologous recombination deficiency means MOC is unlikely to respond to platinum-based therapy/PARP inhibitors.

ABSTRACT

Objective. Mucinous ovarian carcinoma (MOC) is an uncommon ovarian cancer histotype that responds poorly to conventional chemotherapy regimens. Although long overall survival outcomes can occur with early detection and optimal surgical resection, recurrent and advanced disease are associated with extremely poor survival. There are no current guidelines specifically for the systemic management of recurrent MOC. We analyzed data from a large cohort of women with MOC to evaluate the potential for clinical utility from a range of systemic agents.

Methods. We analyzed gene copy number ($n = 191$) and DNA sequencing data ($n = 184$) from primary MOC to evaluate signatures of mismatch repair deficiency and homologous recombination deficiency, and other genetic events. Immunohistochemistry data were collated for ER, CK7, CK20, CDX2, HER2, PAX8 and p16 ($n = 117$ – 166).

Results. Molecular aberrations noted in MOC that suggest a match with current targeted therapies include amplification of *ERBB2* (26.7%) and *BRAF* mutation (9%). Observed genetic events that suggest potential efficacy for agents currently in clinical trials include: *KRAS/NRAS* mutations (66%), *TP53* missense mutation (49%), *RNF43* mutation (11%), *ARID1A* mutation (10%), and *PIK3CA/PTEN* mutation (9%). Therapies exploiting homologous recombination deficiency (HRD) may not be effective in MOC, as only 1/191 had a high HRD score. Mismatch repair deficiency was similarly rare (1/184).

Conclusions. Although genetically diverse, MOC has several potential therapeutic targets. Importantly, the lack of response to platinum-based therapy observed clinically corresponds to the lack of a genomic signature associated with HRD, and MOC are thus also unlikely to respond to PARP inhibition.

1. Introduction

Mucinous ovarian carcinoma (MOC) is a rare histotype of epithelial ovarian cancer (EOC), comprising 3–5% of EOC cases [1] with distinct epidemiological differences including weaker associations with reproductive and hormonal factors such as parity and oral contraceptive use [2]. Diagnosis is often at an early stage, with surgical resection of large unilateral tumors resulting in curative outcomes in many cases. However, recurrent and in particular high-grade MOC are classically resistant to conventional platinum/taxane therapy [1,3]. Median survival for Stage III/IV disease is <15 months compared to 41 months for serous and 51 months for endometrioid histologies [4]. Nonetheless, there are no alternative approved treatment guidelines due to a lack of evidence for efficacy. Internationally coordinated attempts to develop MOC clinical trials to assess regimens designed for mucinous gastrointestinal cancers unfortunately met with little success, with recruitment of these rare cases proving to be highly challenging and overt clinical efficacy not observed with the number of primary MOC cases included [5].

As a strategic and much needed step toward the development of novel and targeted therapies for MOC, an international collaborative effort was formed to amass the largest known cohort of patients with annotated primary MOCs. With investigation including extensive genomic, transcriptomic, immunohistochemical and associated clinical data, we aimed to evaluate current and alternate therapeutic options for this rare and chemotherapy resistant tumor type.

2. Materials and methods

2.1. Cohort and pathology review

The GAMuT cohort has been described previously (Supplementary Table 1) [6]. Centers and investigators with specialized ovarian cancer interest were approached to contribute to an international collaboration to advance the knowledge and potential for mucinous ovarian cancers. We obtained primary mucinous tumor samples, and metastases to the ovary from other sites, from 12 different sources in four countries: Australia: Royal Women's Hospital, the Victorian Cancer Biobank, The Hudson Institute of Medical Research (all Victoria); Garvan Institute, The Gynaecological Oncology Biobank at Westmead (New South Wales); Queensland Institute for Medical Research (Queensland); Australian Ovarian Cancer Study (Australia-wide); United Kingdom: Southampton, and Edinburgh Cancer Research Centre; United States: the Mayo Clinic (MN); Canadian Ovarian Experimental Unified Resource (COEUR, Quebec, Canada) and OVCARE (British Columbia, Canada). All women provided informed consent for the use of their tissue for research and this study was conducted in accordance with the Declaration of Helsinki. All cases underwent expert pathology review of at least one diagnostic slide by PEA, MC, JP, CBG or MK, as well as clinical review to confirm primary mucinous ovarian status. Clinical data was collected by medical record review or tissue bank databases.

Metastatic cases were mucinous tumors excluded as being primary ovarian, mostly from the lower gastro-intestinal tract ($n = 12$), upper gastro-intestinal tract ($n = 9$) or uterus ($n = 4$), 1 unknown.

2.2. Genetic data

DNA was extracted from microdissected tumor cells as described [6]. DNA sequencing was performed using either whole genome ($n = 5$), exome ($n = 46$) or targeted sequencing ($n = 133$) using an Agilent SureSelect panel of 507 genes [6]. Four new cases analyzed with the targeted panel are included that were not part of Cheasley et al. Detected variants were filtered as previously described to obtain a high-confidence set of somatic variants. Data are available through the European Genome Archive, submission EGAS00001003545. Mutation figures generated by Mutation mapper in the cBioPortal [46].

Existing SNP array data were used when available for copy number data. Otherwise copy number data were obtained from exome sequencing using AdTex [7], whole genome sequencing using FACETS (v0.5.6) [8], and from the targeted sequencing panel using CopywriteR [9]. Thresholds were \log_2 ratios of ± 0.2 for gains and losses, >0.6 for high level gains and <-1 for homozygous deletions.

We evaluated HRD by mutational signatures (exome/whole genome only) [10] as well as copy number profiles (HRD score). HRD score was calculated as described [11], except that calls were made manually due to the diverse platforms used and the relative simplicity of most genomes.

2.3. Immunohistochemistry

Immunohistochemical staining was performed by the Peter MacCallum Cancer Centre Anatomical Pathology department using standard clinical assays. For ER, we considered any staining in $>1\%$ of cells to be positive. In 18/132 cases, ER staining status was obtained from the pathology report. HER2 was scored according to international guidelines for breast cancer, with 0 and 1+ considered negative, 2+ equivocal, and 3+ positive [12]. Final amplification status for equivocal cases was determined by copy number analysis using sequencing or SNP array data (Supplementary Table 2).

