Abstract

We present physical properties of radio galaxies (RGs) with $f_{1.4 \text{ GHz}} > 1 \text{ mJy}$ discovered by Subaru Hyper Suprime-Cam (HSC) and Very Large Array Faint Images of the Radio Sky at Twenty-Centimeters (FIRST) survey. For 1056 FIRST RGs at $0 < z \leq 1.7$ with HSC counterparts in about 100 deg², we compiled multi-wavelength data of optical, near-infrared (IR), mid-IR, far-IR, and radio (150 MHz). We derived their color excess $(E(B - V)_*)$, stellar mass, star formation rate (SFR), IR luminosity, the ratio of IR and radio luminosity $(q_{\rm IR})$, and radio spectral index $(\alpha_{\rm radio})$ that are derived from the spectral energy distribution (SED) fitting with CIGALE. We also estimated Eddington ratio based on stellar mass and integration of the best-fit SEDs of active galactic nucleus (AGN) component. We found that $E(B - V)_*$, SFR, and IR luminosity clearly depend on redshift while stellar mass, $q_{\rm IR}$, and $\alpha_{\rm radio}$ do not significantly depend on redshift. Since optically faint ($i_{\rm AB} \ge 21.3$) RGs that are newly discovered by our RG survey tend to be high redshift, they tend to not only have a large dust extinction and low stellar mass but also have high SFR and AGN luminosity, high IR luminosity, and high Eddington ratio compared with optically bright ones. The physical properties of a fraction of RGs in our sample seem to differ from a classical view of RGs with massive stellar mass, low SFR, and low Eddington ratio, demonstrating that our RG survey with HSC and FIRST provides us curious RGs among entire RG population.

Key words: catalogs – infrared: galaxies – methods: observational – methods: statistical – radio continuum: galaxies

1. Introduction

In the last decade, observational and theoretical works have reported that feedback from radio active galactic nuclei (AGNs) harbored in radio galaxies (RGs) and radio-loud quasars can play an important role in the formation and evolution of galaxies (e.g., Croton et al. 2006; Fabian 2012). Mechanical injection of energy from RGs provides an impact on the gas reservoirs in galaxies and galaxy clusters (Morganti et al. 2013). Such AGN feedback could regulate star formation (SF) and even the growth of supermassive black holes (SMBHs) in galaxies. Therefore, it is important to investigate the physical properties related to SF and AGN activity for RGs as a function of redshift in order to understand a full picture of the formation and evolution of galaxies.

A multi-wavelength data set of optical and infrared (IR) for RGs is crucial for studying their physical properties, such as stellar mass, AGN/SF activity, and star formation rate (SFR). For example, a combination of National Radio Astronomy Observatory Very Large Array (VLA) Sky Survey (NVSS; Condon 1989)

or the VLA Faint Images of the Radio Sky at Twenty-Centimeters survey (FIRST; Becker et al. 1995), and the Sloan Digital Sky Survey (SDSS; York et al. 2000) provided a lager number of RGs with optical counterparts in the local universe (Ivezić et al. 2002; Best et al. 2005; Helfand et al. 2015), allowing us a statistical investigation of those "optically bright" RGs with r < 22.2 mag at redshift z < 0.5. These objects have been well studied in terms of UV/optical properties (e.g., de Ruiter et al. 2015), morphologies (e.g., Liske et al. 2015; Aniyan & Thorat 2017; Lukic et al. 2018), mid-IR (MIR) properties (e.g., Gürkan et al. 2014), and far-IR (FIR) properties (e.g., Gürkan et al. 2015, 2018), as well as black hole (BH) mass and its accretion rate (e.g., Best & Heckman 2012). Almost all of the optically bright local RGs have elliptical hosts with stellar mass of $>10^{10.5} M_{\odot}$ and SFR of $<10 M_{\odot} \text{ yr}^{-1}$ (Best & Heckman 2012). Only a small fraction of the local RGs has relatively small stellar mass with moderate star-forming activities (Smolčić 2009; Best & Heckman 2012).

At the high-z universe (z > 1), known RGs are powerful or radio-luminous $(L_{\text{radio}} \gtrsim 10^{26} \text{ W Hz}^{-1})$, corresponding to >0.1 mJy). The powerful high-z RGs are dominated by the evolved stellar populations with a stellar mass of $10^{11-12} M_{\odot}$ (e.g., Rocca-Volmerange et al. 2004; Seymour et al. 2007; Casey et al. 2009). The IR luminosity ($L_{\rm IR}$) of those powerful high-z RGs often exceed $10^{12} L_{\odot}$ that is classified as ultraluminous IR galaxy (ULIRG; Sanders & Mirabel 1996). They also show the evidence of high SFR and high BH accretion rate through IR and submillimeter observations (e.g., Chapman et al. 2010; Magnelli et al. 2010; Seymour et al. 2012; Drouart et al. 2014; Bonzini et al. 2015). On the other hand, Falkendal et al. (2019) investigated the SFR of those powerful high-z RGs based on multi-wavelength SEDs, taking into account their synchrotron emission. They reported that their SFRs are indeed lower than those of a main sequence of galaxies, suggesting an importance of multi-wavelength analysis for RGs.

Deep radio and optical observations enable us to find much fainter RGs (see Padovani 2016, and references therein) and to provide a comprehensive understanding by connecting RGs between local and high-z universe. Delvecchio et al. (2018)investigated RGs in the VLA-COSMOS field (Smolčić et al. 2017b) based on a multi-wavelength data set (Laigle et al. 2016; Smolčić et al. 2017a). They found that an average BH mass accretion rate, represented by a ratio of bolometric luminosity to stellar mass, increases with increasing redshift up to $z \sim 4$. They also reported that this trend is similar to the fact that a fraction of star-forming host galaxies also increase with increasing redshift. Although their statistical experiment was performed with a relatively small area ($\sim 2 \text{ deg}^2$), a wide-field survey with deep radio and optical facilities enables us to find a large number of "optically faint" RGs, providing us a laboratory to investigate their evolution in more high resolutions in redshifts and luminosities.

Recently, Yamashita et al. (2018, Paper I) performed a systematic search for RGs and quasars as a project called "The Wide and Deep Exploration of Radio Galaxies with Subaru HSC (WERGS)." They reported the result of optical identifications of radio sources detected by FIRST with the Hyper Suprime-Cam (HSC; Miyazaki et al. 2012, 2018) (see also, Furusawa et al. 2018; Kawanomoto et al. 2018; Komiyama et al. 2018 Subaru Strategic Program survey (HSC–SSP); Aihara et al. 2018a). By cross-matching the final data release of the FIRST survey (Helfand et al. 2015) with HSC S16A data (Aihara et al. 2018b), they found 3579 optical counterparts of FIRST sources in a 154 deg² of a HSC-SSP Wide field (see Section 2.1). Their radio flux densities at 1.4 GHz (20 cm) are above 1 mJy, while about 60% of them are optically faint ones with $i \ge 21.3$ mag that are undetected by the SDSS, allowing us to explore a new parameter space, i.e., optically faint bright radio sources. Plenty of RG and quasar samples also gives us an opportunity to discover a specially rare population, for example, a radio galaxy (RG) at high redshift (T. Yamashita et al. 2019, in preparation) and extremely radio-loud quasars (K. Ichikawa et al. 2019, in preparation).

This is the second in a series of papers from the WERGS project, in which we report the physical properties of radioloud galaxies at $0 < z \le 1.7$ with *i*-band magnitude between 18 and 26 that are derived from the spectral energy distribution (SED) fitting of multi-wavelength data. In this paper, we follow the same definition of RGs and quasars as adopted in Yamashita et al. (2018). But we removed stellar objects, i.e., radio-loud quasars that are optically unresolved objects based on optical morphology (see Yamashita et al. 2018), and focus only on RGs that have optically resolved morphologies.

The structure of this paper is as follows. Section 2 describes the sample selection of RGs, the multi-wavelength data set, and our SED modeling. In Section 3, we report the result of SED fitting and the derived physical quantities of RGs detected by the HSC and FIRST. In Section 4, we discuss a possible selection bias, an uncertainty of our SED fitting, and BH mass accretion rate for our sample. We summarize this work in Section 5. All information about our RG sample, such as coordinates, multi-band photometry, and derived physical quantities, is available as a catalog (see Appendix A). We also provide best-fit SED templates of those RGs (see Appendix B). Throughout this paper, the adopted cosmology is a flat universe with $H_0 = 70$ km s⁻¹ Mpc⁻¹, $\Omega_M = 0.27$, and $\Omega_{\Lambda} = 0.73$, which are same as those adopted in Yamashita et al. (2018). Unless otherwise noted, all magnitudes refer to the AB system.

2. Data and Analysis

2.1. Sample Selection

Figure 1 shows a flow chart of our sample selection process. The original sample was drawn from 3579 RGs and quasars in Yamashita et al. (2018), who used the HSC-SSP and FIRST data. The HSC-SSP is an ongoing optical imaging survey with five broadband filters (g-, r-, i-, z-, and y-band) and four narrowband filters (see Aihara et al. 2018a; Bosch et al. 2018; Coupon et al. 2018; Huang et al. 2018). This survey consists of three layers, Wide, Deep, and UltraDeep, and this work uses S16A Wide-layer data¹² obtained from 2014 March to 2016 January, providing a forced photometry of g-, r-, i-, z-, and y-band with a 5σ limiting magnitude of 26.8, 26.4, 26.4, 25.5, and 24.7, respectively (Aihara et al. 2018b). The HSC-SSP Wide-layer covers six fields (XMM-LSS, GAMA09H, WIDE12H, GAMA15H, HECTOMAP, and VVDS; see Table 1 in Yamashita et al. (2018) for detailed coordinates of each field). The typical seeing is about 0.000 in the *i*-band, and the astrometric uncertainty is about 40 mas in root mean square (rms). Taking into account the photometric and astrometric flags, Yamashita et al. (2018) eventually extracted 23,795,523 HSC objects in the 154 deg^2 for cross-matching with FIRST (see Section 2.1 in Yamashita et al. 2018 for more detail).

The FIRST project completed radio imaging survey at 1.4 GHz with a spatial resolution of 5." 4 (Becker et al. 1995; White et al. 1997) covering 10,575 deg², which is completely overlapping with the survey footprint of the HSC-SSP Widelayer, and the final release catalog of FIRST (Helfand et al. 2015) is publicly available. Before cross-matching with the HSC, Yamashita et al. (2018) made a flux-limited FIRST sample with flux density at 1.4 GHz greater than 1.0 mJy. Taking into account a flag that tells a source is a spurious detection near a bright source, Yamashita et al. (2018) eventually extracted 7072 FIRST objects in the 154 deg² for the cross-matching with the HSC (see Section 2.2 in Yamashita et al. 2018 for more detail). By cross-matching the HSC S16A Wide-layer catalog and FIRST final data release catalog with a search radius of 1", 3579 objects (including RGs and radioloud quasars) were selected (see Section 3 in Yamashita et al. 2018 for more detail).

 $[\]frac{12}{12}$ The S16A data (Wide, Deep, and UltraDeep) is available in 2019 as a public data release 2 (Aihara et al. 2019). Although Yamashita et al. (2018) used UltraDeep data in addition to Wide data, this work focuses only on Wide data.

