8 Running title: Plant diversity and aphid symbionts

9 Keywords: Plant diversity, multitrophic interactions, Hamiltonella, Regiella, endosymbiont, aphid

10

11

12 **Abstract**

13 Symbiotic bacteria in herbivorous insects can have strong beneficial impacts on their host's survival,
14 including conferring resistance to natural enemies such as parasitoid wasps or pathogens while also
15 imposing energetic costs on the host resulting in cost-benefit trade-offs. Whether these trade-offs
16 favour the hosting of symbionts depends on the growth environment of the herbivore. Long-term
17 experimental grassland studies have shown that increasing plant species richness leads to an
18 increased diversity of associated herbivores and their natural enemies. Such a change in natural
19 enemy diversity, related to changes in plant diversity, could also drive changes in the community of
20 symbionts hosted by the herbivorous insects. Aphids are one model system for studying symbionts in
21 insects, and effects of host-plant species and diversity on aphid-symbiont interactions have been
22 documented. Yet, we still understand little on the mechanisms underlying such effects. We review the
23 current state of knowledge on how biodiversity can impact aphid-symbiont communities and the
24 underlying drivers. Then, we discuss this in the framework of sustainable agriculture, where increased
25 plant biodiversity, in the form of wildflower strips, is used to recruit natural enemies to crop fields for
26 their pest control services. While aphid symbionts have the potential to reduce biological control
27 effectiveness through conferring protection for the host insect, we discuss how increasing plant and
28 natural enemy biodiversity can mitigate these effects and identify future research opportunities.
29 Understanding how to promote beneficial interactions in ecological systems can help in the
30 development of more sustainable agricultural management strategies.

31

32 **Background**

33 Insects are a dominant component of biodiversity in terrestrial ecosystems, driving important
34 ecosystem functions (e.g. pollination, herbivory, pest-control) thereby affecting nutrient cycling (Yang
35 & Gratton, 2014). Plant-feeding herbivorous insects form the second trophic level in food webs and
36 can cause important feedback effects such as changes in plant community composition and diversity
37 (Brown & Gange, 1999), and increase the speed of nutrient cycling (Belovsky & Slade, 2000; Nitschke
38 et al., 2015). At higher trophic levels, carnivores, omnivores, and parasitoids can control herbivore
39 communities by regulating their density and composition together with pathogens (bacteria, fungi).
40 The total of these antagonists is often referred to as "natural enemies" (Van Driesche & Hoddle,

41 2009). It is increasingly recognized that the microorganisms associated with an individual (its
42 microbiome) can influence a host's biology and modify their response to interactions with other
43 species, or the abiotic environment (Bordenstein & Theis, 2015). Such effects have been well-studied
44 in plants where beneficial microbes can boost plant resistance to pathogens, herbivores, and adverse
45 soil conditions (Vandenkoornhuysen et al., 2015). More recently, bacterial symbionts hosted by insect
46 herbivores have been identified as additional important components of ecosystems that can mediate
47 trophic interactions (McLean et al., 2016; Simon et al., 2017). These bacterial symbionts are highly
48 specialised and can have diverse ecological and evolutionary effects on their hosts, for example by
49 providing essential nutrients or resistance to natural enemies (Berendsen et al., 2012; Feldhaar,
50 2011; Ferrari & Vavre, 2011; Moran et al., 2008).

51 *Aphid-symbiont interactions*

52 Aphids and their highly-specialised bacterial symbionts are one model system for studying the
53 microbiome of insects; with aphid microbiome work focused on the roles of specialised
54 endosymbionts rather than the impact of gut microbiota that is often studied in other insects (Engel &
55 Moran, 2013). The diversity of the aphid microbiome is surprisingly low (Sugio et al., 2015), with one
56 obligate (primary), and nine common facultative (secondary) bacterial symbionts that have been
57 identified from screening in many different aphid species across the world (Zytynska & Weisser,
58 2016). Despite this low diversity, these bacterial symbionts can have strong effects on aphid survival.
59 The main obligate symbiont (*Buchnera aphidicola*) is found in almost all aphid species providing the
60 aphid with essential amino acids (Douglas, 1992). Aphid facultative symbionts have wide-ranging
61 beneficial effects but hosting a symbiont can also have an associated cost due to nutritional demands
62 of the symbiont leading to reduced longevity and fecundity in the aphid (reviewed by Oliver et al.,
63 2014). The extent of these costs is also likely context-dependent on host-plant quality, temperature, or
64 related to which other symbionts are co-hosted by the aphid, and underlies the cost-benefit trade-off
65 in hosting these potentially protective symbionts (Kwiatkowski et al., 2012). Therefore, not all aphids
66 will host all available symbionts in a population, leading them to be an interesting subject for studying
67 community-level effects of plant-insect-microbe interactions. Aphid symbionts are predominantly
68 vertically transmitted from mother to offspring, but there is also evidence of horizontal transfer of
69 symbionts among aphids during sexual reproduction (Moran & Dunbar, 2006), by parasitoids when