3. Results

The current cohort includes collected tissues and associated clinical data from 12 archival sources from four different countries. Tissue and/or data was collected from 202 MOC cases diagnosed between 1993 and 2017 (Table 1, Supplementary Table 1). Available clinical data varied widely between sources, but in brief includes 157 early stage (FIGO I-II) and 25 late stage (III-IV) cases. Sequencing data was obtained by whole exome or whole genome sequencing (WES/WGS, $n = 51$) or using a targeted panel ($n = 133$). For comparison, we include

data for mucinous borderline tumors (n = 28) and mucinous tumors that are metastases from extra-ovarian sites (n = 26).

3.1. Clinical management

A review of management was possible in 167 of the 201 cases. A total of 89 women (53%) were treated with surgery alone. For the cases with chemotherapy details available, 72/74 (97%) women received a platinum-based regimen, usually with a taxane in the first line (61/74, 82%) (Supplementary Fig. 1). Stage was strongly correlated with chemotherapy provision, increasing from 33% of patients diagnosed with Stage I MOC (41/124) to 83% for Stage II-IV (35/42). Data for second and subsequent line therapy was limited to 23 cases, across which it was notable that 16 different therapeutic regimens were prescribed, illustrating the lack of treatment guidelines or consensus for the management of this rare subset of ovarian cancer.

3.2. Homologous recombination deficiency

Homologous recombination deficiency (HRD) is an important clinical correlate in ovarian cancer, strongly predicting response to platinum-based therapies and PARP inhibition. Of 51 cases analyzed by WES/WGS, no cases showed a point mutational signature of HRD [10]. A single case carried a pathogenic *BRCA2* mutation (8923; Asn1784HisfsTer2), however, the allele frequency in tumor tissue was only 0.23 and this case had a low copy-number derived HRD score [11]. A co-existing *TP53* mutation had an allele frequency of 0.75, suggesting moderate tumor purity. Copy number loss and allelic imbalance across chromosome 13 indicates the loss-of-function *BRCA2* allele, likely germline, may have been lost in the tumor, with detection of the allele attributable to the presence of non-tumor cells in the DNA extraction. Therefore, while occurring in a *BRCA2* carrier, the MOC appeared unlikely to be an HRD-driven tumor. Copy number analysis of 191 cases found just one with a profile complex enough to be classified as HRD-high (Fig. 1A, score > 55; case WB87/8583). This HRD-high case had a co-existing *TP53* mutation but no mutations in HRD-related genes. Pathology review of diagnostic slides confirmed a high-grade mucinous histology, including areas of borderline differentiation. Seven other cases (3.8%) showed an HRD score of >42, placing them in a category of possible responders [13].

3.3. Mismatch repair deficiency (MMR)

We evaluated the presence of MMR deficiency by mutation burden analysis and identifying cases with mutations in any of the genes in the pathway. One case of the 184 sequenced MOC (C1981) carried a high mutation burden on targeted sequencing (>40 variants per Mb [14], Fig. 1B) and a mutation in *MSH6* (p.Arg1334SerfsTer7), although no germline DNA was available to determine if this was somatic or not. A second MOC case (IC381) diagnosed at age 73 carried a germline *MSH6* variant (c.4065_4066insTTGA, p.Lys1358AspfsTer2); the tumor

did not carry an elevated number of mutations, nor LOH of the wild-type allele. This variant occurred just 5 amino acids before the natural termination codon, and thus its impact on *MSH6* function may be minimal, with variants in a similar region classified as class 1 or 2 (benign) in ClinVar [15], for example c.4068_4071dup (p.Lys1358Aspfs) is classed “likely benign”. In contrast, 4/23 (17%) mucinous tumors metastatic to the ovary (two colorectal, two endometrial) had a high mutation burden and/or truncating mutation in one of *MSH2* or *MSH3*. Thus, as MOC cases harboring a high mutational burden are rare, single agent therapy with immune checkpoint inhibitors is unlikely to be helpful for the majority.

3.4. *HER2* and *HER3*

Copy number data were assessed in 191 cases, with *ERBB2* amplification found in 51 cases (26.7%). Amplifications were all high level and focal, similar to those seen in breast and gastric cancer (Fig. 2, Supplementary Fig. 2). IHC for *HER2* was carried out in 61 of 191 cases. We compared our copy number results derived from SNP arrays and sequencing to IHC and observed strong concordance of 3+ staining with amplified and 0/1+ with non-amplified status in MOC (56/61, 91.8%). Two cases were amplified but IHC negative (10673, 8981), and three cases were either 2+ for IHC but not amplified (8488, VOA1675) or 2+ and amplified (IC392). The reasons for the 2+ interpretation varied. In two MOC (IC392, VOA1675) this was likely due to a subclonal amplification whereby intense membranous IHC staining was only focally present (Fig. 2C). Amplified/IHC positive cells may have been sampled (IC392) or not (VOA1675) from the frozen tumor piece used for DNA extraction. In contrast, for 8488 sequencing data indicated a low-level copy number gain across all of 17q associated with 2+ staining.

In one MOC case (8981) with negative *HER2* IHC from a tissue microarray (TMA), but positive copy number amplification by sequencing, we repeated in situ analyses using whole sections. The results provide evidence for intratumoral heterogeneity (Supplementary Fig. 2). The sensitive sequencing assay was able to detect an amplification, but the original IHC by TMA did not contain the part of the tumor that was amplified. Interestingly, this case was primarily a borderline tumor, and a small group of cells showing abnormal morphology within the full section was the only area positive by CISH but showed only modest protein staining (Supplementary Fig. 2).

We observed no *ERBB2* mutations, but a small number of *ERBB3* mutated tumors were detected in our cohort (n = 8, 4.3% MOC, Supplementary Fig. 3). The mutation distribution was similar to that seen in COSMIC [16], with the majority of variants being observed in the receptor and furin domains.

