ABSTRACT

Background

According to international guidelines and literature, all patients with intermittent claudication should receive an initial treatment of cardiovascular risk modification, lifestyle coaching, and supervised exercise therapy. In the literature, supervised exercise therapy often consists of treadmill or track walking. However, alternative modes of exercise therapy have been described and yielded similar results to walking. This raises the following question: which exercise mode produces the most favourable results? This is the first update of the original review published in 2014.

Objectives

To assess the effects of alternative modes of supervised exercise therapy compared to traditional walking exercise in patients with intermittent claudication.

Search methods

The Cochrane Vascular Information Specialist searched the Cochrane Vascular Specialised Register, CENTRAL, MEDLINE, Embase and CINAHL databases and World Health Organization International Clinical Trials Registry Platform and ClinicalTrials.gov trials registers to 4 March 2019. We also undertook reference checking, citation searching and contact with study authors to identify additional studies. No language restriction was applied.

Selection criteria

We included parallel-group randomised controlled trials comparing alternative modes of exercise training or combinations of exercise modes with a control group of supervised walking exercise in patients with clinically determined intermittent claudication. The supervised walking programme needed to be supervised at least twice a week for a consecutive six weeks of training.

Data collection and analysis

Two review authors independently selected studies, extracted data, and assessed the risk of bias for each study. As we included studies with different treadmill test protocols and different measuring units (metres, minutes, or seconds), the standardised mean difference (SMD) approach was used for summary statistics of mean walking distance (MWD) and pain-free walking distance (PFWD). Summary estimates were obtained for all outcome measures using a random-effects model. We used the GRADE approach to assess the certainty of the evidence.

Modes of exercise training for intermittent claudication (Review)

Main results

For this update, five additional studies were included, making a total of 10 studies that randomised a total of 527 participants with intermittent claudication (IC). The alternative modes of exercise therapy included cycling, lower-extremity resistance training, upper-arm ergometry, Nordic walking, and combinations of exercise modes. Besides randomised controlled trials, two quasi-randomised trials were included. Overall risk of bias in included studies varied from high to low. According to GRADE criteria, the certainty of the evidence was downgraded to low, due to the relatively small sample sizes, clinical inconsistency, and inclusion of three studies with risk of bias concerns.

Overall, comparing alternative exercise modes versus walking showed no clear differences for MWD at 12 weeks (standardised mean difference (SMD) -0.01, 95% confidence interval (CI) -0.29 to 0.27; $P = 0.95$; 6 studies; 274 participants; low-certainty evidence); or at the end of training (SMD -0.11, 95% CI -0.33 to 0.11; $P = 0.32$; 9 studies; 412 participants; low-certainty evidence). Similarly, no clear differences were detected in PFWD at 12 weeks (SMD -0.01, 95% CI -0.26 to 0.25; $P = 0.97$; 5 studies; 249 participants; low-certainty evidence); or at the end of training (SMD -0.06, 95% CI -0.30 to 0.17; $P = 0.59$; 8 studies, 382 participants; low-certainty evidence). Four studies reported on health-related quality of life (HR-QoL) and three studies reported on functional impairment. As the studies used different measurements, meta-analysis was only possible for the walking impairment questionnaire (WIQ) distance score, which demonstrated little or no difference between groups (MD -5.52, 95% CI -17.41 to 6.36; $P = 0.36$; 2 studies; 96 participants; low-certainty evidence).

Authors' conclusions

This review found no clear difference between alternative exercise modes and supervised walking exercise in improving the maximum and pain-free walking distance in patients with intermittent claudication. The certainty of this evidence was judged to be low, due to clinical inconsistency, small sample size and risk of bias concerns. The findings of this review indicate that alternative exercise modes may be useful when supervised walking exercise is not an option. More RCTs with adequate methodological quality and sufficient power are needed to provide solid evidence for comparisons between each alternative exercise mode and the current standard of supervised treadmill walking. Future RCTs should investigate outcome measures on walking behaviour, physical activity, cardiovascular risk, and HR-QoL, using standardised testing methods and reporting of outcomes to allow meaningful comparison across studies.