70 ovipositing eggs into aphids (Gehrer & Vorburger, 2012), or even through infected honeydew (Darby
71 & Douglas, 2003).

72 A number of recent reviews have summarised the known protective effects of aphid facultative
73 symbionts (Guo et al., 2017; Oliver et al., 2014), and their distribution among natural populations
74 (Zytynska & Weisser, 2016). Here, we briefly describe the effect of these symbionts on aphids in
75 relation to how these effects may alter aphid populations in natural systems. In general, symbionts
76 protect aphids against more specialised natural enemies including entomopathogenic fungi and
77 parasitoid wasps, yet once an aphid population is small, then generalist predators can help to reduce
78 populations further. Thus, here we discuss the diversity of the whole natural enemy community as the
79 combination of specialist parasitoid wasps, pathogenic fungi, and generalist predators.

80 Aphid symbionts have been found to confer resistance against parasitoid wasps, which are specialist
81 natural enemies that lay an egg into an aphid, and as the larva develops it consumes the aphid,
82 eventually emerging as an adult from the aphid mummy (hardened shell of a parasitized aphid). The
83 level of protection that is afforded by symbionts varies across aphid species/genotypes and symbiont
84 strains (Cayetano et al., 2015; Leclair et al., 2016; Vorburger et al., 2010), but in general leads to
85 increased aphid survival with potential for extinction of the natural enemy (Sanders et al., 2016).

86 Experimental work has confirmed the protective effects of symbionts against parasitoids by the well-
87 studied symbionts *Hamiltonella defensa* (reviewed in Guo et al., 2017; Oliver et al., 2014; Zytynska &
88 Weisser, 2016), *Regiella insecticola* (Hansen et al., 2012; Vorburger et al., 2010), and X-type (PAXS)
89 (Heyworth & Ferrari, 2015). It is now known that the mechanism by which *Hamiltonella* symbionts
90 protect the aphid is via a bacteriophage in the bacteria itself, which releases a toxin that can kill the
91 developing larva (Moran et al., 2005). Mechanisms of effect by the other symbionts are still to be fully
92 determined.

93 Other protective effects against natural enemies include increased aphid survival when challenged by
94 fungal pathogens for aphids hosting *Regiella insecticola*, *Rickettsia*, or *Spiroplasma* (Lukasik et al.,
95 2013a; Lukasik et al., 2013b; Scarborough et al., 2005). Another symbiont, *Rickettsiella*, has been
96 implicated in altering the body colour of aphids, with subsequent effects on parasitism and predation
97 rates across green and pink colour morphs of the pea aphid (*Acyrtosiphon pisum*) (Tsuchida et al.,
98 2014b; Tsuchida et al., 2010). Variable infection rates of this symbiont across populations could alter

99 the relative densities of each aphid colour morph, with cascading effects on the natural enemy
100 populations (Tsuchida et al., 2014b). Finally, symbionts can also mitigate abiotic stress factors.
101 *Serratia symbiotica* symbionts can protect an aphid host against heat-shock (Chen et al., 2000;
102 Russell & Moran, 2006), potentially enabling aphids to withstand high summer temperatures in more
103 sun-exposed habitats or as protection against higher microclimatic temperatures within sparser plant
104 communities.

105 The interaction between aphids and their symbionts has often been studied in a laboratory setting,
106 with artificial curing or introduction of specific symbiont strains (as first described by Simon et al.,
107 2007) determining the different effects that symbionts can have on their aphid hosts (reviewed in Guo
108 et al., 2017). However, much of this work is focused on only a few aphid or symbiont species; for
109 example, research is dominated by studies on the symbiont *Hamiltonella defensa* in pea aphids
110 (*Acyrtosiphon pisum*) (Oliver et al., 2014). Moreover, very few laboratory studies have introduced
111 multiple symbionts (but see Doremus & Oliver, 2017; Leclair et al., 2017; Leclair et al., 2016; Lukasik
112 et al., 2013a; McLean et al., 2018; Oliver et al., 2006; Tsuchida et al., 2014a), while field-collected
113 aphids have been found to co-host up to four symbionts per individual (Ferrari et al., 2012; Russell et
114 al., 2013; Smith et al., 2015; Zytynska et al., 2016). Until now, more than 150 aphid species have
115 been studied for bacterial symbiont from field-collected aphids and, while it is important to keep
116 documenting symbiont infection rates, it is now time to go beyond descriptive field studies to further
117 explore the role of these symbionts in the ecological community.