3.5. Other targetable genes

We assessed 184 cases for mutations in other potentially targetable genes (Fig. 2). We observed 16 (8.7%) cases with *BRAF* mutations in MOC, however, 7 of these cases did not carry the typical V600E mutation

Table 1
– Cohort for genomic and IHC analysis.

	Discovery sequencing	Validation sequencing	Copy number	IHC (ER)
Mucinous borderline (n = 109)	9	18	39	80
Mucinous carcinoma (n = 198)	51	133	191	132
Grade				
G1	21 (41%)	62 (47%)	86 (45%)	61 (46%)
G2	22 (43%)	55 (42%)	79 (41%)	51 (39%)

II	2 (4%)	8 (6%)	10 (5%)	9 (7%)
III-IV	10 (20%)	17 (13%)	25 (13%)	22 (17%)
Stage missing	2 (4%)	6 (4%)	9 (5%)	3 (2%)
Extra-ovarian metastases (n = 36)	2	24	29	23

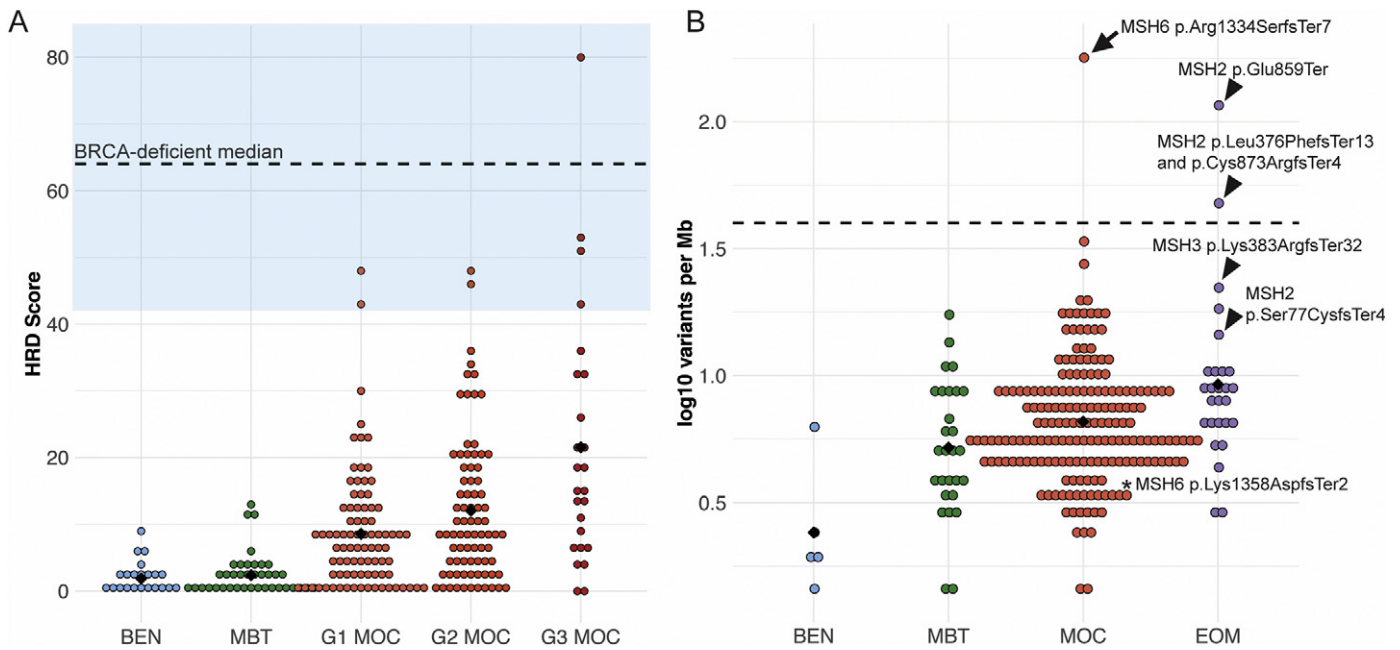

Fig. 1. Prevalence of DNA damage repair pathways. A. Homologous recombination deficiency was measured as in Marquard et al. [11] (HRD Score) and shows that MOC rarely have a score above that used to predict response to platinum or PARP inhibitors (BRCA-deficient median and blue zone indicating HRD Score >42 that may respond to platinum from Telli et al. [13]). Black diamond is the mean HRD Score. B. Mismatch repair deficiency is also rare, as indicated by the mutation burden: Mutations per Mb, log₁₀ transformed, black diamond is the mean, dashed line is a suggested threshold for mismatch-repair deficiency detection from Nowak et al. [14]. Arrow, MOC with *MSH6* mutation, arrowheads, extra-ovarian metastases (EOM) with MMR gene mutations, *, MOC with *MSH6* mutation that is likely non-pathogenic. BEN, benign mucinous tumor, MBT, mucinous borderline tumor.

(Supplementary Fig. 3), and four of these seven also carried a *KRAS* mutation (although three of these were atypical but likely still oncogenic: p.Lys5Asn, p.Gly13dup and p.Gln61His). *KRAS* mutations were observed in 118/184 MOC (64%) and *NRAS* in 3/184 cases (1 also with a *KRAS* mutation).

Fifteen of 184 MOC and 4/39 mucinous borderline tumors were found to harbor mutations in *PIK3CA*. However, the mutation spectrum was very different to that in COSMIC, with 8 variants in the PI3-kinase domain, just one at the p.H1047 hotspot and two nearby, and the remaining 8 at other unusual locations in the first 500 amino acids (Supplementary Fig. 3). In COSMIC, <20% of the mutations are outside of the hotspots in exons 9 and 20 (+/- 5 amino acids), but these comprised 10/19 (53%) of the mutations we observed. This 2.5-fold higher rate of non-hotspot mutations is significantly different from expected based on COSMIC ($p = 0.003$, binomial exact two-tailed test). Two of 185 MOC had inactivating events in *PTEN* (1 truncating mutation, 1 homozygous deletion) that were exclusive of *PIK3CA* mutations.