Figure 1. Flow chart of the sample selection process.

Before compiling multi-wavelength data, we made a parent RG sample. First, we removed 55 stellar objects (i.e., radioloud quasars) based on optical morphological information (see Yamashita et al. 2018). For 3579 - 55 = 3524 RGs, we then narrowed down the sample to 2118 objects in three fields with a total area of $\sim 94.7 \text{ deg}^2$ (GAMA09H, WIDE12H, and GAMA15H) where multi-wavelength data are available. We then removed 175 objects that are not covered by FIR observation (see Section 2.1.4), which yielded 1943 RGs. The sky distribution of those 1943 RGs is shown in Figure 2. For those objects, we then complied the multi-wavelength data from u-band, near-IR (NIR), MIR, FIR, and radio data, as well as spectroscopic or photometric redshift. After removing 897 objects with photometric data less than 10, and unreliable photometric redshift and/or photometric redshift greater than 1.7 (see Section 2.1.6), we finally selected 1943 - 897 = 1056objects (hereafter "HSC-FIRST RGs") with multi-wavelength data and reliable redshift in this work.

2.1.1. u-band Data

The *u*-band data were taken from the Kilo-Degree Survey (KiDS; de Jong et al. 2013),which is an ESO public survey carried out with the VLT Survey Telescope (VST) and OmegaCAM camera (Kuijken 2011). We used the Data Release (DR) 3 (de Jong et al. 2017), which consists of 48,736,590 sources with a limiting magnitude of 24.3 mag (5σ in a 2" aperture) in *u*-band. The typical full width at half maximum (FWHM) of point-spread function (PSF) for *u*-band detected point sources is about 1".¹³ Before the cross-matching, we extracted 42,252,797 sources with FLAG_U = 0 to ensure clean photometry in *u*-band (see de Jong et al. 2015, 2017 for more detail).

2.1.2. Near-IR Data

We compiled NIR data from the VISTA Kilo-degree Infrared Galaxy Survey (VIKING; Arnaboldi et al. 2007) DR3¹⁴ that includes 73,747,647 sources in ~1000 deg² with NIR taken by the VISTA InfraRed Camera (VIRCAM; Dalton et al. 2006). We used *J*-, *H*-, and *Ks*-band with a median 10 σ (Vega)magnitude limit of 20.1, 19.0, and 18.6 mag, respectively. Objects with a PSF FWHM of < 1."2 was observed in VIKING. Before the cross-matching, we selected 63,028,265 objects with primary_source=1 and (jpperrbits < 256 or hpperrbits < 256 or kspperrbits <256) to ensure clean photometry for uniquely detected objects (see also Toba et al. 2015; Noboriguchi et al. 2019).

2.1.3. Mid-IR Data

The MIR data were taken from *Wide-field Infrared Survey Explorer* (*WISE*; Wright et al. 2010). We utilized W1 (3.4 μ m), W2 (4.6 μ m), W3 (12 μ m), and W4 (22 μ m) data in ALLWISE (Cutri et al. 2014) that consists of 747,634,026 sources. The 5σ detection limits¹⁵ in W1, W2, W3, and W4 band are approximately 0.054, 0.071, 0.73, and 5 mJy, respectively. The angular resolutions in W1, W2, W3, and W4 band are 6."1, 6."4, 6."5, and 12."0, respectively. We extracted

¹⁴ http://eso.org/rm/api/v1/public/releaseDescriptions/107

¹⁵ http://wise2.ipac.caltech.edu/docs/release/allwise/expsup/sec2_3a.html

Figure 2. Spatial distribution (J2000.0) of 1943 HSC-FIRST radio galaxies (black points) in GAMA09H (top), WIDE12H (middle), and GAMA15H (bottom) field. Blue, green, and red squares represent survey footprint of KiDS, VIKING, and H-ATLAS, respectively. Those regions are completely covered by ALLWISE and TGSS. There are 754, 344, and 845 HSC-FIRST objects in the GAMA09H, WIDE12H, and GAMA15H, respectively.

741,753,366 sources with (w1sat = 0 and w1cc_map = 0) or (w2sat = 0 and w2cc_map = 0) or (w3sat = 0 and w3cc_map = 0), or (w4sat = 0 and w4cc_map = 0) in the ALLWISE catalog (Cutri et al. 2014), to have secure photometry at either band (see the Explanatory Supplement to the ALLWISE Data Release Products¹⁶ for more detail).

2.1.4. Far-IR Data

We also used FIR data that were provided by a project of *the Herschel Space Observatory* (Pilbratt et al. 2010) Astrophysical Terahertz Large Area Survey (H-ATLAS; Eales et al. 2010; Bourne et al. 2016). The data were taken with the Photoconductor Array Camera and Spectrometer (PACS; Poglitsch et al. 2010) at 100 and 160 μ m and with the Spectral and Photometric Imaging REceiver instrument (SPIRE; Griffin et al. 2010) at 250, 350, and 500 μ m are 11."4, 13."7, 17."8, 24."0, and 35."2, respectively. We used H-ATLAS DR1 (Valiante et al. 2016) containing 120,230 sources in the galaxy and mass assembly (GAMA) fields. The 1 σ noise for source detection (that includes confusion and instrumental noise) is 44, 49, 7.4, 9.4, and 10.2 mJy at 100, 160, 250, 350, 350, and 500 μ m, respectively (Valiante et al. 2016).

2.1.5. Ancillary Radio Data

The radio data were taken from observations with the Giant Metrewave Radio Telescope (GMRT; Swarup 1991). We used

continuum flux density at 150 MHz (~1.99 m) provided by the Tata Institute of Fundamental Research (TIFR) GMRT Sky Survey (TGSS) alternative data release (ADR; Intema et al. 2017), which includes 623,604 radio sources in 36,900 deg². The median rms noise of sources is $3.5 \text{ mJy beam}^{-1}$, with a spatial resolution of about 25''.

2.1.6. Cross-identification of Multi-band Catalogs

We then cross-identified those catalogs (KiDS, VIKING, ALLWISE, H-ATLAS, and TGSS) with HSC-FIRST RGs.¹ By using a search radius of 1" for KiDS and VIKING, 3" for ALLWISE, 10" for H-ATLAS, and 20" for TGSS, 1051 (54.1%), 1564 (80.5%), 1482 (76.3%), 257 (13.2%), and 471 (24.2%) objects were cross-identified by KiDS, VIKING, ALLWISE, H-ATLAS, and TGSS, respectively. We note that 3/1051 (~0.3%) and 2/471 (~0.4%) objects have two candidates of counterpart for VIKING and TGSS sources, respectively, within the search radius. We choose the nearest object as a counterpart for such cases. For cross-matching with other catalogs (KiDS, ALLWISE, and H-ATLAS), one-to-one identification was realized. The matches by chance coincidence are estimated by generating mock catalogs with random positions, in the same manner as Yamashita et al. (2018). We generated mock catalogs of KiDS, VIKING, ALLWISE, H-ATLAS, and TGSS data where source position in each catalog is shifted from the original one to $\pm 1^{\circ}$ or $\pm 2^{\circ}$ along the

¹⁶ http://wise2.ipac.caltech.edu/docs/release/allwise/expsup/index.html

¹⁷ We always use right assignation and decl. in the HSC catalog as coordinates of HSC–FIRST objects.

right assignation direction (see Yamashita et al. 2018 for more detail). We then cross-identified HSC–FIRST RGs with those mock catalogs with the exactly same search radii. We found that the chance coincidence of cross-matching with the KiDS, VIKING, ALLWISE, H-ATLAS, and TGSS catalogs is about 5.0%, 1.9%, 3.4%, 9.3%, and 0.6%, respectively.

We also compiled photometric and spectroscopic redshift. For spectroscopic redshift, we utilized the SDSS DR12 (Alam et al. 2015), the GAMA project DR2 (Driver et al. 2011; Liske et al. 2015), and WiggleZ Dark Energy Survey project DR1 (Drinkwater et al. 2010). For photometric redshift, we employed a custom-designed Bayesian photometric redshift code (MIZUKI; Tanaka 2015) to estimate the photometric redshift (photo-z) of HSC-FIRST objects in the same manner as Yamashita et al. (2018), in which we used z_{best} as a photometric redshift (see also Tanaka et al. 2018). In order to perform an accurate SED fitting, we preferentially used spectroscopic redshift. For objects without spectroscopic redshift, we used their z_{best} if they have a reliable photometric redshift, i.e., $0 < z_{\text{best}} \leq 1.7$,¹⁸ $\sigma_{z_{\text{best}}} < 0.1$, and reduced χ^2 of $z_{\text{best}} \leq 5.0$. These criteria are optimized based on the comparison with spectroscopic redshift for the WERGS sample in Yamashita et al. (2018) (see also Tanaka et al. 2018). However, the influence of the above criteria on physical quantities derived from the SED fitting is still unclear, which will be discussed in Section 4.2.1. In addition to the above redshift (quality) cut, we extracted objects with $>3\sigma$ detection in at least 10 photometric bands among 20 photometric data $(u, g, r, i, z, y, J, H, K_s$ -band; 3.4, 4.6, 12, 22, 100, 160, 250, 350; 500 μ m; and 150 and 1400 MHz) to avoid an overfitting for our SED fitting method (see Section 2.2). Consequently, 1056 HSC-FIRST RGs with multi-band photometry and reliable redshift were left (see Figure 1). Among 1056 objects, the redshifts of 224, 44, and 3 objects were taken from the SDSS DR12, GAMA DR2, and WiggleZ DR1, respectively, while the redshifts of the remaining 785 objects were taken from MIZUKI. The HSC-FIRST RG catalog, which includes basic information such as redshift and multi-band photometry, is accessible through an online service. Format and column descriptions of the catalog are summarized in Table 3.

2.2. SED Modeling with CIGALE

We here employed CIGALE¹⁹ (Code Investigating GALaxy Emission; Burgarella et al. 2005; Noll et al. 2009; Boquien et al. 2019) in order to perform a detailed SED modeling in a self-consistent framework with considering the energy balance between the UV/optical and IR. In this code, we are able to handle many parameters, such as star formation history (SFH), single stellar population (SSP), attenuation law, AGN emission, dust emission, and radio synchrotron emission.