118 *Aphid-symbiont interactions in natural food webs*

119 Transferring what we know from controlled laboratory studies to understand field dynamics has
120 proved reasonably complex. Controlled laboratory studies have generally compared populations of
121 single aphid species (but see Sanders et al., 2016) where every individual hosts a symbiont to
122 populations that are all uninfected by symbionts (i.e. with no variation in the frequency of infection).
123 Yet, in natural systems, the diversity of (1) symbionts, (2) aphids, (3) natural enemies, and (4) host
124 plants, will all act together to influence population and community dynamics of all these interacting
125 species.

126 A trade-off between the protective benefits and fitness costs of hosting symbionts (Kwiatkowski et al.,
127 2012), means that symbiont infection is rarely fixed in a population (i.e. often less than 100% of

128 aphids will host any given symbiont within a population; Zytynska and Weisser (2016)). For example,
129 co-hosting of symbionts *Serratia* and *Hamiltonella* conferred high protection against parasitoid wasps
130 in the lab, but the prevalence of these 'superinfected' aphids was low in the field due to a strong
131 fitness cost (Oliver et al., 2006). However, other studies have found strong positive associations in the
132 field between these two symbionts across multiple aphid species (Leonardo & Muiru, 2003; Zytynska
133 et al., 2016) suggesting that fitness costs can be variable across systems. Further, different strains of
134 the same symbiont species can have variable effects on both the level of protection and the
135 associated costs to the host (Cayetano et al., 2015; Leclair et al., 2016; Vorburger et al., 2010). The
136 extent to which different symbiont strains are present within a single aphid population is unknown, but
137 *Hamiltonella* strains vary among different pea aphid (*A. pisum*) lineages (Leclair et al., 2016).
138 Similarly, both the protection conferred and associated fitness costs of symbionts can also vary
139 dependent on the genotype of the aphid, and the genotype of the natural enemy (e.g. parasitoid
140 wasp) (reviewed in Vorburger, 2014).

141 Natural communities are comprised of multiple aphid species, competition between which can be
142 modified through variable symbiont infection rates across aphid species. At 100% infection rate, an
143 experimental study showed that a protective symbiont could drive the extinction of unprotected aphid
144 species and their specialist natural enemies (Sanders et al., 2016). However, with reduced symbiont
145 infection rates across all aphid species, this could stabilise the community leading to increased
146 potential for co-existence as we often see in the field (Zytynska et al., 2016).

147 Studies have also shown that the occurrence of individual aphid bacterial symbionts can be
148 influenced by the host-plant species on which an aphid feeds (Brady & White, 2013; Henry et al.,
149 2015; Russell et al., 2013; Simon et al., 2003). For example, *Hamiltonella* had a high infection
150 frequency in *Aphis craccivora* aphids collected from alfalfa (*Medicago sativa*), but it was absent in all
151 aphids collected from black locust (*Robinia pseudoacacia*) (Brady & White, 2013). In contrast, those
152 aphids collected on black locust were found to be infected by *Arsenophonus* (Brady & White, 2013),
153 which is now known to be involved in specialisation on this host-plant species (Wagner et al., 2015).
154 Another well-studied example are pea aphids (*A. pisum*) that have distinct genetically-differentiated
155 host races associated with different plant species. Secondary symbiont infection is thought to play a
156 role in host plant specialisation as different symbiont communities were found among different host
157 races (McLean et al., 2011; Oliver et al., 2014; Russell et al., 2013; Tsuchida et al., 2004). In

158 particular, pea aphids hosting *Hamiltonella* are more likely to be found on *Lotus*, *Ononis* or *Medicago*
159 plants, and those with *Regiella* on *Trifolium* (Ferrari et al., 2012; Russell et al., 2013).