PLAIN LANGUAGE SUMMARY

How effective are supervised exercise programmes compared to supervised walking programmes for treating intermittent claudication?

Why this question is important

Intermittent claudication is the medical term for pain in the lower leg (or both legs) that develops during exercise (for example, walking) and usually goes away after a few minutes' rest. This pain is produced by a restriction of blood flow to the leg muscles. This restriction in blood flow is caused by the partial blockage of arteries (vessels that deliver oxygen-rich blood around the body) by a build-up of fatty deposits (atherosclerosis). This results in a reduced oxygen supply reaching the leg muscles.

International guidelines recommend that people with intermittent claudication should exercise by walking (for example, on a treadmill) while supervised by a physical or exercise therapist. The goal of these exercises is to increase the distance people can walk, and to limit the impact of intermittent claudication on their quality of life.

Supervised walking programmes are not the only type of supervised exercise available. There are other options, such as strength training, Nordic walking (walking with specially designed poles to exercise the upper as well as the lower body) or cycling. To find out how effective other types of supervised exercise programmes are compared to supervised walking programmes, we reviewed the evidence from research studies.

How we identified and assessed the evidence

First, we searched for all relevant studies in the medical literature. We then compared the results, and summarised the evidence from all the studies. Finally, we assessed how certain the evidence was. We considered factors such as the way studies were conducted, study sizes, and consistency of findings across studies. Based on our assessments, we categorised the evidence as being of very low, low, moderate or high certainty.

What we found

We found ten studies on a total of 527 people with intermittent claudication. The studies compared supervised walking programmes against:

- * exercises to strengthen the leg muscles (four studies);
- * Nordic walking (three studies);
- * cycling (one study);

Modes of exercise training for intermittent claudication (Review)

- * arm ergometry (pedalling with the arms on an exercise machine – one study);
- * a combination of different types of exercise (four studies).

The programmes lasted between six and 24 weeks.

The evidence suggests that there may be little to no difference between supervised walking and other types of supervised exercise in terms of:

- * the average maximum distance that people can walk after 12 weeks of exercise, or once they have completed the exercise programme;
- * the average distance that people can walk without feeling pain after 12 weeks of exercise, or once they have completed the exercise programme; or
- * disability (after 12 to 24 weeks of exercise).

We do not know if there is a difference in quality of life, since the studies that investigated this used different measurement tools to assess it, and we could not compare the results.

What this means

This review suggests that supervised walking and other types of supervised exercise programmes may have similar effects on how far people with intermittent claudication can walk, and how far they can walk without pain. However, our confidence in this finding is limited, mainly because:

- * the studies we reviewed were small;
- * the types of supervised walking exercises that were evaluated varied across studies; and
- * concerns about how some studies were conducted.

Future studies that use robust methods and include large numbers of people are needed to provide stronger evidence for comparing different types of supervised exercise programmes for intermittent claudication.

How-up-to date is this review?

The evidence in this Cochrane Review is current to March 2019.

SUMMARY OF FINDINGS

Summary of findings 1. Alternative modes of exercise compared to walking exercise for people with intermittent claudication

Alternative modes of exercise compared to walking exercise in people with intermittent claudication (IC)

Patient or population: patients with IC
Setting: hospital or community-based (supervised exercise therapy)
Intervention: alternative modes of exercise
Comparison: walking exercise