We assumed an SFH of two exponential decreasing SFR with different e-folding times (Ciesla et al. 2015, 2016). We adopted the stellar templates provided from Bruzual & Charlot (2003) assuming the initial mass function (IMF) in Chabrier (2003), and the standard default nebular emission model included in CIGALE (see Inoue 2011). Dust attenuation is modeled by using the Calzetti et al. (2000) law with color

excess $(E(B - V)_*)$. We note that even if we employ the dust attenuation law of the Small Magellanic Cloud that would be applicable to dusty starburst galaxies, resultant physical properties are consistent with what we present in this work within error. The reprocessed IR emission of dust absorbed from UV/optical stellar emission is modeled assuming dust templates of Dale et al. (2014). For AGN emission, we also utilized models provided in Fritz et al. (2006), where we fixed some parameters that determine the density distribution of the dust within the torus to avoid a degeneracy of AGN templates in the same manner as Ciesla et al. (2015). We parameterized the ψ parameter (an angle between the AGN axis and the line of sight) that corresponds to a viewing angle of the tours. We also parameterize AGN fraction (f_{AGN}) , which is the contribution of IR luminosity from AGN to the total IR luminosity (Ciesla et al. 2015). For radio synchrotron emission from either SFG or AGN, we parameterized a correlation coefficient between FIR and radio luminosity $(q_{\rm IR})$ and the slope of powerlaw synchrotron emission (α_{radio}) (but see Sections 3.5.6 and 3.5.7). We define α_{radio} from the measured radio flux density at observed-frame frequencies at 150 MHz and 1.4 GHz, assuming a power-law radio spectrum of $f_{\nu} \propto \nu^{-\alpha_{\rm radio}}$;

$$\alpha_{\rm radio} = \frac{\log(F_{\rm 150\ MHz}/F_{\rm 1.4\ GHz})}{\log(\nu_{\rm 1.4\ GHz}/\nu_{\rm 150\ MHz})}.$$
 (1)

This synchrotron emission is cut off at 100 μ m; that is, a default value adopted in CIGALE that would be optimized for normal star-forming galaxies. However, the synchrotron emission may contribute to fluxes/luminosities even at $<100 \,\mu m$, especially for radio-loud AGNs (e.g., Mason et al. 2012; Privon et al. 2012; Falkendal et al. 2019; Rakshit et al. 2019). In this work, we choose $30 \,\mu\text{m}$ as a cutoff wavelength of the synchrotron emission with a single power law, in the same manner as Lyu & Rieke (2018) (see also Pe'er 2014). We have confirmed that the choice of cutoff wavelength does not significantly affect the following results. Table 1 lists the detailed parameter ranges adopted in the SED fitting (see also Matsuoka et al. 2018; Chen et al. 2019; Toba et al. 2019). In addition to the energy balance between UV/optical and IR part, CIGALE takes into account the balance between IR and radio luminosity that is parameterized by $q_{\rm IR}$, which are eventually an essential framework in CIGALE.

To find a best-fit SED and calculate physical properties and their uncertainties, CIGALE employed an analysis module socalled pdf_analysis. This module computes the likelihood (that corresponds to χ^2) for all the possible combinations of parameters and generates the probability distribution function (PDF) for each parameter and each object. But before computing the likelihood, the module scaled the models by a factor (α) to obtain physically meaningful values (so-called extensive physical properties) such as stellar masses and IR luminosities, where α can be derived as follows:

$$\alpha = \frac{\sum_{i} \frac{f_{i}m_{i}}{\sigma_{i}^{2}}}{\sum_{i} \frac{m_{i}^{2}}{\sigma_{i}^{2}}} + \frac{\sum_{j} \frac{J_{j}m_{j}}{\sigma_{j}^{2}}}{\sum_{j} \frac{m_{j}^{2}}{\sigma_{j}^{2}}},$$
(2)

where f_i and m_i are the observed and model flux densities, f_j and m_j are the observed and model extensive physical properties, and σ is the corresponding uncertainties (see Equation (13) in Boquien et al. 2019). Finally, pdf_analysis computes the

¹⁸ Yamashita et al. (2018) reported that the HSC–SSP photo-*z* derived by MIZUKI could be secure at $z \le 1.7$ based on comparison with spectroscopic redshift in COSMOS field (see Section 5.1.2 in Yamashita et al. 2018 for more detail).

probability-weighted mean and standard deviation that correspond to resultant value and its uncertainty for each parameter, in which α is considered as a free parameter. This approach is fully valid as far as one compares models built from the same set of parameters (see Section 4.3 in Boquien et al. 2019 for full explanation of this module) (see also, Salim et al. 2007).

Under the parameter setting described in Table 1, we fit the stellar, AGN, SF, and radio components to at most 20 photometric points (u, g, r, i, z, y, J, H, Ks-band, and 3.4, 4.6, 12, 22, 100, 160, 250, 350, and 500 µm, and 150 and 1400 MHz) of 1056 HSC-FIRST RGs observed with KiDS, HSC, VIKING, ALLWISE, H-ATLAS, FIRST, and TGSS. For optical data, we used MAG_AUTO_U as a u-band photometry that is a default magnitude²⁰ while q/r/i/z/ycModel Mag were used for g-, r-, i-, z-, and y-band photometry (Bosch et al. 2018; Huang et al. 2018). For NIR data, we used Petrosian (1976) magnitude (see the release note of the VIKING DR3). Each magnitude was corrected for Galactic foreground extinction following Schlegel et al. (1998). The VIKING catalog contains the Vega magnitude of each source, and we converted these to AB magnitude, using offset values $\Delta m (m_{AB} = m_{Vega} + \Delta m)$ for J, H, and K_s -band of 0.916, 1.366, and 1.827, respectively.²¹ For MIR and FIR data, w1-4mpro were utilized to estimate MIR flux densities (Wright et al. 2010; Toba et al. 2014) while

Figure 3. Histogram of *i*-band magnitude of HSC–FIRST RGs (black line) and those with reduced χ^2 of the SED fitting smaller than 5.0 (gray region), where *i*-band magnitude is corrected for the Galactic foreground extinction (see Section 2.2). The vertical dashed line is the threshold (*i* = 21.3 mag) between SDSS-level and HSC-level RGs.

F100/160/250/350/500BEST were used for FIR flux densities (see Valiante et al. 2016). ALLWISE catalog contains the Vega magnitude of each source, and we converted these to AB magnitude, using Δm for 3.4, 4.6, 12, and 22 μ m of 2.699, 3.339, 5.174, and 6.620, respectively.²² It is known that flux densities at 250, 350, and 500 μ m could be boosted especially for faint sources (so-called flux boosting or flux bias) that are caused by a confusion noise and instrument noise. Hence we corrected this effect by using the correction term provided in Table 6 of Valiante et al. (2016). For radio data, FINT and STOTAL were used for flux densities at 1.4 GHz and 150 MHz, respectively (see Helfand et al. 2015; Interna et al. 2017 for more detail). We used flux density at a wavelength when signal-to-noise ratio (S/N) is greater than 3 at that wavelength. If an object was undetected, we put 3σ upper limits at those wavelengths.²³ Although the photometry employed in each catalog is different, their flux densities are expected to trace the total flux densities. Therefore, the influence of different photometry is likely to be small. Nevertheless, it is worth investigating whether or not physical properties can actually be estimated in a reliable way given an uncertainty of each photometry, which will be discussed in Section 4.2.4.

3. Results

3.1. Histogram of i-band Magnitude and Redshift

Figure 3 shows a histogram of *i*-band magnitude for 1056 HSC–FIRST RGs. Here, we define the "SDSS-level objects" and "HSC-level objects" based on the Galactic foreground extinction-corrected *i*-band magnitude in the same manner as Yamashita et al. (2018). We call objects with i < 21.3 mag the SDSS-level objects as a reference of optically bright RGs, while we call objects with $i \ge 21.3$ mag the HSC-level objects as a reference of optically bright RGs, while we call objects as the SDSS-level and HSC-level objects as a reference of optically faint RGs. We found that 577 and 479 objects are classified as the SDSS-level and HSC-level objects, respectively, meaning that we have a statistically

conv2ab'²³ CIGALE can handle SED fitting of photometric data with upper limit when one employs the method presented by Sawicki (2012). This method computes χ^2 by introducing the error function (see Equations (15) and (16) in Boquien et al. (2019).

Figure 4. Histogram of redshift of HSC–FIRST RGs (solid line) and those with reduced χ^2 of the SED fitting smaller than 5.0 (shaded region). Red and blue line are the SDSS- and HSC-level objects in 1056 HSC–FIRST RGs. Red and blue regions are those in the 835 subsample (see Section 3.5).

robust sample of optically faint RGs that are newly discovered by the WERGS project (Yamashita et al. 2018).

Figure 4 shows a histogram of redshift for 1056 HSC–FIRST RGs. The mean values of redshift for the SDSS- and HSC-level objects are 0.57 and 1.10, respectively, meaning that HSC-level objects have larger redshift than SDSS-level objects, which is consistent with what Yamashita et al. (2018) reported.

3.2. Result of SED Fitting

Figure 5 shows examples of the SED fitting with CIGALE.²⁴ We confirmed that 568/1056 (~54%) objects have reduced $\chi^2 \leq 3.0$, while 835/1056 (~79%) objects have reduced $\chi^2 \leq 5.0$, which means that the data are moderately well fitted with the combination of the stellar, AGN, SF, and radio components by CIGALE.

We note that each quantity derived by the SED fitting would not be uniquely determined for some objects even if their reduced χ^2 is good enough, because there is a possibility of degeneracy among input parameters. We checked the PDF of each quantity for randomly selected objects. We confirmed that there is basically no prominent secondary peak of their PDFs, suggesting that the derived physical quantities are reliably determined. The physical quantities such as stellar mass and SFR for 1056 HSC–FIRST RGs are also accessible through the online service (see Table 3 for the catalog description).

3.3. Radio and Optical Luminosity as a Function of Redshift

Figure 6(a) shows the rest-frame 1.4 GHz radio luminosity $(L_{1.4 \text{ GHz}})$ of 835 HSC–FIRST RGs as a function of redshift. To make sure of the parameter space of our RGs with respect to previously discovered RGs, RGs selected with the SDSS (Best & Heckman 2012) and RGs found by VLA-COSMOS 3 GHz large project (Smolčić et al. 2017a, 2017b) are also plotted. $L_{1.4 \text{ GHz}}$ in unit of W Hz⁻¹ is *k*-corrected luminosity at rest-frame 1.4 GHz, which is derived by using the following

formula:

$$L_{1.4 \text{ GHz}} = \frac{4\pi d_L^2 F_{1.4 \text{ GHz}}}{(1+z)^{1-\alpha_{\text{radio}}}},$$
(3)

where d_L is luminosity distance, $F_{1.4 \text{ GHz}}$ is observed-frame flux density at 1.4 GHz, and α_{radio} is the radio spectral index we estimated in Equation (1). We note that 190/835 objects have TGSS (150 MHz) data and thus their α_{radio} are securely estimated. If an object did not have α_{radio} due to the nondetection of TGSS, we adopted a typical spectral index of RGs, $\alpha_{\text{radio}} = 0.7$ (e.g., Condon 1992) to estimate $L_{1.4 \text{ GHz}}$. For radio sources selected with either the SDSS or VLA-COSMOS, we also used 0.7 as the spectral index to calculate $L_{1.4 \text{ GHz}}$ if the object did not have radio spectral index (see e.g., Smolčić et al. 2017a). We confirmed that our RG sample distributes much higher redshift (z > 0.5) than SDSS-selected RGs, while radio luminosity of our RGs sample is larger than that of VLA-COSMOS radio sources, with a median rms of 2.3 μ Jy beam⁻¹.

Figure 6(b) shows the rest-frame *i*-band absolute magnitude (M_i) as a function of redshift. M_i of our RG sample was estimated based on the best-fit SED output by CIGALE. Since the VLA-COSMOS catalog (Smolčić et al. 2017a) does not contain M_i , we used the COSMOS2015 catalog (Laigle et al. 2016), in which absolute magnitudes in optical and NIR bands were estimated based on the SED fitting. For SDSS-selected RGs in Best & Heckman (2012), we did not apply for *k*-correction. But their M_i can be approximately used for absolute magnitude at the rest frame because they are low-*z* objects. We confirmed that our RG sample has intermediate value of M_i between SDSS-selected and VLA-COSMOS radio sources.