160 Given these associations between individual host plants, aphid species, and symbionts within an
161 aphid, host-plant diversity has strong potential to increase aphid symbiont diversity through altering
162 interactions between aphids and other trophic levels. In the following part of this review we summarise
163 known effects of plant diversity on insect communities, with a focus on aphids, and then explore this
164 in relation to how plant diversity can mediate aphid-symbiont-natural enemy interactions. In particular,
165 we examine how these interactions might influence pest regulation in agroecosystems and the
166 implications of integrating plant diversity into biological control methods for regulating aphid pest
167 populations.

168

169 **Plant diversity effects**

170 *Plant diversity effect on insect communities*

171 The global loss of species in recent centuries (Butchart et al., 2010) has raised questions about the
172 functional importance of biodiversity (Schläpfer & Schmid, 1999). Over 20 years of research has
173 demonstrated that biodiversity is of critical importance for ecosystem functioning, as a decline in
174 biodiversity is typically associated with lower performance and greater temporal variability in
175 performance in many ecosystem functions (e.g., Allan et al., 2013; Balvanera et al., 2006).
176 Biodiversity experiments are a crucial tool for studying these species loss effects, where the diversity
177 of (most often) plant communities are manipulated experimentally to study associated animal
178 communities and ecosystem functions with plant species richness as the explanatory variable
179 (Weisser et al., 2017). Such experiments have demonstrated that plant diversity affects the
180 abundance and diversity of invertebrates (Borer et al., 2012; Haddad et al., 2011; Hertzog et al.,
181 2016b; Scherber et al., 2010). These patterns have now been confirmed for many different
182 invertebrate taxa across different years (Ebeling et al., 2018). Both herbivores and carnivores strongly
183 benefit from an increase in plant species richness with higher species richness, and abundance of
184 both trophic levels (Borer et al., 2012; Ebeling et al., 2018; Haddad et al., 2001; Vehviläinen et al.,
185 2007). The ratio between herbivore and plant biomass (herbivore load) significantly decreased with
186 plant species richness, whereas the ratio between predator and herbivore biomass (predator-prey

187 ratio) did not show any significant change across the gradient of plant species richness (Ebeling et al.,
188 2018). While herbivores were directly affected by plant species richness and not by plant biomass
189 (Hertzog et al., 2016b), effects of plant diversity on predator communities (e.g. abundance and
190 diversity) are likely driven by plant diversity-induced changes in the herbivore communities, which
191 serve as a food resource for predators (Hertzog, 2017).

192 As a consequence of changes in the consumer community, plant diversity also affects ecosystem
193 functions mediated by these consumers (Ebeling et al., 2014; Scherber et al., 2010). In grasslands,
194 rates of herbivory (Meyer et al., 2017) and predation (Hertzog et al., 2017) increased with higher plant
195 species richness, whereas parasitism rate of aphids by wasps showed a decrease with increasing
196 plant diversity (Ebeling et al., 2012; Petermann et al., 2010b). Overall, this work has shown that multi-
197 trophic interactions can be stabilized by high plant diversity (Ebeling et al., 2012; Haddad et al., 2011).

198 *Plant diversity effects on aphids*

199 Aphids and their natural enemies have also been studied in biodiversity experiments with manipulated
200 plant species richness. Petermann et al. (2010a); (2010b) measured the densities and species
201 richness of aphids and parasitic wasps (primary, secondary and facultative tertiary parasitoids of
202 aphids) that naturally colonised grassland plots, along experimental gradients of plant species
203 richness. They found that the densities and richness of species at all trophic levels were influenced by
204 changes in plant species richness. The effects were rarely direct but instead mediated by the
205 abundance and species richness of aphid host plants and subsequent trophic levels. The herbivore
206 and primary parasitoid levels were directly affected by changes in plant species richness, with highest
207 insect densities and species richness occurring at intermediate plant species richness (Petermann et
208 al., 2010b). In another experiment, aphid abundance increased with a higher number of plant
209 functional groups (Koricheva et al., 2000). In addition to densities and species richness of aphids and
210 parasitic wasps, life-history traits of aphids (production of winged morphs) and their parasitoids
211 (emergence rates) were also affected by plant species richness (Petermann et al., 2010a).