Other molecularly targeted agents that are not currently in the clinic, but are in clinical trials include Wnt-pathway inhibitors (*RNF43* mutations), mutant p53 reactivating drugs (*TP53* missense mutations) and epigenetic modifiers (*ARID1A* mutations). Mutations in these genes are detected in our cohort at varying frequencies (Table 2).

We evaluated whether any mutations were enriched in grade 3 tumors, as a proxy for the infiltrative subtype of MOC that is at higher risk of recurrence [17], and found that mutations in *PIK3CA* were more common in grade 3 than other grades (grade 3 6/24 versus grade 1, 4/83 and grade 2, 5/77, $p = 0.049$, Fishers exact test with Benjamini-Hochberg correction for multiple testing). Conversely, mutations in *RNF43* were absent in grade 3 cases (corrected p value = 0.003).

3.6. Estrogen receptor (ER) status

We evaluated ER expression in 132 MOC cases, with positive staining seen in 14 cases (10.6%, Supplementary Fig. 4). There was a trend for ER positivity to increase with grade from 5% of grade 1 cases up to 20% of grade 3 cases ($p = 0.035$, Cochran-Armitage test for trend,

$Z = -2.10$). In contrast, just 1/80 borderline cases (1.25%) were ER+ (Fig. 2C). ER staining in MOC was positively associated with tumor PAX8 staining, with 8/12 ER+ cases also PAX8+ (Supplementary Fig. 4). The genetic events in this group were distinct, with significantly fewer *TP53* mutations and *CDKN2A* losses in ER+ MOC and significantly more *CTNNB1* mutations (Supplementary Fig. 4).

4. Discussion

In molecular profiling of MOC, we have identified current therapies that are unlikely to be effective (cisplatin, PARPi, immune checkpoint inhibitors), and in contrast, we highlight a range of targeted therapies worthy of focus, which could have an impact in the near future on individual cases of MOC (Table 2). The low rate of HRD in MOC is consistent with previous studies showing a generally stable genomic profile and a low rate of germline *BRCA1/2* mutations [18]. It is also consistent with the reported lack of response to platinum-based therapies, although we were unable to directly correlate HRD scores with response. It is important to highlight that we should avoid prescribing therapy for patients with a rare cancer if there is evidence for a high probability that patients are highly unlikely to receive benefit. Instead, such patients would be better off having investigation for molecular matching of therapy, if evidence suggests the likelihood of targetable aberrations in their rare tumor type [19].

Early reports suggested an association of MMR deficiency with non-serous ovarian cancer histotypes, including mucinous carcinoma [20]. This indication, together with the potential for MMR deficiency in gastrointestinal/endometrial origin tumors with adnexal metastasis [21,22], means it is not uncommon for clinicians to request immunohistochemistry of MMR proteins in MOC. More recent studies have suggested that MMR-deficient ovarian cancer is only common in the endometrioid histotype [23,24]. The difference in the rates of MMR deficiency observed in our study compared to older cohorts may be explained by our careful selection of primary MOC, whereas older studies will include cases of endometrial and colorectal origin. The detection of MMR deficiency in a fairly high proportion of our non-