The discrepancy between our RG sample and VLA-COSMOS RG sample in M_i (Figure 6(b)) is much smaller than that in $L_{1.4 \text{ GHz}}$ (Figure 6(a)), suggesting that our RGs tend to trace higher radio-loudness sources, which is one of the advantages of the WERGS project, where even VLA-COSMOS might not be able to trace. In summary, Figure 6 reminds us that our RG survey with HSC and FIRST explores a new parameter space: relatively high-*z* luminous RGs. We should keep in mind the above parameter space in the following discussions.

3.4. WISE Color-Color Diagram

Figure 7 shows the *WISE* color–color diagram ([3.4]–[4.6] versus [4.6]–[12]) for 148 HSC–FIRST RGs with S/N > 3 in 3.4, 4.6, and 12 μ m that were drawn from 1056 RG sample. The anticipated MIR colors for various populations of objects are shown with different colors (Wright et al. 2010), which provides us a qualitative view of galaxies. We found that the HSC-level objects tend to be redder than the SDSS-level objects in both colors of [3.4]–[4.6] and [4.6]–[12]. The majority of the SDSS-level objects is located at regions of spirals and LIRGs, while the HSC-level objects are located at regions of Seyferts, starburst galaxies, and ULIRGs.

About 49% of HSC–FIRST RGs with S/N > 3 in 3.4, 4.6, and 12 μ m are located within the AGN wedge defined by Mateos et al. (2012, 2013), who suggested reliable MIR color selection criteria for AGN candidates based on the *WISE* and wide-angle Bright Ultrahard *XMM-Newton* survey (BUXS: Mateos et al. 2012). This means that roughly half of the RG sample is outside of the wedge, which is in good agreement

 $^{^{24}}$ Since CIGALE assumed that the maximum wavelength for radio data was rest frame 1 m, CIGALE did not work for our data set, including TGSS (2 m) data for low-z objects. We modified CIGALE code (radio.py) to solve this issue as suggested by Prof. Denis Burgarella through a private communication.

Figure 5. Examples of the SED (flux density as a function of wavelength in rest frame) and result of the SED fitting for our sample. The black points are photometric data where the down arrows mean 3σ upper limit. The blue, yellow, red, and green lines show stellar, AGN, SF, and radio component, respectively. The black solid lines represent the resultant SEDs. We provide best-fit SEDs for all 1056 HSC–FIRST RGs with derived physical properties (see Tables 3 and 4).

Figure 6. (a) Rest-frame 1.4 GHz radio luminosity and (b) the absolute *i*-band magnitude at the rest frame as a function of redshift. Yellow and blue circles represent SDSS-detected RGs (Best & Heckman 2012) and RGs discovered by the VLA-COSMOS project (Smolčić et al. 2017a), respectively. Red circles represent HSC–FIRST RGs with reduced $\chi^2 \leq 5.0$.

with previous works on radio-loud galaxies (Gürkan et al. 2014; Banfield et al. 2015), suggesting that the AGN selection based on the AGN wedge seems to be biased toward a subsample among the entire AGN population (see also Toba et al. 2014, 2015; Ichikawa et al. 2017).

What makes the difference between objects inside and outside of the AGN wedge? One possibility is a difference of radio luminosity between them, since radio luminosity is a good tracer of AGN power, as suggested by previous works (e.g., Banfield et al. 2015; Singh et al. 2015; Singh & Chand 2018). We checked this possibility for our sample, where we used the rest-frame radio luminosity at 1.4 GHz that is drawn from Yamashita et al. (2018) assuming a power-law radio spectrum of $f_{\nu} \propto \nu^{-0.7}$.

Figure 7 shows the histogram of rest-frame 1.4 GHz luminosity, indicating a systematic difference in radio luminosity for objects inside and outside of the AGN wedge. The mean values of rest-frame 1.4 GHz luminosity for objects inside and outside of the AGN wedge are $\log L_{1.4 \text{ GHz}} \sim 24.8$ and $\sim 24.4 \text{ W Hz}^{-1}$, respectively, supporting the previous works. An alternative indicator of AGN power is a radio-loudness that is defined as flux ratio of rest-frame radio and optical band. We used the radio-loudness at rest frame (R_{rest}), a ratio of the rest-frame 1.4 GHz flux to the rest-frame g-band flux as used in Yamashita et al. (2018). Figure 7 also shows the histogram of R_{rest} , indicating a systematic difference in R_{rest} for objects inside and outside of the AGN wedge. The mean values of R_{rest} for objects inside and outside of the AGN wedge are log $R_{\text{rest}} \sim 2.4$ and ~ 1.9 , respectively, indicating that objects

Figure 7. (Top) *WISE* color–color diagram of 148 HSC–FIRST RGs with S/N > 3 in 3.4, 4.6, and 12 μ m. Blue and red circles are SDSS- and HSC-level RGs, respectively. Yellow and green circles are SDSS-detected FIRST FR I and FR II RGs with r < 17.8 mag, respectively, that are obtained from Capetti et al. (2017a, 2017b). Regions with different color shading show typical MIR colors of different populations of objects (Wright et al. 2010). The solid lines illustrate the AGN selection wedge defined from Mateos et al. (2012, 2013). (Bottom) Histogram of rest-frame 1.4 GHz luminosity ($L_{1.4 \text{ GHz}}$) and rest-frame radio-loudness (R_{rest}) for objects inside (magenta) and outside (black) of the AGN wedge. The mean values are shown in dashed lines.

with larger radio-loudness tend to be located in the AGN wedge, as we expected.

We note that there are almost no objects at elliptical galaxies in the *WISE* color–color diagram (Figure 7), which is mainly interpreted as a selection bias of our HSC–FIRST RGs. Since the saturation limit of the HSC for point sources at *r*-band and *i*-band are 17.8 and 18.4 mag, respectively (Aihara et al. 2018b), the HSC–FIRST RG sample does not contain those optically bright objects. In Figure 7, we also plot RGs with *r*-band magnitude smaller than 17.8 mag provided by Capetti et al. (2017a, 2017b), who released Fanaroff & Riley (1974) (FR) I and II RG catalogs²⁵ selected with the SDSS and FIRST. The redshift, optical absolute magnitude, and radio luminosity range of those RGs are 0.02 < z < 0.15, $-23.7 < M_R < -20.3$, and $23.3 < \log L_{1.4 \text{ GHz}}$ [W Hz⁻¹] < 25.8, respectively. They show elliptical-like MIR colors, which means that optically too bright objects are located at the region of elliptical galaxies. In addition to the selection bias, there is a possibility that MIR colors of RGs would be different from normal elliptical galaxies. Banfield et al. (2015) reported that [4.6]–[12] color of RGs selected from the Radio Galaxy Zoo²⁶ sample shows significantly redder than that of typical elliptical galaxies. This indicates that the dust emission of RGs may be enhanced compared with normal quiescent elliptical galaxies (see also Goulding et al. 2014; Gürkan et al. 2014). Indeed, Martini et al. (2013) reported that active elliptical

 $[\]frac{25}{5}$ Since the catalogs do not contain *WISE* magnitudes, we cross-identified their *WISE* counterparts with a search radius of 3" by ourselves.

Figure 8. (a) The color excess $(E(B - V)_*)$, (b) stellar mass, (c) SFR, (d) IR luminosity contributed from AGNs, (e) total IR luminosity, (f) radio spectral index (α_{radio}) , and (g) q_{IR} of HSC–FIRST RGs as a function of redshift. The color code is *i*-band magnitude. The histograms show the SDSS-level (blue), HSC-level (red), and total (black) objects. The dashed lines are mean values of each quantity for SDSS-level (blue) and HSC-level (red) objects. 835 RGs are plotted in panels (a) to (e) while 190 RGs with FIRST and TGSS data are plotted in panels (f) and (g).

galaxies tend to have a large dust mass compared with inactive elliptical galaxies, which supports the above hypotheses.

3.5. Physical Properties of HSC-FIRST Radio Galaxies

We present the physical properties of HSC–FIRST RGs with being conducted a reliable SED fitting. Hereafter, we will focus on a subsample of 835 HSC–FIRST RGs with reduced χ^2 of the SED fitting smaller than 5.0. In this work, we investigate the following quantities output directly from CIGALE; (i) dust extinction, (ii) stellar mass, (iii) SFR, (iv) AGN luminosity, (v) IR luminosity, and those calculated by ourselves; (vi) radio spectral index, and (vii) L_{IR}/L_{radio} coefficient (q_{IR}) as a function of redshift, which are summarized in Figure 8. Among subsample, 501 and 334 objects are classified as the SDSS- and HSC-level objects with a mean redshift of 0.56 and 1.11, respectively (see Figures 3 and 4).

3.5.1. Dust Extinction

Figure 8(a) shows color excess, $E(B - V)_*$ as a function of redshift, where $E(B - V)_*$ is an indicator of dust extinction of host galaxy. We found that there is a clear correlation between redshift and $E(B - V)_*$; optically fainter RGs at high redshift

are affected by larger dust extinction. The mean values of $E(B - V)_*$ of the SDSS- and HSC-level objects are ~0.19 and ~0.45, respectively. Indeed, 5 HSC-level objects with mean $E(B - V)_*$ of 0.45 satisfy a criterion of IR-bright dust-obscured galaxies with S/N > 3 at 22 μ m (see e.g., Toba et al. 2015; Toba & Nagao 2016; Toba et al. 2017b, 2018; Noboriguchi et al. 2019).

3.5.2. Stellar Mass

Figure 8(b) shows stellar mass as a function of redshift. The stellar mass of our RG sample does not significantly depend on redshift, and thus the distributions of stellar masses for the SDSS- and HSC-level objects are similar. However, the mean values of stellar mass of the SDSS- and HSC-level objects are $\log(M_*/M_{\odot}) \sim 11.26$ and ~ 11.08 , respectively, indicating that the HSC-level RGs could tend to have less massive stellar mass compared with the SDSS-level ones.

3.5.3. Star Formation Rate (SFR)

Figure 8(c) shows SFR as a function of redshift. We found that the SFR increases with increasing redshift, and thus the HSC-level objects are systematically larger than those of the

SDSS-level objects. The mean values of SFR of the SDSS- and HSC-level objects are log SFR ~0.55 and ~1.51 M_{\odot} yr⁻¹, respectively. About one-quarter of the HSC-level objects have SFR >100 M_{\odot} yr⁻¹, which is consistent with what was reported in the *WISE* color–color diagram (Figure 7).

3.5.4. AGN Luminosity

Figure 8(d) shows IR luminosity contributed from AGN that is defined as L_{IR} (AGN) = $f_{AGN} \times L_{IR}$ (Ciesla et al. 2015), where L_{IR} is total IR luminosity (see Section 3.5.5). We found that the L_{IR} (AGN) increases with increasing redshift, and thus the HSC-level objects seem to have systematically larger AGN luminosity than the SDSS-level objects. The mean values of log [L_{IR} (AGN)/ L_{\odot}] of the SDSS- and HSC-level objects are ~10.56 and ~11.32, respectively.