Outcomes	Anticipated absolute effects* (95% CI)		Relative effect (95% CI)	Nº of participants (studies)	Certainty of the evidence (GRADE)	Comments
	Risk with walking exercise	Risk with alternative modes of exercise				
Maximum walking distance (12 weeks)	-	SMD 0.01 lower (0.29 lower to 0.27 higher)	-	274 (6 studies)	⊕⊕⊕⊕ LOW 1 2 3	This translates to no clear difference in MWD after 12 weeks of training when comparing alternative modes of exercise with walking exercise.
Maximum walking distance (at end of training, ranging from 6 to 24 weeks)	-	SMD 0.11 lower (0.33 lower to 0.11 higher)	-	412 (9 studies)	⊕⊕⊕⊕ LOW 1 2 3	This translates to no clear difference in MWD at the end of training when comparing alternative modes of exercise with walking exercise.
Pain-free walking distance (12 weeks)	-	SMD 0.01 lower (0.26 lower to 0.25 higher)	-	249 (5 studies)	⊕⊕⊕⊕ LOW 1 2 3	This translates to no clear difference in PFWD after 12 weeks of training when comparing alternative modes of exercise with walking exercise.
Pain-free walking distance (at end of training, ranging from 6 to 24 weeks)	-	SMD 0.06 lower (0.3 lower to 0.17 higher)	-	382 (8 studies)	⊕⊕⊕⊕ LOW 1 2 3	This translates to no clear difference in PFWD at the end of training when comparing alternative modes of exercise with walking exercise.
Health-related QoL (at end of training, ranging from 12 to 24 weeks)	-	-	-	-	-	Four studies reported HR-QoL using different outcome measurements so meaningful comparison was not possible.
Self-reported functional impairment (WIQ)	-	MD 5.52 lower (17.41 lower to 6.36 higher)	-	96 (2 studies)	⊕⊕⊕⊕ LOW 1 3 4	This translates to little or no important difference in the WIQ score when comparing alternative modes of exercise with walking exercise.

(at end of training, ranging from 12 to 24 weeks)

***The risk in the intervention group** (and its 95% confidence interval) is based on the assumed risk in the comparison group and the **relative effect** of the intervention (and its 95% CI).

CI: confidence interval; **IC:** intermittent claudication; **HR-QoL:** health related quality of life; **MD:** mean difference; **MWD:** maximum walking distance; **PFWD:** pain-free walking distance; **QoL:** quality of life; **SMD:** standardised mean difference; **WIQ:** Walking Impairment Questionnaire

GRADE Working Group grades of evidence

High certainty: We are very confident that the true effect lies close to that of the estimate of the effect

Moderate certainty: We are moderately confident in the effect estimate: The true effect is likely to be close to the estimate of the effect, but there is a possibility that it is substantially different

Low certainty: Our confidence in the effect estimate is limited: The true effect may be substantially different from the estimate of the effect

Very low certainty: We have very little confidence in the effect estimate: The true effect is likely to be substantially different from the estimate of effect

- 1 The certainty of evidence was downgraded one level, because of evidence of clinical inconsistency, as studies used different alternative modes of exercise in the control groups.
- 2 The certainty of evidence was downgraded one level, because this analysis included 3 studies with risk of bias concerns.
- 3 The possibility of publication bias could not be ruled out, yet we did not consider it sufficient to downgrade the certainty of the evidence.
- 4 The certainty of evidence was downgraded one level, because results were based on a relatively small sample size.

BACKGROUND

This review includes a glossary of abbreviations and definitions (Table 1).

Description of the condition

Peripheral arterial disease (PAD) is a chronic arterial occlusive disease caused by progressive atherosclerosis. Several arterial segments can be affected, such as the aorta and iliac, femoral, popliteal, and tibial arteries in the limbs. Approximately 202 million people are affected with PAD of the lower extremities, defined as an ankle-brachial index below 0.90 in either leg (Fowkes 2013). The incidence of PAD increases with age, in particular after the age of 40 years. In high-income countries, PAD affects 5.41% of men and 5.28% of women at the age of 45 to 49 years. This prevalence rises to 18.83% in men and 18.38% in women at the age of 85 to 89 years (Fowkes 2013). The most common symptom is intermittent claudication (IC), defined as a cramping pain in the muscles of the leg(s) that occurs during exercise and is relieved by a short period of rest. Because of this symptom, patients have a reduced pain-free and maximum walking capacity, which restricts the patients' activity and mobility, leading to diminished health-related quality of life (Dumville 2004; McDermott 2001).