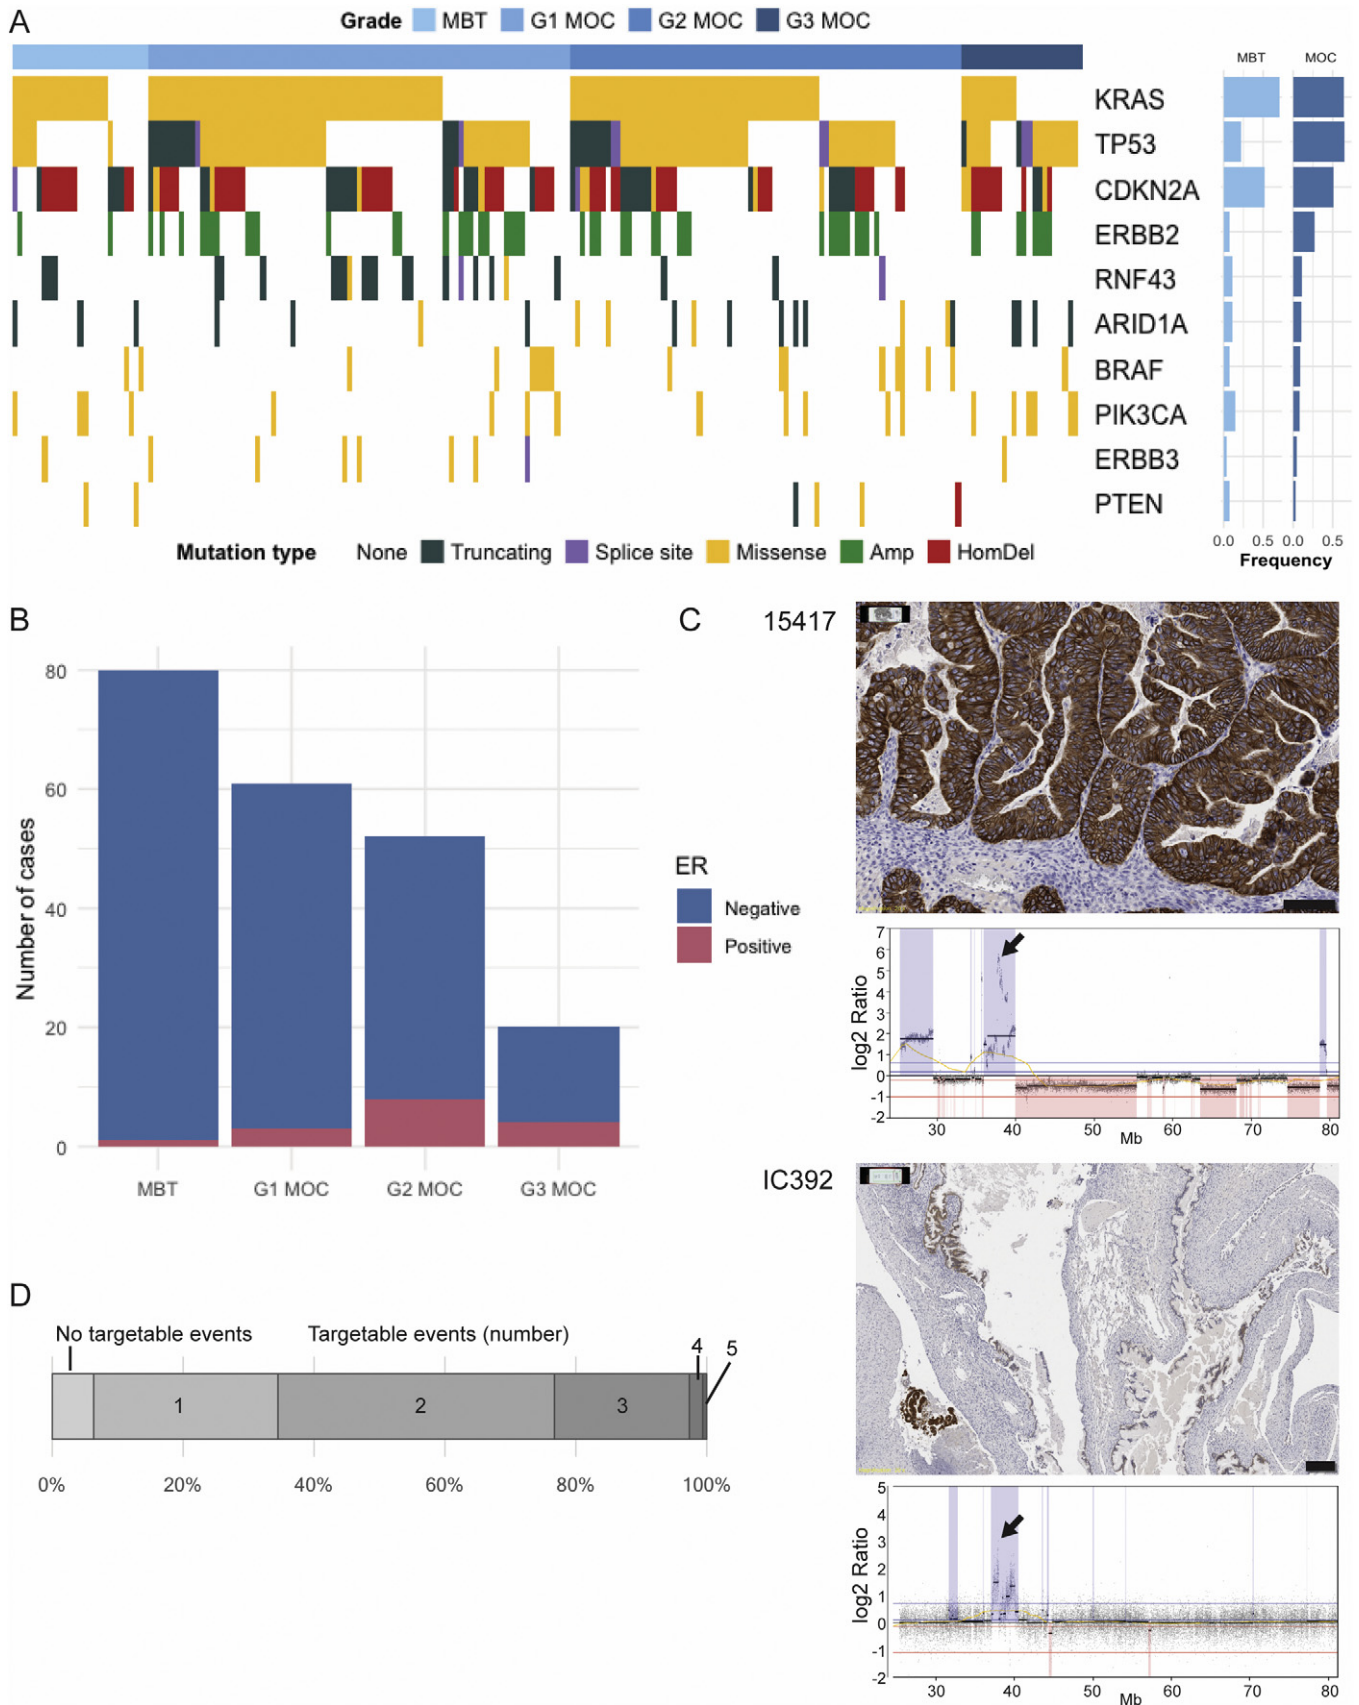

Fig. 2. Targetable events in mucinous ovarian cancer. A. Genetic events potentially targetable in MOC. MBT = mucinous borderline tumor n = 27, G1 MOC n = 83, G2 MOC n = 78, G3 MOC n = 24. Mutation type: Amp = Amplification (*ERBB2* only); HomDel = Homozygous deletion (*CDKN2A* only). B. ER immunohistochemistry status by MOC grade. C. *ERBB2* amplification and HER2 immunohistochemistry. Case 15417 showing concordance of 3+ staining and high-level amplification (Scale bar 100 μ m). Table 2
Potentially targetable events in MOC.

Genetic event	N ^a in MOC (%)	Potential therapy
Currently in the clinic for other cancer types	79 (42.9%)	
<i>ERBB2</i> amplification	51 (26.7%)	Anti Her2 monoclonal antibody therapy, Anti Her2 Mab conjugate therapies, Anti-Her2 tyrosine kinase inhibitors
<i>BRAF</i> mutation (any)	16 (8.7%)	<i>BRAF</i> inhibitors
<i>BRAF</i> mutation (V600E)	9 (4.9%)	
High HRD score (>55)	1 (0.5%)	Platinum salts, PARP inhibitors
Moderate HRD score (42–55)	7 (3.8%)	
ER positivity	14 (10.6%)	Anti-estrogens, CDK4/6 inhibition
Mismatch repair deficiency	1 (0.5%)	Immune checkpoint inhibitors
Currently in trials for other cancer types	167 (90.8%)	
<i>KRAS</i> , <i>NRAS</i> mutation	118, 3 (65.8%)	Broad spectrum RAS/RAF inhibition, MEK inhibition
<i>TP53</i> missense mutation	90 (48.9%)	Mutant p53 reactivators
<i>RNF43</i> mutation	21 (11.4%)	FZD inhibition, PORCN inhibitors
<i>ARID1A</i> mutation	19 (10.3%)	Epigenetic modifiers (e.g. BET inhibitors, EZH2 inhibitors), ATR inhibitors
<i>PIK3CA</i> mutation, <i>PTEN</i> inactivating	15, 2 (9.2%)	PI3-kinase inhibitors, AKT inhibitors
<i>ERBB3</i> mutation	8 (4.3%)	Anti-Her2 tyrosine kinase inhibitors, anti-Her3 Mab conjugate therapies
Not yet targetable		
<i>CDKN2A</i> inactivating	82 (44.6%)	
<i>TP53</i> truncating/ESS mutation	30 (16.3%)	