3.5.5. IR Luminosity

Figure 8(e) shows IR luminosity as a function of redshift. We can see a similar trend to AGN luminosity; IR luminosity increases with increasing redshift, and thus IR luminosities of the HSC-level objects are larger than those of the SDSS-level objects. The mean values of log ($L_{\rm IR}/L_{\odot}$) of the SDSS- and HSC-level objects are ~11.31 and ~12.04, respectively. This is basically consistent with the fact that the majority of the SDSS and HSC objects are LIRGs and ULIRGs, respectively, reported in Section 3.4.

We note that because our RG sample may be affected by Malmquist bias as shown in Figure 6, the difference particularly in SFR, L_{IR} (AGN), and L_{IR} between SDSS- and HSC-level objects is basically due to the difference of their redshift distributions. In other words, redshift dependence of $L_{\rm IR}$, $L_{\rm IR}$ (AGN), and SFR may be caused by the sensitivity limit of IR bands. On the other hand, it is natural that M_* does not show a redshift dependence, because the sensitivity of optical bands with HSC is much deeper than that of the IR bands. If we compare SFR, L_{IR} (AGN), and L_{IR} of SDSS- and HSC-level objects at an overlapped redshift range (0.5 < z < 1.0) (see Figure 4), the differences of mean values of SFR, L_{IR} (AGN), and L_{IR} are 0.31, 0.30, and 0.25 dex, respectively. We also note that particularly SFR and AGN luminosity would also have an additional uncertainty probably due to a poor constraint of SED given a limited number of data points in MIR and FIR (see Section 4.2.4).

3.5.6. Radio Spectral Index

We present radio spectral index (α_{radio}) and luminosity ratio of IR and radio wavelength (q_{IR}) in the following subsections. Although our sample always has 1.4 GHz data, only one-quarter of objects have 150 MHz data as reported in Section 2.1.6. This means that it is quite hard to determine the radio properties with CIGALE for objects without counterparts of TGSS given a limited number of data points and input parameters. Indeed, the radio spectral index and q_{IR} can be analytically derived by assuming a radio spectrum. So, we focus on 190 HSC–FIRST RGs with both 1.4 GHz and 150 MHz flux densities in Sections 3.5.6 and 3.5.7.

We derive the radio spectral index (α_{radio}) based on Equation (1). Figure 8(f) shows radio spectral index as a function of redshift. There is no clear correlation between α_{radio} and redshift, which is consistent with previous works (Blundell et al. 1999; Bornancini et al. 2010; Calistro Rivera et al. 2017). The mean value of α_{radio} of 190 HSC–FIRST RGs is ~0.73, which is consistent with what was reported in de Gasperin et al. (2018), who investigated radio spectral index over 80% of the sky based on the NVSS and TGSS. The mean values of α_{radio} of the SDSS- and HSC-level objects are ~0.72 and ~0.74, respectively. De Gasperin et al. (2018) reported that the absolute value of radio spectral index increases with radio flux densities. Because radio flux densities at 150 MHz and 1.4 GHz of the HSC-level objects are slightly larger than those of SDSS-level objects, the tiny difference of α_{radio} between SDSS- and HSC-level objects could be explained as a difference of their radio flux densities.

3.5.7. q_{IR}

The ratio of IR and radio luminosity (q_{IR}) is defined as follows (see also Helou et al. 1985; Ivison et al. 2010):

$$q_{\rm IR} = \log\left(\frac{L_{\rm IR}/3.75 \times 10^{12}}{L_{1.4 \rm ~GHz}}\right),$$
 (4)

where $L_{\rm IR}$ is the total IR luminosity in unit of W derived from CIGALE. 3.75×10^{11} is the frequency (Hz) corresponding to 80 μ m, which is used for making $q_{\rm IR}$ a dimensionless quantity. $L_{1.4 \text{ GHz}}$ in unit of W Hz⁻¹ is *k*-corrected luminosity at rest-frame 1.4 GHz, which is derived by Equation (3).

Figure 8(g) shows q_{IR} as a function of redshift. Although there is no clear dependence of q_{IR} on redshift, the mean value of 190 HSC–FIRST RGs is 0.34, which is significantly lower than that of pure SF galaxies whose q_{IR} is ~2–3 (Yun et al. 2001; Bell 2003; Ivison et al. 2010). This is reasonable because it is known that radio-loud galaxies/AGNs with log $L_{radio} > 24$ W Hz⁻¹ tend to have significantly small q_{IR} with wide dispersion (Sajina et al. 2008; Calistro Rivera et al. 2017; Williams et al. 2018). We will discuss this point later by using "radio-excess parameter" in Section 4.5.

The mean values of $q_{\rm IR}$ of SDSS- and HSC-level objects are ~0.37 and ~0.31, respectively. Calistro Rivera et al. (2017) reported that $q_{\rm IR}$ could be decreased with increasing redshift, while Read et al. (2018) reported that $q_{\rm IR}$ could also be decreased with increasing specific SFR (sSFR \equiv SFR/ M_*). Because HSC-level objects are located at higher redshift and they have smaller stellar mass and higher SFR (i.e., higher sSFR), as mentioned in Sections 3.5.2 and 3.5.3, the difference in $q_{\rm IR}$ between SDSS- and HSC-level objects may be explained by the difference of their redshift and sSFR.

3.6. Composite Spectrum

Finally, we show a composite spectrum of the SDSS- and HSC-level objects in Figure 9. Here we performed the median stacking only for 190 HSC–FIRST RGs with reliable radio spectral index. In optical to NIR regime, HSC-level objects are typically less luminous compared with SDSS-level objects, suggesting that HSC-level objects are more affected by dust extinction and their stellar masses are smaller than those of the SDSS-level objects, as reported in Sections 3.5.1 and 3.5.2. Once wavelength is beyond 1 μ m, hot dust emission heated by AGNs and cold dust emission heated by SF will be dominant for HSC-level objects, indicating that HSC-level objects have a large AGN and SF luminosity (i.e., large IR luminosity and SFR)

Figure 9. Composite SEDs of SDSS- (blue) and HSC-level (red) RGs with reliable α_{radio} . Shared regions represent standard deviation of the median stacking SEDs. These SED templates are available in Table 4.

compared with SDSS-level objects, as reported in Sections 3.5.3–3.5.5. The best-fit SED template of each HSC–FIRST RG is available in Table 4.

4. Discussion

4.1. Selection Bias

As described in Sections 2 and 3, we selected 1056 objects with reliable redshift and reasonable redshift cut among 1943 RGs and eventually investigated physical properties for 835 RGs with SED fitting. This means that 1943 - 835 = 1108 (~57%) objects were excluded in this work, which would affect the results we presented above.

To check whether or not we would select a specific population among the entire HSC-FIRST RG sample, we investigated their optical colors. Figure 10 shows a color-color diagram of r - i versus i - z for the entire sample of 1943 objects and subsample of 835 objects. Because the HSC-FIRST RG sample requires all the detections of r, i, and z-band with S/N > 5 (see Yamashita et al. 2018), all objects in the entire sample and subsample are plotted in this figure. A twosided K-S test does not rule out a hypothesis that the distribution of i - z for the subsample of 835 RGs is the same as that for the entire sample of 1943 RGs at >99.9% significance, which is also supported by a Wilcoxon rank-sum test. On the other hand, those two tests find that two distributions of r - i are statistically different. This could suggest that physical quantities of the subsample of 835 RGs may be (more or less) affected by selection bias, which we should keep in mind in the following discussions.

4.2. Possible Uncertainties

We discuss the possible uncertainties of physical properties derived by CIGALE. We consider the following four things: how (i) the uncertainty of photometric redshift and (ii) the difference in spatial resolution of each catalog affect the derived physical quantities, and comparison of resultant physical quantities with (iii) spectroscopically derived ones and (iv) those derived from the mock catalog. We find that our RG sample is likely to have additional uncertainties, especially for SFR and AGN luminosity. However, it is hard to estimate the exact uncertainty for an individual object because we infer

Figure 10. Color–color diagram of r - i and i - z. The 1943 HSC–FIRST RG sample, and 835 RGs whose physical properties are studied in this work, are shown in black and magenta circles, respectively. Histogram of each color is also shown with solid lines (an entire sample of 1943 objects) and magenta-shaded regions (a subsample of 835 objects).

the additional uncertainty based on a sort of Monte Carlo simulation. Therefore, we do not include/propagate those possible uncertainties to the original ones output by CIGALE, and focus on a statistical view of possible uncertainties.

4.2.1. Uncertainty of Photometric Redshift

We selected 1056 HSC–FIRST RGs with reliable redshifts as described in Section 2. In particular, we allowed relative errors of photo-*z* to be at most 10%. Here we discuss how the uncertainty of photo-*z* affects the derived physical quantities with SED fitting, by performing the following test. First, we assumed a Gaussian distribution with a mean (a photo-*z* of an object) and sigma (its photo-*z* error) for each object, and randomly chose one value among the distribution as an adopted redshift. We then conducted the SED fitting with CIGALE under the exact same parameter as what we used in this work for 785 objects whose redshifts came from photo-*z* with MIZUKI (see Section 2.1.6).

Figure 11 shows the differences in $E(B - V)_*$, log M_* , log SFR, log L_{IR} (AGN), and log L_{IR} derived from CIGALE in this work and those derived from CIGALE with random redshift assuming a Gaussian for each object as a function of redshift. The mean values of each quantity are almost zero, while the standard deviations of $\Delta E(B - V)_*$, $\Delta \log M_*$, $\Delta \log SFR$, $\Delta \log L_{IR}$ (AGN), and $\Delta \log L_{IR}$ are 0.03, 0.09, 0.25, 0.10, and 0.10, respectively. We found that $\Delta \log SFR$ is slightly larger than others due to a relatively large fraction of outliers, suggesting that SFR is most sensitive to uncertainty of photometric redshift. We should keep in mind these possible uncertainties caused by photo-*z* error.

4.2.2. Influence of Difference in Spatial Resolution of Each Catalog on Physical Quantities

As described in Section 2, we combined multi-wavelength catalogs with different spatial resolutions. In particular, because the angular resolutions of *Herschel* and GMRT are relatively poor, we adopted 10" and 20" as a search radius to crossidentify with H-ATLAS and TGSS, respectively. If there are multiple IR/radio sources within the search radii but H-ATLAS/TGSS could not resolve them, their FIR and radio (150 MHz) flux densities could be overestimated, which

Figure 11. The differences in $E(B - V)_*$, stellar mass, SFR, L_{IR} (AGN), and L_{IR} derived from CIGALE in this work and those derived from CIGALE with a random redshift assigned to each RG assuming a Gaussian probability function for the estimated photometric redshift. (a) $\Delta E(B - V)_*$, (b) $\Delta \log M_*$, (c) $\Delta \log$ SFR, (d) $\Delta \log L_{IR}$ (AGN), and (e) $\Delta \log L_{IR}$ as a function of redshift. The right panels show a histogram of each quantity. The red dotted lines are the $\Delta = 0$.

induces a systematic offset for physical quantities, such as IR luminosity and radio spectral index, that are derived by SED fitting (see e.g., Pearson et al. 2018). This effect would be severe for fainter objects at high-*z* universe (i.e., HSC-level RGs). If we could deblend those sources and re-measure FIR and radio flux densities for an individual object, it would provide us (more or less) an accurate measurement of flux density, although the deblending process may also have an uncertainty, which is beyond the scope of this paper. Therefore, we briefly discuss a possible influence of relatively large beam sizes of H-ATLAS and TGSS on derived physical quantities.