Moreover, given that PAD is a systemic disease which is characterised by generalised atherosclerosis, individuals with IC have an increased total risk of cardiovascular events beyond the claudication symptoms. Patients with IC have a five-year all-cause mortality rate of 10% to 15% and a 20% chance of a non-fatal cardiovascular event (Aboyans 2018). When IC progresses to critical limb ischaemia, an even higher mortality rate of 25% after one year is found (Conte 2015).

Description of the intervention

All patients with IC should receive a multicomponent therapy consisting of cardiovascular risk management, lifestyle counselling, and exercise therapy to reduce the associated serious health risks (Aboyans 2018; Gerhard-Herman 2017). Several randomised controlled trials and systematic reviews have compared walking exercise supervised by a physical or exercise therapist to non-supervised exercise, usual care, placebo, single walking advice, endovascular interventions, or bypass surgery (Fakhry 2018; Hageman 2018; Lane 2017; Parmenter 2015). The current evidence supports supervised exercise therapy as the primary treatment to improve walking capacity and health-related quality of life in patients with IC. Furthermore, community-based supervised exercise appears to be at least as efficacious as programmes provided in a hospital setting (Bendermacher 2007; Kruidenier 2009; Nicolai 2010). Less attention has been paid to the mode of (supervised) exercise. Besides traditional walking, alternative modes of supervised exercise training, such as cycling, upper-extremity cycle ergometer exercise, Nordic walking, and strength training exist and are associated with a significantly improved walking capacity (Golledge 2018; Parmenter 2011; Tompra 2015). Notably, this update includes Nordic walking as an alternative exercise mode, in contrast to the original review in which Nordic walking was considered a different walking protocol (Lauret 2014). Recent research has provided new insights on the potential benefits of Nordic walking. This core-focused walking technique substantially differs from traditional walking, as it

engages the muscles of the arms and trunk to reduce the load on the legs during walking (Golledge 2018).

Exercise training often provokes the claudication symptoms, depending on the protocol used (pain-free walking or walking until maximum pain). This can be considered as an adverse event, which is particularly relevant to patients in the context of expectation management. It generally takes several weeks for the patient to experience improvement and this type of treatment requires perseverance from the patient. Research has demonstrated that supervised exercise therapy is safe and has an exceedingly low all-cause complication rate (Gommans 2015).

How the intervention might work

Physical activity, which includes exercise, is associated with many health benefits (Piercy 2018). In patients with IC, exercise therapy significantly reduces symptoms and improves health-related quality of life. The exact mechanism for these benefits remains unclear and is probably multifactorial. A number of potential mechanisms have been suggested, such as induction of vascular angiogenesis, metabolic adaptations within skeletal muscle, improved endothelial flow-mediated dilatation, reduced inflammatory activation, reduced endothelial and mitochondrial dysfunction, improved walking efficiency, and increased pain tolerance (Conte 2015; Haas 2012; Harwood 2016). Additionally, supervised exercise therapy potentially reduces cardiovascular risk (Jansen 2019).

If walking ability is severely compromised by IC symptoms, traditional walking exercise may not provide sufficient stimulus to improve aerobic capacity. In those patients, alternative modes of aerobic exercise might be more beneficial than traditional walking. An example is Nordic walking, which is a core-focused walking technique which reduces the load on the legs during walking (Golledge 2018). Cycling is also a non-weight-bearing mode of exercise; and muscle strength seems to be associated with improved walking ability, which might explain the potential benefits of progressive resistance training of the lower limbs (Parmenter 2013b).