212 As for the consumers in general, changes in densities and species richness of aphids and their
213 associated natural enemies translated into differences in ecosystem functions. Petermann et al.
214 (2010b) calculated two ecosystem functions: aphid load (the number of aphid individuals per host
215 plant biomass used as a proxy for herbivory) and parasitism rate. Aphid load was highest at

216 intermediate plant species richness and negatively affected by both host plant biomass and host plant
217 species richness. Parasitism rate was mostly affected indirectly via aphid density and overall weakly
218 negatively related to plant species richness (Petermann et al., 2010b). Studying rates of predation,
219 rather than parasitism, on aphids that were experimentally exposed by glueing individuals onto to
220 plastic labels at the soil surface of plots of differing plant species richness, Hertzog et al. (2017)
221 showed higher rates of aphid predation at higher plant species richness. This increase in predation
222 rates is likely explained by an increase in predator abundance and diversity and reduced antagonistic
223 interactions between different predator species (Hertzog et al., 2017). In contrast, a microcosm study
224 found decreased consumption of aphids at higher plant species richness when the number of
225 predators was held constant (Aquilino et al., 2005). In the same study, there was an increased aphid
226 consumption at higher diversity of natural enemies (Aquilino et al., 2005). As abundance and species
227 richness of both aphids and predatory and parasitic arthropods increase with plant species richness in
228 the field (see above), a combination of positive bottom-up and negative top-down effects on aphid
229 survival determines the overall response of aphids to plant species richness (Petermann et al.,
230 2010b). The above studies already illustrate that the overall effect of plant species richness on aphid
231 populations is variable, likely depending on the study context. The small number of available studies
232 currently prevents a quantitative synthesis of plant diversity effects on aphids. Further, plant diversity
233 effects on aphids are likely also altered by the protective microbiome associated with the aphids.

234 *Plant diversity effects on aphid symbiont communities*

235 Plant diversity likely influences aphid symbionts given the documented effects on the aphid hosts, the
236 natural enemies, and via the microclimate around aphid host plants. Yet, at present only a single
237 study has investigated changes in aphid symbionts along a plant diversity gradient. Here, three
238 different aphid species were collected along a gradient of plant species richness in a grassland
239 biodiversity experiment. Each aphid species was collected from a different host-plant and examined
240 for the presence of common aphid symbionts (Zytynska et al., 2016). Aphids were documented to
241 frequently co-host multiple symbionts. In all three distinct plant-aphid species combinations, plant
242 diversity significantly affected the species richness of the hosted symbionts. However, the effect of
243 plant diversity differed at the level of the individual aphid (i.e. the number of symbionts that one single
244 aphid was hosting) and across the local population (i.e. the proportion of aphids hosting particular
245 symbiont combinations) (Figure 1). While aphids tended to co-host more symbionts at lower plant

246 diversity, the opposite was true across the population where a greater richness and diversity of
247 symbionts was present at higher plant diversities (Zytynska et al., 2016). On average, the effect was
248 to decrease/increase the symbiont species richness by one symbiont and due to the survival impact
249 of these symbionts, this can have strong ecological implications. However, this study was based on
250 correlations between the plant species richness of a plot and the symbionts hosted across the aphids
251 and was therefore not able to elucidate any mechanisms driving these effects. There are many
252 potential ways in which plant diversity can drive changes in aphid symbiont communities, and we
253 expand on this to explore how these mechanisms can explain the observed patterns.

254 *Potential mechanisms*

255 The mechanisms driving changes in the aphid symbiont community could occur at either the level of
256 the individual aphid or at the level of the whole aphid population. Individual aphids will experience the
257 direct protective effects (increased survival) but also the associated costs (reduced fitness) of hosting
258 symbionts. The frequency of different aphid-symbiont combinations across the population, along with
259 the relative frequency of selection pressures (e.g. natural enemy abundances), will then drive effects
260 at the population level. For example, a population with two aphid-symbiont combinations (one
261 protected, one unprotected) and no natural enemy would favour the unprotected aphid due to higher
262 growth rates. Whereas, if the natural enemy is present, the protected aphid would be favoured,
263 despite reduced growth rates (survival is more important than high growth). The selection pressures
264 for hosting symbionts and associated costs and benefits can change between plant communities of
265 high and low diversity.

266 In a low plant diversity system, there may be a restricted set of natural enemies with higher overall
267 parasitism rate (Petermann et al., 2010b). Here, a particular combination of symbionts will provide
268 greatest survival chances to individual aphids, and at the population level, if all aphids host this
269 particular optimal combination of symbionts, then there will be low symbiont diversity (Figure 2). Any
270 impacts on aphid fitness will be shared by all aphids, reducing the effects of within-species
271 competition through variable symbiont costs. In a stand with higher plant diversity and increased
272 natural enemy diversity (Petermann et al., 2010b), the per-capita chance of an individual aphid being
273 attacked by a specific natural enemy is low, but the chance of being attacked by at least one of the
274 various types is high. Assuming there are high fitness costs to hosting all protective symbionts, one

275 strategy for individual aphids is to host fewer symbionts and trade-off full protection with higher
276 reproductive outputs. Therefore, in diverse systems where there is no single optimal symbiont
277 community, the population will exhibit higher symbiont diversity (Figure 2). Aphid population structure
278 can also then be further influenced by within-species competition via variable fitness effects of hosting
279 the different symbiont communities, also dependent on the local natural enemy community
280 composition.