First, we check a possibility of overestimate of FIR flux densities in H-ATLAS by using the ALLWISE catalog, whose sensitivity and angular resolution are better than those of *Herschel* (see Section 2.1.3). We count all nearby *WISE* sources around an object with a search radius of 10". If more than one *WISE* source is found around that object, those IR sources would contribute to FIR flux densities that are unresolved by *Herschel*, and their FIR flux densities would be overestimated. We confirm that 89/835 (~11%) objects have multiple *WISE* counterparts within 10". Here we test whether or not their IR luminosity has a systematically large value due to boost of their FIR flux densities.

Figure 12 shows the histogram of IR luminosity for 835 HSC– FIRST RGs and 89 objects with multiple *WISE* counterparts. We find that there is no systematic difference between them. The mean IR luminosity of 89 objects is $\log(L_{\rm IR}/L_{\odot}) \sim 11.48$,

Figure 12. The distribution of IR luminosity for HSC-FIRST RGs. The yellow-shaded region corresponds to objects with multiple *WISE* counterparts.

Figure 13. The distribution of radio spectral index for HSC-FIRST RGs. The green-shaded region corresponds to objects with multiple FIRST counterparts.

which is in good agreement with that of all HSC–FIRST RGs, suggesting that poor angular resolution of H-ATLAS does not significantly affect the measurement of FIR flux densities.

Next, we check a possibility of overestimate of radio flux density at 150 MHz in TGSS by using the FIRST catalog, whose sensitivity and angular resolution (6'') are better than those of GMRT. We count all nearby FIRST sources around an object with a search radius of 20", and confirm that 27/190 (~14%) objects have multiple FIRST counterparts within 20". Here we test whether or not their radio spectral index (α_{radio}) have systematically large value due to a boost of their 150 MHz flux densities. Figure 13 shows the histogram of radio spectral index for 190 HSC-FIRST RGs, and 27 objects with multiple FIRST counterparts. We find that 27 objects systematically have large $\alpha_{\rm radio}$. Their mean $\alpha_{\rm radio}$ is 1.19, which is significantly larger than that of all HSC-FIRST RGs, suggesting that radio spectral indices of some RGs have a potential to be overestimated. We note that radio morphology of some RGs looks different from optical/IR; for example, they have radio lobes in addition to radio core, which makes the cross-identification between optical and radio complicated. We visually checked radio images to see how many RGs could have that kind of complex morphology. We found that 48/835 (~5.7%) of our RGs sample would have such morphology. Their mean α_{radio} is 1.05, which is also larger than the typical value of HSC-FIRST RGs, suggesting that flux

density at 150 MHz taken by TGSS with poor spatial resolution may measure even emission from lobes, and thus that their α_{radio} may be overestimated.

4.2.3. Comparison with Spectroscopically Derived Quantities

We derived $E(B - V)_*$, stellar mass, and SFR based on photometric data with SED fitting, as presented in Sections 2 and 3. Here, we check the consistency between those quantities derived based on CIGALE and spectroscopic data. We compiled the stellar masses from the SDSS DR12 stellar-MassPCAWiscBC03 table, which are derived using the method of Chen et al. (2012) with the SSP models of Bruzual & Charlot (2003). Because a default IMF adopted in the stellarMassPCAWiscBC03 table is Kroupa (2001), we converted their Kroupa stellar masses to those with Chabrier (2003) IMF by subtracting 0.05 dex from the logarithm of stellar masses, in the same manner as Chen et al. (2012). For $E(B - V)_*$, we utilized the SDSS DR12 emissionLinesPort table, in which objects are fitted using an adaptation of the publicly available Gas AND Absorption Line Fitting (GANDALF; Sarzi et al. 2006) and penalized PiXel Fitting (pPXF; Cappellari & Emsellem 2004). Stellar population models for the continuum come from Maraston & Strömbäck (2011) and Thomas et al. (2011). For SFR, we used an emission line-based SFR where we selected [O II] $\lambda\lambda$ 3726,3729 doublet, which is known as a good indicator of SFR (e.g., Kennicutt 1998). We used a relation suggested by Kewley et al. (2004) to estimate [O II]-based SFR (SFR_[O II]):

$$SFR_{[O II]} = (6.58 \pm 1.65) \times 10^{-42} L_{[O II]}^{cor},$$
(5)

where $L_{[O II]}^{cor}$ is the extinction-corrected [O II] luminosity in units of erg s⁻¹, which is calculated using the following formula (see Calzetti et al. 1994; Domínguez et al. 2013):

$$L_{\rm [O II]}^{\rm cor} = L_{\rm [O II]}^{\rm obs} \, 10^{0.4k_{\rm [O II]} E(B-V)_{\rm gas}},\tag{6}$$

where $L_{[O II]}^{obs}$ is the observed [O II] luminosity, $k_{[O II]}$ is the extinction value at $\lambda = 3727$ Å provided by Calzetti et al. (2000), and $E(B - V)_{gas}$ is the color excess estimated from emission lines. The observed [O II] flux and $E(B - V)_{gas}$ are tabulated in emissionLinesPort table.

Figure 14 shows the differences in $E(B - V)_*$, stellar mass, and SFR derived from CIGALE and those derived from the SDSS spectroscopic data (i.e., the stellarMassPCA-WiscBC03 and emissionLinesPort tables). We found that $E(B - V)_*$ derived from CIGALE is slightly overestimated by 0.03 dex, while $\log M_*$ derived from CIGALE is significantly underestimated by 0.27 dex (see Figures 14(a) and (b)). However, this offset is consistent with what was reported in Chen et al. (2012), who compared stellar masses derived from their method with principal component analysis (PCA) and those derived from the SDSS 5-band photometry. They reported that the PCA-based stellar mass shows a systematically positive offset. We also note that assumed SFH in Chen et al. (2012) differs from that in this work, which would also induce a systematic difference of $E(B - V)_*$ and stellar mass. The mean value of $\Delta \log$ SFR is 0.06, which is negligibly small, while its standard deviation is 0.77, which is very large, as shown in Figure 14(c). Because a typical uncertainty of [O II]-based SFR is about 0.6 dex, whether or not the above large offset is significant is still unclear. Another possibility of the large dispersion of $\Delta \log$ SFR may be a contamination of

Figure 14. The differences in $E(B - V)_{*}$, stellar mass, and SFR derived from CIGALE and those derived from the SDSS DR12 spectroscopic data (stellarMassPCAWiscBC03 and emissionLinesPort table). (a) $\Delta E(B - V)_{*}$, (b) $\Delta \log M_{*}$, and (c) $\Delta \log$ SFR as a function of redshift. The right panels show a histogram of each quantity. The red dotted lines are the $\Delta = 0$.

the AGN extended emission line region. Recently, Maddox (2018) reported that [O II] is not always a good indicator of SFR for AGNs when strong [Ne V] λ 3426 is present in the AGN spectrum. Roughly a quarter of the RG sample with SDSS spectra has a prominent [Ne V] line with S/N > 5.0, and thus their [O II]-based SFR would have a large uncertainty. Nevertheless, we should keep in mind the possibility of those systematic uncertainties. On the other hand, this test is only appreciable to SDSS-level objects (z < 0.8) and thus we need to check whether or not the resultant quantities of HSC-level objects is reliable through another way (see Section 4.2.4).

4.2.4. Comparison with Physical Quantities Derived from Mock Catalog

Since CIGALE has a procedure to asses whether or not physical properties can actually be estimated in a reliable way through the analysis of a mock catalog, we here discuss the influence of photometric uncertainty on the derived physical quantities. To make the mock catalog, CIGALE first uses the photometric data for each object based on the best-fit SED, and then modifies each photometry by adding a value taken from a Gaussian distribution with the same standard deviation as the observation. This mock catalog is then analyzed in the exact same way as the original observations (see Boquien et al. 2019 for more detail).

Figure 15 shows the differences in $E(B - V)_*$, stellar mass, SFR, L_{IR} (AGN), and L_{IR} derived from CIGALE in this work and those derived from the mock catalog as a function of redshift. The mean values of $\Delta E(B - V)_*$, $\Delta \log M_*$, $\Delta \log$ SFR, $\Delta \log L_{IR}$ (AGN), and $\Delta \log L_{IR}$ are 0.03, -0.03, 0.14, 0.15, and 0.32, respectively. In particular, we can see a secondary peak in $\Delta \log$ SFR and $\Delta \log L_{IR}$ (AGN) regardless of redshift. This suggests that SFR and AGN luminosity are sensitive to uncertainty of photometry, which may be a limitation of our SED fitting method given a limited number of data points in MIR and FIR.

Figure 15. The differences in $E(B - V)_*$, stellar mass, SFR, L_{IR} (AGN), and L_{IR} derived from CIGALE in this work and those derived from the mock catalog. (a) $\Delta E(B - V)_*$, (b) $\Delta \log M_*$, (c) $\Delta \log$ SFR, (d) $\Delta \log L_{IR}$ (AGN), and (e) $\Delta \log L_{IR}$ as a function of redshift. The right panels show a histogram of each quantity. The red dotted lines are the $\Delta = 0$.

4.3. Stellar Mass and SFR Relation as a Function of Redshift

It is well known that the stellar mass and SFR of galaxies are correlated, and the majority of galaxies follow a relation called the main sequence (MS) (e.g., Brinchmann et al. 2004; Daddi et al. 2007; Elbaz et al. 2007). This relation has evolved toward high redshift (e.g., Speagle et al. 2014; Lee et al. 2015; Tomczak et al. 2016). Galaxies undergoing active SF (so-called starburst galaxies) lie above the MS, while those without active SF (so-called passive galaxies) lie below the MS. The stellar mass and SFR are fundamental physical quantities of galaxies, and thus investigating the relation (M_*-SFR) provides us a clue of galaxy evolution. Here we investigate the stellar mass and SFR relation for HSC-FIRST RGs to see if there is any difference between SDSS- and HSC-level RGs. Because stellar masses and SFRs of RGs depend on *i*-band magnitude and redshift (see Figures 8(b) and (c)), we check M_* -SFR for SDSS- and HSC-level RGs as a function of redshift.

Figure 16 shows the stellar mass and SFR for HSC–FIRST RGs as a function of redshift. The M_* –SFR relations of MS galaxies as a function of redshift are also plotted, and are provided by Pearson et al. (2018). They measured stellar mass and SFR by using multi-wavelength data including UV to FIR. They also employed CIGALE to derive those quantities by assuming the same SFH, SSP, and IMF as this work. This is important to do a fair comparison because different assumptions of SFH, SSP, and IMF induces a systematic offset for stellar mass and (particularly) SFR (e.g., Maraston et al. 2010).

Figure 16. Stellar mass and SFR for HSC–FIRST RGs as a function of redshift. Blue and red points are the SDSS- and HSC-level RGs, respectively. The green lines are the main sequences (MSs) of SF galaxies at each redshift range provided by Pearson et al. (2018). The green-shaded regions correspond to an intrinsic scatter of each green line.