Why it is important to do this review

In most studies, supervised exercise programmes involve treadmill or track walking that is of sufficient intensity to provoke claudication symptoms. Walking exercise is alternated with rest over the course of a 30- to 60-minute session. Unfortunately, not all patients with IC are able to complete the exercise protocol because of concomitant comorbidity, such as arthrosis, chronic obstructive pulmonary disease, stroke, or cardiac complaints. For these patients, an adjusted protocol or alternative exercise regimen may be proposed. Being able to offer several modes of exercise might improve therapy adherence, as this enables better alignment with personal preferences. Combinations of aerobic and muscle-strengthening activities might be preferable, as these provide the most extensive health benefits according to the Physical Activity Guidelines (Piercy 2018).

This systematic review aims to determine the effect of alternative exercise modes on walking distance and health-related quality of life in patients with IC, compared to traditional walking exercise. Other Cochrane systematic reviews have demonstrated favourable results for supervised exercise programmes compared to usual care

and non-supervised programmes (Hageman 2018; Lane 2017). We solely compared different exercise modalities between supervised programmes.

This is the first update of the original review published in 2014 (Lauret 2014). The original review concluded that there was no clear difference between supervised walking exercise and alternative exercise modes in improving the maximum and pain-free walking distance, but also highlighted the need for more studies with larger sample sizes. The international guidelines for the management of IC recommend considering the use of alternative exercise modes (such as cycling, upper-arm ergometry and strength training) to improve walking ability and functional status when walking is not an option for patients (Aboyans 2018; Gerhard-Herman 2017). In this update, we have presented all the currently available evidence on alternative exercise modes to help patients and healthcare providers determine which may offer the most benefit to them.

OBJECTIVES

To assess the effects of alternative modes of supervised exercise therapy compared to traditional walking exercise in patients with intermittent claudication.

METHODS

Criteria for considering studies for this review

Types of studies

We included parallel-group randomised controlled trials (RCTs) comparing (combinations of) alternative modes of exercise training (for example, ergometry, strength training, aerobic exercise, Nordic walking, etc.) with traditional walking exercise in patients with intermittent claudication (IC). Quasi-randomised trials were also included, but were distinguished from properly randomised trials in 'Risk of bias' assessment. We excluded cross-over, factorial, or cluster-RCTs.

Types of participants

We included studies where the study participants consisted of adults (18 years and older) with clinically determined IC (Fontaine II or Rutherford 1 to 3 (Aboyans 2018)), who were considered for conservative treatment. We excluded studies of participants with asymptomatic lower-limb atherosclerosis identified by testing. When studies described a mixture of asymptomatic and symptomatic participants, we contacted the authors to ask if a subanalysis was available. If not, we excluded these studies.

Types of interventions

We included all RCTs comparing alternative modes of exercise training (e.g. arm ergometry, strength training, cycling, Nordic walking, etc.) or combinations of exercise modes with a control group of traditional walking exercise. All exercise programmes had to be supervised at least twice a week during six consecutive weeks of training. We excluded studies reporting an exercise programme with a duration of less than six weeks of training or with less than two supervised sessions a week.

We excluded all types of mechanical intermittent compression treatments as we did not consider them to be exercise training. We excluded studies comparing different settings of walking

exercise (supervised versus unsupervised, community versus hospital-based) or comparisons of different walking protocols (low-versus high-frequency training, low- versus high-intensity training, different treadmill exercise protocols).

Types of outcome measures

Studies were included only if reported outcome measures were available at baseline and after at least six weeks of follow-up.