^a Mutation data denominator = 184; copy number denominator = 191.

ovarian mucinous cohort supports this contention. Our findings suggest little benefit from reflex MMR IHC testing for MOC unless there was a strong suspicion of extra-ovarian origin. The low rate of MMR-deficiency suggests that single agent immune checkpoint inhibition may have limited potential benefit, however the immune microenvironment remains unexplored in MOC, and it is necessary to assess whether these tumors are immunologically “hot” by other mechanisms and could therefore benefit [25].

Previous data in MOC found that *ERBB2* amplification was present in ~20% of cases [26], and our data found a similar proportion. Targeting HER2 in MOC has been attempted anecdotally with mixed results [26] but a clinical trial failed to recruit enough patients. The high-level and focal nature of the amplifications and the strong over-expression in most MOC suggests this could be a viable target, however, response cannot be guaranteed. We observed substantial heterogeneity in the presence of amplification, and in the strength of HER2 positive staining by IHC (e.g. 10405, Supplementary Fig. 2). *ERBB2* amplification appears to be a relatively late event in MOC development, as it occurs significantly less frequently in borderline tumors. Heterogeneity within the carcinoma component may indicate firstly, that treatment with anti-HER2 therapies may not be effective on all tumor cells and secondly, that recurrence testing may be required for metastatic disease. Additionally, anti-HER2 antibody monotherapy (e.g. trastuzumab) is most effective in the presence of a strong immune infiltrate [27] and a combination with a small molecule tyrosine kinase inhibitor may be required in tumors with low immune response. Alternatively, a conjugate therapy that exploits an antibody to the overexpressed HER2 to deliver a toxic payload may be of greater efficacy (e.g. Trastuzumab-DM1 or Trastuzumab-deruxtecan). In addition, the strong co-existence of *TP53* mutation with *ERBB2* amplification provides a strong rationale for attempting p53 normalizing therapies [28] in combination with anti-HER2 therapy.

It is unclear at present whether mutations in *ERBB3* lead to long-term responses by small molecular inhibitors. A recent basket trial did not see any responses to neratinib across several tumor types [29]. In addition, the same trial saw responses in *ERBB2* mutated tumors, most often in breast cancer but not colorectal cancer. Differences in response were also observed depending on the mutation type and location. In the MOSCATO trial, the best response of an *ERBB3* mutated tumor was a partial response to combined trastuzumab and lapatinib, while stable disease was recorded in 7/9 patients treated with afatinib (n = 2), combined trastuzumab and lapatinib (n = 2), lapatinib alone (n = 1) or other combinations (n = 2) [30]. The best responses to lapatinib were in tumors with mutations in the tyrosine kinase domain [30], however only one of the mutations detected in our MOC cohort was

located in this domain. The small percentage of MOC with *ERBB3* mutations could present an alternative therapeutic opportunity but will likely require combination therapy.

BRAF inhibitors are in current clinical practice for melanoma and show promise for low-grade serous ovarian carcinoma [31], but have shown little efficacy in colorectal carcinoma [32]. Whether MOC would respond to this class of agent remains unclear but again may be worthy of exploration. The high rate of non-V600E mutations in MOC suggests a lower potential response to existing *BRAF* inhibitors such as vemurafinib, but MOC may be responsive to new combined RAS-RAF inhibitors. *BRAF*, *NRAS* and *KRAS* mutant cases together comprise over 70% of MOC and these women could now be included in combination clinical trials of dual RAS/RAF inhibitors such as BGB-283 [33] (e.g. NCT03905148). Similarly, while we observed an overall mutation rate of ~9% in *PIK3CA/PTEN*, suggesting that targeting the PI3-kinase pathway is worth considering during therapy selection [34], the clinical significance of the frequent *PIK3CA* mutations outside of the usual hotspots is unclear. Inhibitors targeting the PI3-kinase pathway are in clinical development for the management of advanced endometrial, breast and other cancer types (for example alpelisib (*PIK3CA*-mutated) and buparlisib (pan-PI3K) [35]), with some inhibitors not limited specifically to the PI3kinase domains, but others more broadly targeting the AKT/*PTEN*/PI3K pathways. One of the most common genetic events in MOC is *CDKN2A* inactivation, however, whether this gene is a biomarker for response to CDK4/6 inhibition remains an open question that may be tumor-type specific [36].

Low-grade serous and endometrioid ovarian carcinomas have high frequencies of ER protein expression [37]. It has been suggested that these histotypes may respond to hormonal therapy [38–40]. The percentage of ER+ cases we observed (10.6%) is consistent with a recent OTTA study, which found that 16% of MOC had strong ER expression [37], but others report rates as low as 4% up to 19% [41–44]. None of the MOC cases in our cohort appear to have received hormonal therapy, hence hormonal response data within this cohort is unknown. It is worth noting that this subset of ER+ MOC in our cohort appears to be distinct from ER- MOC, based on their genetic features. We speculate that these ER+ cases could represent a subset of MOC with an origin in endometriosis, in a spectrum of tumors incorporating those previously known as “seromucinous” or “endocervical” types. Unfortunately, the clinical and histopathology data with respect to the presence or absence of endometriosis was incomplete in our cohort, and we could not assess this potential association. An alternative explanation is that some of these ER+ cases could in fact have been misdiagnosed endometrioid carcinomas, a recently recognized issue [44]. Data from Rambau et al. showed that the seromucinous type most often resembled an endometrioid ovarian carcinoma at a molecular level [45]. The ER+

MOC in our cohort were intermediate on a molecular level, with more *CTNNB1* mutations than ER- MOC, but more *TP53* mutations and fewer *PIK3CA* mutations than endometrioid carcinomas (Supplementary Fig. 4). Inclusion of ER (and PR [44]) in the diagnostic work-up for MOC in the future will therefore be important, both to exclude misdiagnosed endometrioid cases and for therapeutic stratification. Inclusion of patients with ER positive MOC in trials, for example basket trials of Aromatase Inhibitors, would provide useful information.