At low redshift (0.2 < z < 0.8), the majority of the SDSS-level objects lie below the MSs, indicating that they are passive galaxies, which is consistent with a classical view of RGs in the local universe (Best & Heckman 2012). At intermediate redshift (0.8 < z < 1.1)—that is, an overlapped redshift regime between SDSS- and HSC-level RGs—they are widely distributed on the M_* -SFR plane: from passive, MS, to starburst galaxies. We find that there is no clear difference between SDSS- and HSC-level RGs. At high redshift (1.1 < z < 1.7), the majority of the HSC-level RGs are located at MS, although some HSC-level RGs lie above the MS of SF galaxies. Eventually, we confirmed that our HSC-FIRST RG sample contains various populations, including classical passive RGs, normal SF galaxies, and starburst galaxies.

4.4. AGN Luminosity and SFR Relation as a Function of Redshift

We investigate the relation between AGN and SF activity for HSC–FIRST RGs. Many studies have demonstrated that AGN activity (e.g., AGN bolometric luminosity) correlates with SF

Figure 17. The relationship between IR luminosity contributed from AGN and SFR for HSC–FIRST RGs as a function of redshift. Blue and red points are the SDSS- and HSC-level RGs, respectively.

activity (e.g., FIR luminosity), especially for luminous AGNs (e.g., Netzer 2009; Shao et al. 2010; Rosario et al. 2012; Stanley et al. 2017; Ueda et al. 2018). Although we already showed AGN luminosity and SFR for SDSS- and HSC-level RGs (see Figure 8), we here investigate their relationship as a function of redshift in order to check that there is a difference in SDSS- and HSC-level RGs.

Figure 17 shows the relation between IR luminosity contributed from AGN, L_{IR} (AGN), and SFR as a function of redshift, where L_{IR} (AGN) and SFR are derived in Sections 3.5.4 and 3.5.3, respectively. We find that there is no clear difference in SDSS- and HSC-level RGs at a given redshift.

4.5. Radio-excess Parameter

In Section 3.5.7, we found that q_{IR} of HSC–FIRST RGs is significantly lower than that of pure SF galaxies. Del Moro et al. (2013) defined "radio-excess sources" with $q_{IR} < 1.68$, which corresponds to 3σ deviation from the peak of the distribution for their sample. According to their criterion, all of our HSC–FIRST RGs with TGSS data are radio-excess

Figure 18. $q_{\text{excess}} = \log [L_{1.4 \text{ GHz}}/\text{SFR}(\text{IR})]$ (radio-excess parameter) as a function of redshift. Small dots are radio sources discovered by the VLA-COSMOS 3 GHz large project (Smolčić et al. 2017a). Large circles with red color are our HSC-FIRST RGs. Small red dots mean VLA-COSMOS sources with log $L_{1.4 \text{ GHz}} > 25 \text{ W Hz}^{-1}$. The blue line is the threshold of radio-excess sources that is formulated as $q_{\text{excess}} = 21.984 \times (1 + z)^{0.013}$ (Delvecchio et al. 2017). Objects with q_{excess} greater than this threshold are classified as radio-excess sources.

sources. Even if we calculate q_{IR} for objects without TGSS data by adopting mean value of radio spectral index, about 98% of objects remain radio-excess sources. Why are almost all HSC–FIRST RGs radio-excess sources? We report that this is due to our selection bias by comparing with much fainter RGs.

Here, we define "radio-excess parameter," which was introduced in Delvecchio et al. (2017):

$$q_{\text{excess}} = \log\left(\frac{L_{1.4 \text{ GHz}}}{\text{SFR(IR)}}\right),\tag{7}$$

where $L_{1.4 \text{ GHz}}$ is what we obtained in Equation (3). SFR (IR) is derived from IR luminosity contributed from SF in the same manner as Toba et al. (2017c) (see also Kennicutt 1998; Salim et al. 2016):

$$\log SFR (IR) = \log L_{IR} (SF) - 9.966.$$
 (8)

Delvecchio et al. (2017) defined a threshold of radio-excess sources as a function of redshift; if an object at a redshift *z* has $q_{\rm excess} > 21.984 \times (1 + z)^{0.013}$, the object is classified as a radio-excess source. This definition is fairly consistent with that of Delvecchio et al. (2017); radio-excess objects based on their selection satisfy the criterion of Delvecchio et al. (2017), i.e., their $q_{\rm IR}$ values are less than 1.68.

Figure 18 shows radio-excess parameter as a function of redshift for HSC-FIRST objects with TGSS data. Lowluminosity radio sources found by the VLA-COSMOS 3 GHz large project (Smolčić et al. 2017a, 2017b) are also plotted. We found that almost all RGs with log $L_{1.4 \text{ GHz}} > 25.0 \text{ W Hz}^{-1}$ are classified as radio-excess sources. Because 156/190 (~82%) of the HSC-FIRST RG sample has $\log L_{1.4 \text{ GHz}} > 25.0 \text{ W Hz}^{-1}$, we conclude that the fact that our sources are radio-excess objects may be due to the flux cut $(f_{1.4 \text{ GHz}} > 1.0 \text{ mJy})$ for HSC-FIRST RGs (see Section 2.1). We also confirm that the origin of radio excess is due to AGNs that boost radio luminosity, because their SFRs are basically normal SF galaxies (see Section 3.5.3). Indeed, Del Moro et al. (2013) reported that the fraction of radio-excess objects increases with X-ray luminosity. They also found that roughly half of these radio-excess AGNs are not detected in the deep Chandra X-ray

Figure 19. Ratio of rest-frame 22 and 3.4 μ m luminosities for SDSS-level (red), HSC-level (blue), and total (black) RGs.

data. Taking the fact that HSC-level objects have large $E(B - V)_*$ (see Section 3.5.1) into account, these results could indicate that particularly some HSC-level RGs harbor heavily obscured AGNs.

4.6. Accretion Rate

We discuss the BH mass accretion rate of SDSS- and HSClevel objects. RGs are classified into low-excitation RGs (LERGs) and high-excitation RGs (HERGs) based on their optical spectra (e.g., Laing 1994; Buttiglione et al. 2010). Many works have studied physical properties of LERGs and HERGs, and have revealed that HERGs tend to have low stellar mass and high SFR, while LERGs tend to reside in denser environments (e.g., Best & Heckman 2012; Janssen et al. 2012; Ching et al. 2017). In terms of WISE colors, LERGs are basically distributed at ellipticals/spirals/LIRGs, while HERGs are basically distributed at Seyferts/starbursts/ ULIRGs (Gürkan et al. 2014; Yang et al. 2015; Mingo et al. 2016; Whittam et al. 2018). This result could indicate that the relation between LERGs and HERGs is likely to be similar to that of SDSS- and HSC-level objects (e.g., Prescott et al. 2018). Because the observational characteristics of HERGs and LERGs are mainly driven by the accretion rate on to the SMBH (Best & Heckman 2012), it is expected that the accretion rate of HSC-level objects would differ from that of SDSS-level objects.

First, we checked a difference of observational quantities, the ratio of rest frame 22 and 3.4 μ m in the same manner as Gürkan et al. (2014). Because the rest-frame 22 μ m luminosity is a good tracer of AGN luminosity, while rest-frame 3.4 μ m luminosity roughly corresponds to stellar mass, their luminosity ratio is a proxy of the Eddington-scaled accretion rate. Restframe 3.4 and 22 μ m luminosities were derived from CIGALE, which conducted a convolution integral of best-fit SED with filter response functions of *WISE W*1 and *W*4 bands.

Figure 19 shows a histogram of luminosity ratio of rest frame 22 and 3.4 μ m for HSC–FIRST RGs. There is a clear difference between SDSS- and HSC-level objects; the luminosity ratio of HSC-level objects is systematically larger than that of SDSS-level objects. This result suggests that HSC-level objects have a high Eddington-scaled accretion rate compared with SDSS-level objects.

Next, we performed a rough estimate of Eddington ratio (λ_{Edd}) of our RG sample, in the same manner as Toba et al. (2017a)

Figure 20. A histogram of Eddington ratio for SDSS-level (red), HSC-level (blue), and total (black) RGs.

(see also Mingo et al. 2016; Whittam et al. 2018). The BH mass $(M_{\rm BH})$ was estimated from stellar mass by using an empirical relation with a scatter of 0.24 dex, reported in Reines & Volonteri (2015):

$$\log(M_{\rm BH}/M_{\odot}) = 7.45 + 1.05 \times \log(M_{*}/10^{11}M_{\odot}), \quad (9)$$

and we converted it to Eddington luminosity (L_{Edd}). The bolometric luminosity (L_{bol}) is estimated by integrating the best-fit SED template of AGN component output by CIGALE over wavelengths longward of Ly α .

Figure 20 shows a histogram of λ_{Edd} (= L_{bol}/L_{Edd}) of HSC-FIRST RGs. The HSC-level objects clearly have a large Eddington ratio compared with SDSS-level objects. The mean values of (λ_{Edd}) SDSS- and HSC-level objects are -1.95 and -0.94, respectively, indicating that HSC-level objects have actively growing SMBHs in their center. We note that a fraction of HSC-level objects have $\lambda_{Edd} > 1$. Their Eddington ratios may be overestimated due to underestimation of their black hole mass. We used the empirical relation of stellar mass and BH mass provided by Reines & Volonteri (2015), which is optimized for broad-line AGNs with $6 < \log(M_{\rm BH}/M_{\odot}) < 8$ at z < 0.1. If we use another empirical relation for elliptical galaxies provided by Reines & Volonteri (2015), the resultant BH masses are roughly one order of magnitude larger than those we reported above. McLure et al. (2006) also reported that the BH to bulge mass ratio of radio-loud AGNs increases with increasing redshift; given a bulge mass of an object at z > 1, its BH mass is larger than that of the local universe. Because a large fraction of HSC-level objects are radio-loud AGNs at z > 1, their BH masses would be underestimated. Nevertheless, the difference in Eddington ratio between SDSSand HSC-level objects seems to be significant even if the BH mass of HSC-level objects would be underestimated by 0.5-1 dex.

4.7. Duty Cycle of the HSC-FIRST RGs

Finally, we briefly discuss the duty cycle of SDSS- and HSC-level RGs and their evolutionary link. It should be noted that because our RG sample might be affected by systematic uncertainty and selection bias, as discussed in Sections 4.1 and 4.2, the estimated duty cycle may also have a large uncertainty. Nevertheless, it is worth discussing how the RG sample discovered by the HSC and FIRST can be interpreted in the framework of galaxy formation and evolution. We selected

501 SDSS-level RGs at 0.1 < z < 1.2, while 334 HSC-level RGs were at 0.5 < z < 1.7 in ~94.7 deg². The corresponding co-moving volume density of SDSS- and HSC-level RGs is 8.9×10^{-7} and 3.3×10^{-7} cMpc⁻³, respectively.²⁷ On the other hand, the range of stellar mass derived by CIGALE for SDSS-level RGs is $11.0 < \log(M_*/M_{\odot}) < 11.6$, while that for HSC-level RGs is $10.6 < \log(M_*/M_{\odot}) < 11.5$. According to the stellar mass function of massive galaxies provided by Kajisawa et al. (2009),²⁸ the volume density of galaxies with same redshift and stellar mass range as SDSS- and HSC-level RGs is 3.1×10^{-4} and 7.9×10^{-4} cMpc⁻³, respectively. If we assume that massive galaxies with $\log(M_*/M_{\odot}) \sim 11.0$ have an experience of HSC-FIRST RG phase at least once during a redshift range in which they are observed (i.e., 6.95 and 4.82 Gyr for SDSS- and HSC-level RGs, respectively), the resultant duty cycle of SDSS- and HSC-level RGs is 0.003 $(\sim 19.6 \text{ Myr})$ and 0.0004 $(\sim 2.0 \text{ Myr})$, respectively.