Primary outcomes

- Maximal treadmill walking distance or time (MWD/T)

Secondary outcomes

- Pain-free treadmill walking distance or time (PFWD/T)
- Health-related quality of life scores (HR-QoL)
- Self-reported functional impairment (Walking Impairment Questionnaire)

Search methods for identification of studies

Electronic searches

The Cochrane Vascular Information Specialist conducted systematic searches of the following databases for randomised controlled trials and controlled clinical trials without language, publication year or publication status restrictions:

- Cochrane Vascular Specialised Register via the Cochrane Register of Studies (CRS-Web searched on 4 March 2019);
- Cochrane Central Register of Controlled Trials (CENTRAL) Cochrane Register of Studies Online (CRSO 2019, issue 2);
- MEDLINE (Ovid MEDLINE® Epub Ahead of Print, In-Process & Other Non-Indexed Citations, Ovid MEDLINE® Daily and Ovid MEDLINE®) (searched from 1 January 2013 to 4 March 2019);
- Embase Ovid (searched from 1 January 2013 to 4 March 2019);
- CINAHL Ebsco (searched from 1 January 2017 to 4 March 2019);
- AMED Ovid (searched from 1 January 2017 to 4 March 2019).

The Information Specialist modelled search strategies for other databases on the search strategy designed for CENTRAL. Where appropriate, they were combined with adaptations of the highly sensitive search strategy designed by the Cochrane Collaboration for identifying randomised controlled trials and controlled clinical trials (as described in the *Cochrane Handbook for Systematic Reviews of Interventions* Chapter 6, Lefebvre 2011). Search strategies for major databases are provided in Appendix 1.

The Information Specialist searched the following trials registries on 4 March 2019:

- World Health Organization International Clinical Trials Registry Platform (who.int/trialsearch);
- ClinicalTrials.gov (clinicaltrials.gov).

Searching other resources

We searched the reference lists of relevant studies identified by the above search strategies to identify other relevant citations.

Data collection and analysis

Selection of studies

Two review authors (SJ and UA) independently selected studies for this review. Three review authors (GJ, HF, and JT) confirmed the suitability of selected studies for inclusion. Any disagreements regarding inclusion/exclusion of selected studies were solved through discussion.

Data extraction and management

Two review authors (SJ and UA) independently extracted data using a standard data collection form and entered data into Review Manager (Review Manager 2020). When necessary, additional information from included studies was sought by contacting study authors. The extracted study data consisted of the following:

- study characteristics, including study design, method of randomisation, exclusions post-randomisation, publication year, country, and study period;
- baseline characteristics, including number of participants, losses to follow-up, mean age, gender distribution, and inclusion and exclusion criteria;
- type of interventions, including mode(s) of exercise, duration of programme, number of sessions, number of supervised sessions, and exercise protocol; and
- mean maximum walking distance or time, mean pain-free walking distance or time, mean quality of life scores at baseline and follow-up periods, and functional impairment information.

Assessment of risk of bias in included studies

Two review authors (SJ and UA) assessed the risk of bias for each study according to the checklist of design components, which comprised sequence generation, allocation concealment, blinding of personnel and participants, blinding of outcome assessments, incomplete outcome data, selective reporting, and other forms of bias. Another review author (GJ) confirmed the methodological quality of studies, primarily for adequacy of allocation concealment and follow-up. Due to the intervention (exercise), blinding of participants and personnel was not possible. Although this could introduce bias, we decided to consider the risk of bias to be low, since all studies experienced the same limitation. Consensus was achieved through informal discussion. The adequacy of each category was summarised as having 'low', 'unclear', or 'high' risk, according to criteria provided in the *Cochrane Handbook for Systematic Reviews of Interventions* (Higgins 2019).

Measures of treatment effect

We assessed treatment effects on the MWD and PFWD after 12 weeks follow-up and at the end of training. As studies with different treadmill test protocols and different measuring units (metres, minutes, or seconds) were included, the standardised mean difference (SMD) with 95% confidence intervals (CI) approach was used for summary statistics of MWD and PFWD. The SMDs were interpreted by using rules of thumb for effect sizes, in which a SMD of 0.2 represents a small effect, 0.5 a moderate effect, and 0.8 a large effect (Cohen 1988). For HR-QoL and functional impairment scores, data were only pooled if more than one study used the same questionnaire. Therefore, the summary statistic was expressed as mean difference (MD) with 95% CI.