281 When other interacting species are influenced by plant diversity, this can also have consequences for
282 aphid-symbiont interactions. For example, aphids are often tended by ants that feed on the aphid
283 honeydew and in return provide additional protection against natural enemies (Billick et al., 2007).
284 This can be an obligatory relationship where the aphid requires the ant for survival, but often it is more
285 opportunistic. When aphids were recurrently tended by ants the proportion of aphids hosting
286 *Hamiltonella* symbionts was reduced compared to aphids tended only occasionally by ants (Mandrioli
287 et al., 2016). Ants can also help to maintain the health of an aphid colony by removing sticky
288 honeydew that, if left, can encourage fungal growth (Buckley, 1987), and at least three aphid
289 symbionts have been implicated as improving aphid resistance to fungi, including *Regiella*, *Rickettsia*,
290 and *Spiroplasma*, (Lukasik et al., 2013a; Lukasik et al., 2013b; Scarborough et al., 2005). While plant
291 species richness had no direct effects on ant abundance along a diversity gradient, soil temperature
292 had a positive effect on ant abundance, and plant cover had a negative effect (Hertzog et al., 2016a).
293 As plant cover increases with plant species richness and soil temperature decreases with plant
294 species richness, this suggests potential lower ant abundance and thus lower aphid attendance by
295 ants at higher plant diversity. Reduced protection from natural enemies by ants at high plant diversity
296 would further select for higher symbiont diversity in diverse plant-natural enemy communities.

297 The cost-benefit trade-off of hosting symbionts could also be mediated by plant diversity through
298 changes in host-plant quality. For example, differences in growth stages or strategies of plants can
299 alter phloem composition, with subsequent effects on aphid nutrition (Karley et al., 2002). This could
300 influence the associated fitness costs of co-hosting symbionts, leading to the observed effect of
301 higher proportions of aphids hosting multiple protective symbionts in monocultures. Since the C:N
302 ratio (and also C:P ratios) of plant tissues tends to increase along the plant diversity gradient (Abbas
303 et al., 2013), meaning that nutrient availability decreases, this could indicate lower phloem quality for
304 aphids at higher plant species richness. For pollinators and non-aphid herbivores, it was already

305 demonstrated that higher C:nutrient ratios in the plants translate into increased C:nutrient ratios in the
306 animal tissues (Abbas et al., 2014). Similar effects might also occur in aphids. This is yet to be tested,
307 but could partly explain the reduced occurrences of symbiont superinfections at higher plant
308 diversities.

309 Higher plant diversity can also modify the local microclimate of a host-plant because of an increased
310 density of the plant community (Lorentzen et al., 2008; Marquard et al., 2009) with consequent lower
311 air temperature and increased air and top-soil humidity because of shading (Allan et al., 2013). These
312 changes in microclimate could indirectly influence the protective effect of symbionts that help against
313 heat shock (sun-exposed vs shady patch) (Montllor et al., 2002), or entomopathogenic fungi
314 (humid/shady vs dry/exposed) (Millstein et al., 1982).

315

316 **Implications for aphid biocontrol in agriculture**

317 In agricultural systems, many natural ecological processes are disrupted as a consequence of
318 management methods. By planting large areas with a single crop, herbivore populations can quickly
319 increase their population sizes and avoid control by natural enemies. Aphids are an economically
320 important pest species in agriculture where they can cause direct feeding damage and indirect
321 damage through transmission of devastating crop viruses which are typically controlled by the large-
322 scale application of pesticides (Van Emden & Harrington, 2017). Consequently, agricultural practices
323 including the widespread application of pesticides together with the destruction of natural habitats to
324 create farming land have been identified as an important driver of global species loss (Maxwell et al.,
325 2016) likely contributing the ongoing drastic insect decline (Hallmann et al., 2017).