Because the stellar mass of the vast majority of the optically faint RGs is indeed as massive as the bright RGs, there may be a possibility that they are evolutionally linked. We may be witnessing short duty-cycle phenomena, which may be able to quench SF activity at $z \sim 1.0$ or keep quenching SF activity at $z \sim 0.5$ and to activate AGNs in relatively massive galaxies. On the other hand, the duty cycle of HSC-level RGs seems to be too short as a duration of radio jet activity in powerful RGs. One possibility is that our assumption to derive the duty cycle (i.e., massive galaxies have an experience of HSC–FIRST RG phase at least once during their redshift range) is too strict. If we assume that massive galaxies would have an experience of HSC–FIRST RG phase at least once in the history of the universe, the duty cycle could be about 10 Myr.

5. Summary

In this work, we investigated the physical properties of optically faint RGs with $f_{1.4 \text{ GHz}} > 1 \text{ mJy}$ selected by HSC and FIRST, whose nature has been poorly understood so far. We constructed a subsample of 1056 RGs with reliable redshift and multi-wavelength data from optical to radio, among a sample of 1943 RGs in $\sim 100 \text{ deg}^2$. By conducting the SED fitting with CIGALE, we obtained reliable physical quantities of 835 objects at $0 < z \leq 1.7$. Thanks to the deep optical imaging with HSC, we are able to investigate physical quantities of luminous RGs even at z > 0.5, which cannot be probed by previous optical surveys. We investigate the physical quantities as a function of redshift. In addition, we discuss the physical difference between optically bright, SDSS-level RGs with i < 21.3 mag (mean z = 0.57) and optically faint, HSC-level RGs with $i \ge 21.3 \text{ mag}$ (mean z = 1.10). We summarize resultant properties (mean value of each quantity for SDSSand HSC-level RGs and total RG sample) in Table 2. The main results are as follows.

- 1. Color excess, $E(B V)_*$, increases with increasing redshift, and thus $E(B V)_*$ of HSC-level objects is larger than that of SDSS-level objects (Section 3.5.1).
- 2. Stellar mass is not significantly correlated with redshift. But the mean stellar mass of HSC-level objects is slightly smaller than that of SDSS-level objects. On the other hand, SFR increases with increasing redshift, and thus

 Table 2

 Summary of Physical Properties (the Mean Value of Each Quantity) of 835

 HSC-FIRST RGs

Physical Properties	SDSS-level	HSC-level	Total
$\overline{E(B-V)_*}$	0.19	0.45	0.30
$\log(M_*/M_{\odot})$	11.26	11.08	11.19
$\log SFR [M_* yr^{-1}]$	0.55	1.51	0.93
$\log [L_{IR}(AGN)/L_{\odot}]$	10.56	11.32	10.87
$\log(L_{\rm IR}/L_{\odot})$	11.31	12.04	11.61
$\alpha_{\rm radio}$	0.72	0.74	0.73
$q_{\rm IR}$	0.37	0.31	0.34
$\log \lambda_{ m Edd}$	-1.95	-0.94	-1.54

SFR of HSC-level objects is larger than that of SDSS-level objects (Sections 3.5.2 and 3.5.3).

- 3. Total IR luminosity and IR luminosity contributed from AGN increase with increasing redshift, and thus those luminosities of HSC-level objects are larger than those of SDSS-level objects. Most HSC-level objects are classified as ULIRGs with $\log(L_{\rm IR}/L_{\odot}) > 12.0$ (Sections 3.5.4 and 3.5.5).
- 4. Radio spectral index (α_{radio}) and luminosity ratio of IR and radio (q_{IR}) do not significantly depend on redshift. However, the mean α_{radio} of HSC-level objects is slightly larger than that of SDSS-level objects, while mean q_{IR} of HSC-level objects is smaller than that of SDSS-level objects (Sections 3.5.6 and 3.5.7).
- 5. Eddington ratio (λ_{Edd}) of HSC-level objects is larger than that of SDSS-level objects, suggesting that optically faint HSC-level RGs discovered by HSC and FIRST could be dust-obscured AGNs with actively growing SMBHs (Section 4.6).

Overall, our HSC–FIRST sample seems to have a variety of RGs, including classical ones with massive host, low SFR, and low Eddington ratio, and a sort of new population with less massive host, high SFR, and high Eddington ratio. In particular, the later ones are optically faint and high redshift RGs that cannot be discovered by the SDSS, whose properties differ from a classical view of RGs. We conclude that the WERGS project with HSC and FIRST explores a new population that would be missed by previous surveys.

We gratefully acknowledge the anonymous referee for a careful reading of the manuscript and very helpful comments. We are deeply thankful to Prof. Denis Burgarella, Dr. Médéric Boquien, and Dr. Laure Ciesla for helping us to understand CIGALE code.

Table 3
(Continued)

Column name	Format	Unit	Description
Flag_u	INT		Flag for u-band data (0: CIGALE. 1: CIGALE with 3σ upper limit, 2: non CIGALE
Flag_g	INT		Flag for g-band data (0: CIGALE. 1: CIGALE with 3σ upper limit, 2: non CIGALE
Flag_r	INT		Flag for r-band data (0: CIGALE. 1: CIGALE with 3σ upper limit, 2: non CIGALE
Flag_i	INT		Flag for <i>i</i> -band data (0: CIGALE. 1: CIGALE with 3σ upper limit, 2: non CIGALE
Flag_z	INT		Flag for z-band data (0: CIGALE. 1: CIGALE with 3σ upper limit, 2: non CIGALE
Flag_y	INT		Flag for y-band data (0: CIGALE. 1: CIGALE with 3σ upper limit, 2: non CIGALE
Flag_j	INT		Flag for <i>j</i> -band data (0: CIGALE. 1: CIGALE with 3σ upper limit, 2: non CIGALE
Flag_h	INT		Flag for <i>h</i> -band data (0: CIGALE. 1: CIGALE with 3σ upper limit, 2: non CIGALE
Flag_ks	INT		Flag for ks-band data (0: CIGALE. 1: CIGALE with 3σ upper limit, 2: non CIGALE
Flag_34	INT		Flag for 3.4 μ m data (0: CIGALE. 1: CIGALE with 3 σ upper limit, 2: non CIGALE
Flag_46	INT		Flag for 4.6 μ m data (0: CIGALE. 1: CIGALE with 3 σ upper limit, 2: non CIGALE
Flag_12	INT		Flag for 12 μ m data (0: CIGALE. 1: CIGALE with 3 σ upper limit, 2: non CIGALE
Flag_22	INT		Flag for 22 μ m data (0: CIGALE. 1: CIGALE with 3 σ upper limit, 2: non CIGALE
Flag_100	INT		Flag for 100 μ m data (0: CIGALE. 1: CIGALE with 3 σ upper limit, 2: non CIGALE
Flag_160	INT		Flag for 160 μ m data (0: CIGALE. 1: CIGALE with 3 σ upper limit, 2: non CIGALE
Flag_250	INT		Flag for 250 μ m data (0: CIGALE. 1: CIGALE with 3 σ upper limit, 2: non CIGALE
Flag_350	INT		Flag for 350 μ m data (0: CIGALE. 1: CIGALE with 3 σ upper limit, 2: non CIGALE
Flag_500	INT		Flag for 500 μ m data (0: CIGALE. 1: CIGALE with 3 σ upper limit, 2: non CIGALE
Flag_14G	INT		Flag for 1.4 GHz data (0: CIGALE. 1: CIGALE with 3σ upper limit, 2: non CIGALE
Flag_150M	INT		Flag for 150 MHz data (0: CIGALE. 1: CIGALE with 3σ upper limit, 2: non CIGALE
log_L14G ^a	DOUBLE	$W Hz^{-1}$	Rest-frame luminosity density at 1.4 GHz
log_L14G_err	DOUBLE	$W Hz^{-1}$	Uncertainty of rest-frame luminosity density at 1.4 GHz
E_BV	DOUBLE		Color excess $(E(B - V))$ derived from CIGALE
E_BV_err	DOUBLE		Uncertainty of color excess $(E(B - V))$ derived from CIGALE
log_M	DOUBLE	M_{\odot}	Stellar mass derived from CIGALE
log_M_err	DOUBLE	M_{\odot}	Uncertainty of stellar mass derived from CIGALE
log_SFR	DOUBLE	$M_{\odot} { m yr}^{-1}$	SFR derived from CIGALE
log_SFR_err	DOUBLE	$M_{\odot} { m yr}^{-1}$	Uncertainty of SFR derived from CIGALE
log_SFR_IR	DOUBLE	$M_{\odot} { m yr}^{-1}$	SFR derived from Equation (8)
log_LIR	DOUBLE	L_{\odot}	IR luminosity derived from CIGALE
log_LIR_err	DOUBLE	L_{\odot}	Uncertainty of IR luminosity derived from CIGALE
log_LIR_AGN	DOUBLE	L_{\odot}	IR luminosity contributed from AGN derived from CIGALE
log_LIR_AGN_err	DOUBLE	L_{\odot}	Uncertainty of IR luminosity contributed from AGN derived from CIGALE
alpha_radio	DOUBLE		Radio spectral index (α_{radio}) derived from Equation (1)
alpha_radio_err	DOUBLE		Uncertainty of radio spectral index (α_{radio})
qir	DOUBLE		$q_{\rm IR}$ derived from Equation (4)
qir_err	DOUBLE		Uncertainty of $q_{\rm IR}$
DOF	INT		Degree of freedom for the SED fitting
rechi2	DOUBLE		Reduced χ^2 derived from CIGALE
log_MBH	DOUBLE	M_{\odot}	Black hole mass derived from stellar mass
log_Lbol	DOUBLE	L_{\odot}	Bolometric luminosity derived from the best-fit SED
log_ledd	DOUBLE		Eddington radio (λ_{Edd})

Note.

^a If an object has α_{radio} , log $L_{1.4 \text{ GHz}}$ is derived from Equation (3). Otherwise, we assume $\alpha_{\text{radio}} = 0.7$ for a calculation (see Section 3.3). (This table is available in its entirety in machine-readable form.)

Appendix B Best-fit SED for Each Radio Galaxy

The best-fit SED derived by CIGALE is available in Table 4. We strongly encourage using a template of objects

with reduced $\chi^2 < 5.0$ for science. In addition, if you use the radio part of the best-fit SED, we recommend employing the template only for objects with TGSS detections.

THE ASTROPHYSICAL JOURNAL SUPPLEMENT SERIES, 243:15 (23pp), 2019 July

Table 4 Best-fit SED Template of Each HSC-FIRST RG

Column name	Format	Unit	Description
ID	LONG		Unique id
Wavelength	DOUBLE	μ m	Wavelength
FNU	DOUBLE	mJy	Flux density at each wavelength
LNU	DOUBLE	W	Luminosity density at each
			wavelength

(This table is available in its entirety in machine-readable form.)