In summary, this exploration of the molecular therapeutic landscape of MOC is the largest undertaken to date and has identified many avenues for investigation. We have summarized these avenues in Fig. 3. If we consider all variants reported in this study as potentially targetable, plus the known targets in other cancer types (*BRAF* and *ERBB2/3*), then the proportion of cases with at least one theoretically targetable event was 93.5%, with 65% of cases having two or more targetable events. However, there is currently no evidence for these therapies in MOC.

Given the tissue specificity of some targeted therapies, preclinical data using genomically characterized patient-derived models in vitro and in vivo are urgently required to evaluate efficacy. Nonetheless, multiple clinical trials with specific molecular targets are in progress and women diagnosed with MOC would greatly benefit from trials that performed DNA sequencing to identify the most suitable targeted therapy (Table 2). In addition, in order to maximize benefit, such trials should be targeted to those agents with the greatest pre-clinical efficacy. Clinical response, and lack of response, to targeted therapies must be reported along with biomarker information to build an evidence base in humans. Importantly, 23% of women were found to have MOC harboring three or more targetable mutations which may increase their chance of responding to targeted therapy combinations in the future [19]. This approach contrasts with current practice of prescribing platinum-based chemotherapy, which provides little benefit but imposes considerable toxicity. While these potential targets likely over-represent the reality

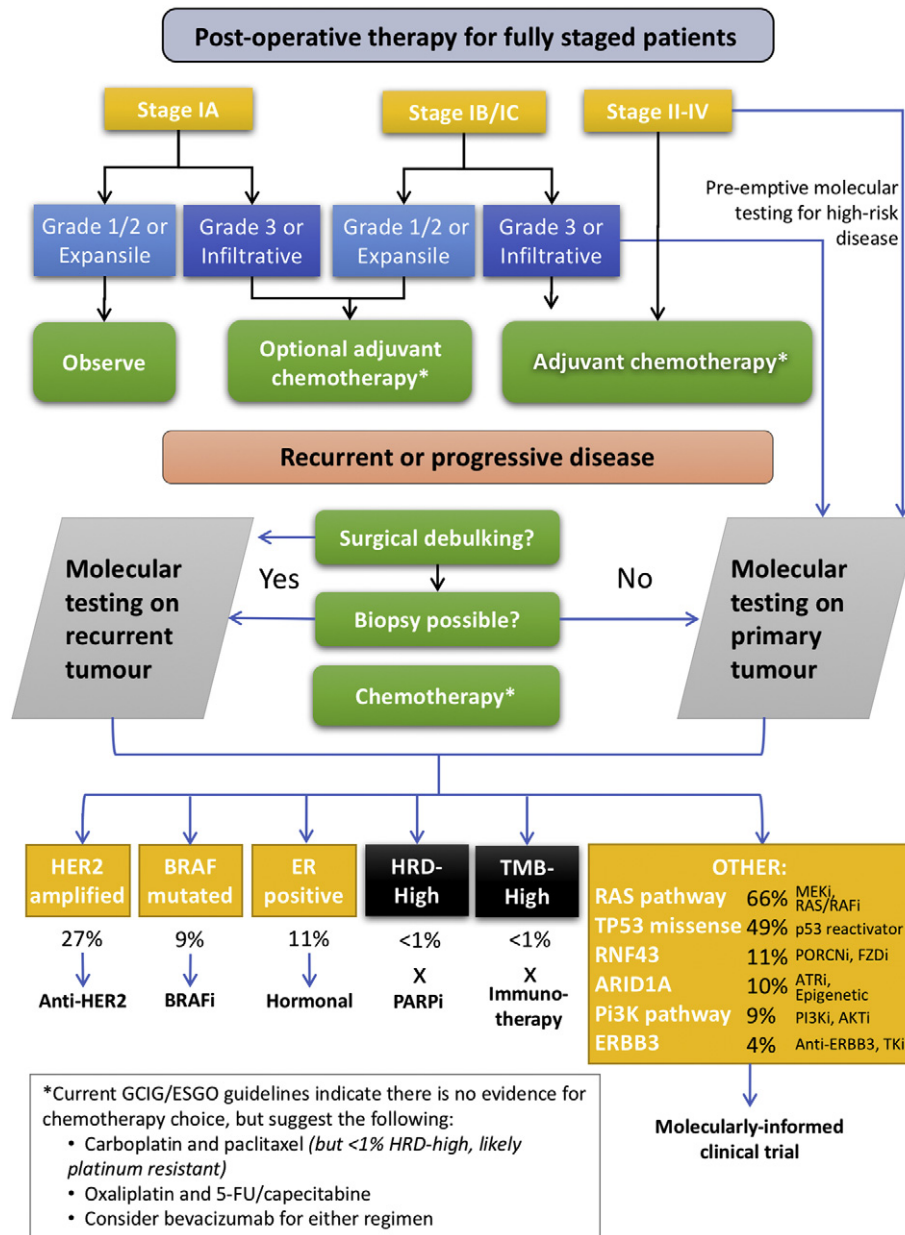

Fig. 3. Clinical pathway for therapy choice in MOC. We suggest that high-risk disease (grade 3/advanced stage/infiltrative subtype) should be pre-emptively tested for genomic events using a suitable panel method, since these are unlikely to respond completely to the adjuvant chemotherapy that will be offered while genomic testing is performed. On recurrence of non-high risk disease, genomic testing should also be performed, preferably on recurrence tumor tissue if this is available through surgical debulking or biopsy. If not, primary tumor tissue could be used. ER, estrogen receptor; HRD, homologous recombination deficiency; TMB, tumor mutational burden; "i", inhibitor. TKi, tyrosine kinase inhibitor.

of tumor response, for a tumor type with such poor outcomes and no specific treatment recommendations the potential for therapeutic exploration appears bright.