326 One strategy for more sustainable agricultural production is (partially) replacing pesticide use by
327 employing biocontrol agents (parasitoid wasps, generalist predators, and entomopathogenic fungi)
328 against aphids. There is evidence that biological control of aphids can be highly successful in closed
329 greenhouse environments (Messelink et al., 2014; Powell & Pell, 2007), but also evidence that this
330 can select for aphids hosting protective symbionts (Oliver et al., 2008; Sanders et al., 2016). The
331 impact of aphid protective symbionts in closed systems is explored by Vorburger (2018), with
332 suggestions to minimise the risk of selecting for symbiont-conferred resistance by deploying
333 parasitoids early in the pest outbreak, or increasing parasitoid-to-aphid ratios. A further suggestion

334 that is highly relevant to our proposal is to overcome the selection of resistant aphid/symbiont strains
335 by increasing the diversity of the interacting community. This can be achieved by increasing the
336 genetic diversity of a single parasitoid wasp species (Hafer & Vorburger, 2018) or by increasing
337 species diversity of the natural enemies. In a greenhouse system, such diversity can be achieved
338 through release of specific natural enemy communities.

339 In low diversity agricultural fields, the associated low diversity of natural enemies, resulting in low
340 predation rates, can lead to increased symbiont-mediated resistance against the few natural enemies
341 that are present across aphid populations similar to the greenhouse situation described above.
342 However, in the field this resistance must be overcome through other more viable options than mass
343 release of natural enemies. By increasing the diversity of plants in an agricultural landscape, the
344 diversity of natural enemies can be increased as demonstrated in biodiversity experiments (see
345 above). While diversifying plants within agricultural fields is hindered by constraints in farming
346 (planting and harvesting) methodology, increasing flowering plant diversity at field margins in the form
347 of wildflower strips has been suggested as an appropriate method for diversification (Balzan &
348 Moonen, 2014; Blaauw & Isaacs, 2012; Fabian et al., 2013). This has a two-step beneficial effect on
349 pest regulation. First, a greater diversity of natural enemies means there is an increased number of
350 ways to control the aphid populations and redundancy if one natural enemy is unable to establish a
351 viable population. Second, increased diversity of natural enemies will reduce the effect of symbiont-
352 mediated resistance and allow reduction of aphid pest populations by both specialised parasitoids and
353 fungi, and subsequently more effective control by generalist predators that are more likely to drive
354 smaller local populations to extinction. First field trials showed that increasing plant diversity through
355 the planting of wildflower strips has been shown to reduce aphids by 75% due to an increase in
356 natural enemies (Tschumi et al., 2016).

357 There are some ways in which planting of wildflower strips adjacent to agricultural fields can increase
358 the abundance of parasitoid wasps and generalist predators. Adult parasitoid wasps, and many adults
359 of generalist predators (e.g. lacewings or hoverflies) do not feed on the aphids themselves, but rather
360 on flower nectar or even on the aphid honeydew (Lee et al., 2004). It is often the carnivorous larvae
361 that consume aphids. Without additional sugar-based resources, adult wasps have limited lifespans of
362 2-3 days, yet when sugar is supplemented their lifespan can reach two weeks and host-searching
363 behaviour is significantly increased (Russell, 2015), thereby increasing their potential to suppress

364 aphid populations. While changes in nectar resources with plant diversity have not been studied for
365 parasitoid wasps, the frequency of pollinator visits and pollinator species richness increased with a
366 higher amount and diversity of floral resources (Ebeling et al., 2008). Thus, positive effects of plant
367 species richness can also be expected for parasitoid wasps and other generalist predators. Wildflower
368 strips can also act as reservoirs for non-pest aphid species that benefit the establishment and
369 maintenance of viable natural enemy communities. This occurs through the use of targeted plant
370 species, but as yet an optimal set of plant species for common use has not been identified (Frank,
371 2010). Increasing plant diversity can be a suitable replacement, with an assumption that the diversity
372 of plants will enable these services to be established (McLean & Godfray, 2016).

373 One caveat for the application of wildflower strips as a means to control aphids (and potentially also
374 other herbivores) is the choice of the flowering plant community. It is general practice for wildflower
375 strips to be planted with various seed mixes of native plants, with an assumption that there is variation
376 in flowering time and resources (Lu et al., 2014). However, it is essential that tailored flower strips are
377 used to ensure the chosen flowering plants are suitable for maintaining populations of aphid-specific
378 natural enemies, as not all plants are equally suitable (Russell, 2015).

379

380 **Future research opportunities**

381 In this review, we have explored many different ways in which plant diversity can mediate aphid-
382 symbiont interactions. The abundance of literature on aphid-parasitoid interactions and the effect of
383 plant diversity on herbivore natural enemies provides much support for the effect of plant diversity on
384 aphid symbionts to be mediated by top-down selection pressures. Much of this is, however, based on
385 a single study that looked at three different plant-aphid combinations, and therefore we first suggest
386 that these effects are explored further in other field systems.

387 The study of aphid-symbiont-natural enemy interactions in controlled model ecosystems often
388 compares effects of parasitoid wasps on aphid populations that are all infected by symbionts, to those
389 that are uninfected (McLean & Godfray, 2017; Rothacher et al., 2016; Sanders et al., 2016). Yet,
390 rarely do all aphids host symbionts in a population (Zytyńska & Weisser, 2016), and the proportion of
391 aphids hosting protective symbionts has been shown to be rather dynamic across the season in
392 relation to the abundance of natural enemies (Smith et al., 2015). We therefore suggest a focus on

393 developing experimental systems to study the protective effects of symbionts under more realistic
394 conditions, for example with variable starting proportions of symbiont-infected and uninfected aphids.
395 Moreover, the temporal dynamics of natural enemy populations should also be addressed, as rarely
396 will all natural enemies arrive and leave a field system at the same time.

397 Another currently vastly underexplored question regards the differences in the impacts of aphid-
398 symbiont interactions in diverse field systems for aphids that are host-plant specialists compared to
399 those that feed on multiple host plants within a single community. This is related to the impact of plant
400 within-species variation that can drive variation in the distribution of aphids among host plant
401 individuals (Zytynska et al., 2014). The restriction of aphids to single host-plants, or even genotypes
402 within a host-plant, will likely exacerbate the effects of the surrounding plant diversity on aphid-
403 symbiont interactions.

404 Lastly, in the agricultural context, the choice of plant species for wildflower strips must include
405 sufficient resources for parasitoid wasps. Often seed mixtures are chosen for their impact on
406 pollinators, yet a vast amount of variation in the responses of parasitoid wasps to different flowering
407 plants (Russell, 2015) highlights the need to produce seed mixes tailored towards natural enemy
408 communities with ample research opportunities related to the selection of appropriate plant species.

409

410 **Conclusions**

411 There is a growing literature of research documenting the effect of plant diversity on herbivores and
412 higher trophic levels. The expanding number of experimental field systems manipulating biodiversity
413 is a unique platform for now understanding how plant-invertebrate interactions can mediate other
414 less-studied connections between species. The recent acknowledgement of the important role of an
415 individual's microbiota for its health and fitness has boosted research on the role of bacterial
416 symbionts in insects. How insect microbiome interactions are changed in response to the diversity of
417 the food-web in which they are embedded is an emerging topic offering exciting future research
418 opportunities and potential application in sustainable agriculture. While aphid symbionts have the
419 potential to reduce biological control effectiveness through conferring protection for the host insect,
420 increasing plant and natural enemy biodiversity can mitigate these effects. Beyond effects just on
421 natural enemies of pests, increasing landscape complexity can have knock-on effects for other

422 species such as bees, where the environmental landscape and available plant species can modify gut
423 microbiota composition and through this influence their behaviour and fitness (Donkersley et al., 2018;
424 Jones et al., 2018). By integrating plant diversity into agricultural systems, we can limit the impact of
425 unfavourable species interactions, and use diversity to promote beneficial interactions for more
426 sustainable pest control.

720

721

722 Figure 1. The effect of plant diversity on the community of bacterial symbionts within aphids can be
723 studied at the level of the individual aphid or across the local population. Previous work has shown
724 that symbiont species richness within individual aphids decreased with plant species richness,
725 whereas symbiont species richness and diversity increased at the population level. Figure drawn as a
726 graphical representation of results from (Zytynska et al., 2016).

727

728 Figure 2. At low plant diversity there is reduced diversity in the natural enemy community leading to
729 selection for a single optimal combination of symbionts within aphids. At high plant diversity, the
730 increased diversity of natural enemies can select for an increased diversity of symbionts across the
731 aphid population. The figure depicts a very simplified system in order to demonstrate the basic
732 concept underling the effect of plant diversity on aphid symbionts. In the field, additional species
733 interactions, temporal effects, hosting of multiple symbionts, and the presence of other aphid species
734 can all modify the links between plant diversity, natural enemy diversity, and symbiont diversity.