Ethics statement

This study was approved by the Peter MacCallum Cancer Centre and Royal Melbourne Hospital Human Research Ethics Committees, ID #14/76, #01/38 and #2011-248. Informed consent was obtained for all patients in the study. All relevant ethical regulations have been complied with.

Author contributions

Apart from first and senior authors, all are listed in alphabetical order. PEA, MCr, CBG, MK, and JP undertook pathology review of cases; KA, DDLB, YEC, MCh, ADF, CG, JH, CJK, KRK, SHK, CLP, JNM, OMM, JP, ANS and NTr provided access to tissue and/or prepared tissue samples; KA, SA, MCh, SF, AMH, GYH, TJ, CJK, KRK, JNM, CLP, and NTr provided clinical information; KCA, KLG, RL, JL, NTH, MJW and MZ performed bioinformatics analyses; DC, SH, SMH, GLR, SMR, HS, CS, AJS and MCT performed nucleic acid extraction, PCR and Sanger sequencing. DC, and GLR performed sequencing library preparations. KLG and GLR coordinated the study. DC, KLG, CS, MJW and MCT analyzed the data. YCA, IGC, KLG, CLS and MJW conceived of and designed the study and were involved at all stages. KLG prepared the figures and drafted the manuscript, which was then extensively edited by YCA, DDLB, DC, IGC, ADF, MK, SHK, JNM, CLS, and MJW. All other authors read and commented on the manuscript and approved the final version.

Declaration of competing interest

The authors declare no conflicts of interest. ADF, NT and DDLB have received research grant funding from AstraZeneca, unrelated to the contents on this manuscript. DDLB also reports funding from Roche-Genentech and BeiGene, also unrelated. CG reports funding from AstraZeneca, Roche, Clovis, Tesaro, Foundation One, Nucana, Aprea, Novartis, Chugai, and MSD, all outside the submitted work. CLS reports non-financial support and/or other support from Clovis Oncology, Roche, Eisai Australia, Beigene, Sierra Oncology, and AstraZeneca, all outside the submitted work.

Acknowledgements

The authors acknowledge the Bioinformatics and Molecular Genomics Core Facilities of the Peter MacCallum Cancer Centre, which were supported by the Australian Cancer Research Foundation. We thank Margot Osinski and Estefania Vicario (Royal Women's Hospital) for database assistance, Rhiannon Dudley and Nicole Fairweather (Hudson Institute of Medical Research), Maret Böhm (Garvan Institute of Medical Research), Gwo-Yaw Ho (WEHI) and Kimberly Kalli (Mayo Clinic) for assistance in sample collection and/or annotation.

Financial support

This study was supported by the National Health and Medical Research Council of Australia (NHMRC) Grants #APP1045783 and #628434, the Victorian Cancer Agency (Clinical Fellowships to CLS CRF10-20, CRF16014), Cancer Council Victoria (Sir Edward Dunlop Fellowship in Cancer Research to CLS); the Peter MacCallum Cancer Foundation, and the Stafford Fox Medical Research Foundation. This work was made possible through the Australian Cancer Research Foundation, the Victorian State Government Operational Infrastructure Support and Australian Government NHMRC IRIISS. The Bioinformatics and Molecular

Genomics Core Facilities of the Peter MacCallum Cancer Centre were supported by the Australian Cancer Research Foundation.

The following cohorts were supported as follows:

CASCADE: Supported by the Peter MacCallum Cancer Foundation.

AOCS: The Australian Ovarian Cancer Study Group was supported by the U.S. Army Medical Research and Materiel Command under DAMD17-01-1-0729, The Cancer Council Victoria, Queensland Cancer Fund, The Cancer Council New South Wales, The Cancer Council South Australia, The Cancer Council Tasmania and The Cancer Foundation of Western Australia (Multi-State Applications 191, 211 and 182) and the National Health and Medical Research Council of Australia (NHMRC; ID400413 and ID400281).

The Australian Ovarian Cancer Study gratefully acknowledges additional support from Ovarian Cancer Australia and the Peter MacCallum Foundation. The AOCS also acknowledges the cooperation of the participating institutions in Australia and acknowledges the contribution of the study nurses, research assistants and all clinical and scientific collaborators to the study. The complete AOCS Study Group can be found at www.aocstudy.org. We would like to thank all of the women who participated in these research programs.

COEUR: This study uses resources provided by the Canadian Ovarian Cancer Research Consortium's - COEUR biobank funded by the Terry Fox Research Institute and managed and supervised by the Centre hospitalier de l'Université de Montréal (CRCHUM). The Consortium acknowledges contributions to its COEUR biobank from Institutions across Canada (for a full list see http://www.tfri.ca/en/research/translational-research/coeur/coeur_biobanks.aspx).

The Gynaecological Oncology Biobank at Westmead is a member of the Australasian Biospecimen Network-Oncology group, which was funded by the National Health and Medical Research Council Enabling Grants ID 310670 & ID 628903 and the Cancer Institute NSW Grants ID 12/RIG/1-17 & 15/RIG/1-16.

OVCARE receives core funding from The BC Cancer Foundation and the VGH and UBC Hospital Foundation.

Mayo Clinic: National Institutes of Health (R01-CA122443, P30-CA15083, P50-CA136393); Mayo Foundation; Minnesota Ovarian Cancer Alliance; Fred C. and Katherine B. Andersen Foundation.

Edinburgh: We extend our thanks to the Edinburgh Ovarian Cancer Database from which data were collected for this research and the Nicola Murray Foundation for supporting the Nicola Murray Centre for Ovarian Cancer Research.