Unit of analysis issues

We used the individual participant as the unit of analysis. Studies using cross-over design were not included in this review.

Dealing with missing data

Where applicable, missing data were requested from the authors. We expected that most studies reported baseline and final values with the corresponding standard deviations (SD). Where only change scores were provided, final value means were calculated using change score means and baseline data. Standard deviations were imputed using a conservative correlation coefficient of 0.5 for within-patient correlation from baseline to follow-up according to instructions in the *Cochrane Handbook for Systematic Reviews of Interventions* (Higgins 2019).

Assessment of heterogeneity

Statistical heterogeneity was assessed by the Chi²-test ($P < 0.10$ considered as heterogeneous) and the I² statistic (I² > 50% considered as moderate to substantial risk of heterogeneity), in order to assess whether observed variation in trial results was compatible with the variation expected by chance alone (Higgins 2019). A rough guide to help interpretation of the I² statistic is as follows: 0% to 40%: might not be important; 30% to 60%: may represent moderate heterogeneity; 50% to 90%: may represent substantial heterogeneity; and 75% to 100%: considerable heterogeneity.

Assessment of reporting biases

No language restrictions were applied, to prevent language bias. In case of sufficient studies (≥ 10 studies), we planned to assess publication bias with a funnel plot (Higgins 2019). If bias was present (demonstrated by an asymmetrical appearance of the funnel plot), the effect calculated by the meta-analysis would tend to overestimate the intervention effect.

Data synthesis

Data were analysed using Review Manager software (Review Manager 2020). We used final values, SDs, and number of participants to enable calculation of the SMD. The SDs were used to standardise the mean differences to a single scale and to compute study weights. It was assumed that between-study variation in SDs reflected only differences in measurement scales and not differences in the reliability of outcome measures or variability among study populations. As the alternative modes of exercise included in the current review consisted of several different types of exercise, we could not assume that intervention effects across studies were identical. Therefore, the DerSimonian and Laird random-effects model was used to analyse treatment effect, to account for between-study variance (DerSimonian 1986). The data of each study were summarised in forest plots and summary estimates with a 95% CI were calculated. A two-sided P (with a value ≤ 0.05) was considered statistically significant.

Subgroup analysis and investigation of heterogeneity

Treatment effects were based on the outcomes after 12 weeks follow-up and at the end of training, in order to deal with heterogeneity in follow-up duration and because international guidelines recommend a programme duration of 12 weeks. Furthermore, we performed subgroup analyses of each type of alternative exercise mode and combinations of exercise modes,

if more than one trial comparing the specific exercise mode or combinations of exercise to traditional walking was available.

Sensitivity analysis

We examined individual study effects by removing each study one at a time to check whether excluding a particular study significantly changed the results. In addition, we planned to perform sensitivity analyses on the methodological quality of the studies. Studies with apparent risk of bias were removed to examine whether excluding these studies significantly changed the results. Studies with more than one domain at high risk or more than three domains at unclear risk were considered to be at high risk of bias.

Summary of findings and the assessment of certainty of the evidence

We created a 'Summary of findings' table using GRADE-proGDT software ([GRADEproGDT 2015](#)) to present the main review findings for 'Alternative modes of exercise compared to walking exercise

in people with intermittent claudication' ([Summary of findings 1](#)). We included the outcomes listed in [Types of outcome measures](#). These were MWD, PFWD, HRQoL and functional impairment. The system developed by the Grades of Recommendation, Assessment, Development and Evaluation Working Group (GRADE working group) was used for grading the certainty of the evidence as high, moderate, low and very low, based on within-study risk of bias, directness of evidence, heterogeneity, precision of effects estimates, and risk of publication bias ([Atkins 2004](#)).

RESULTS

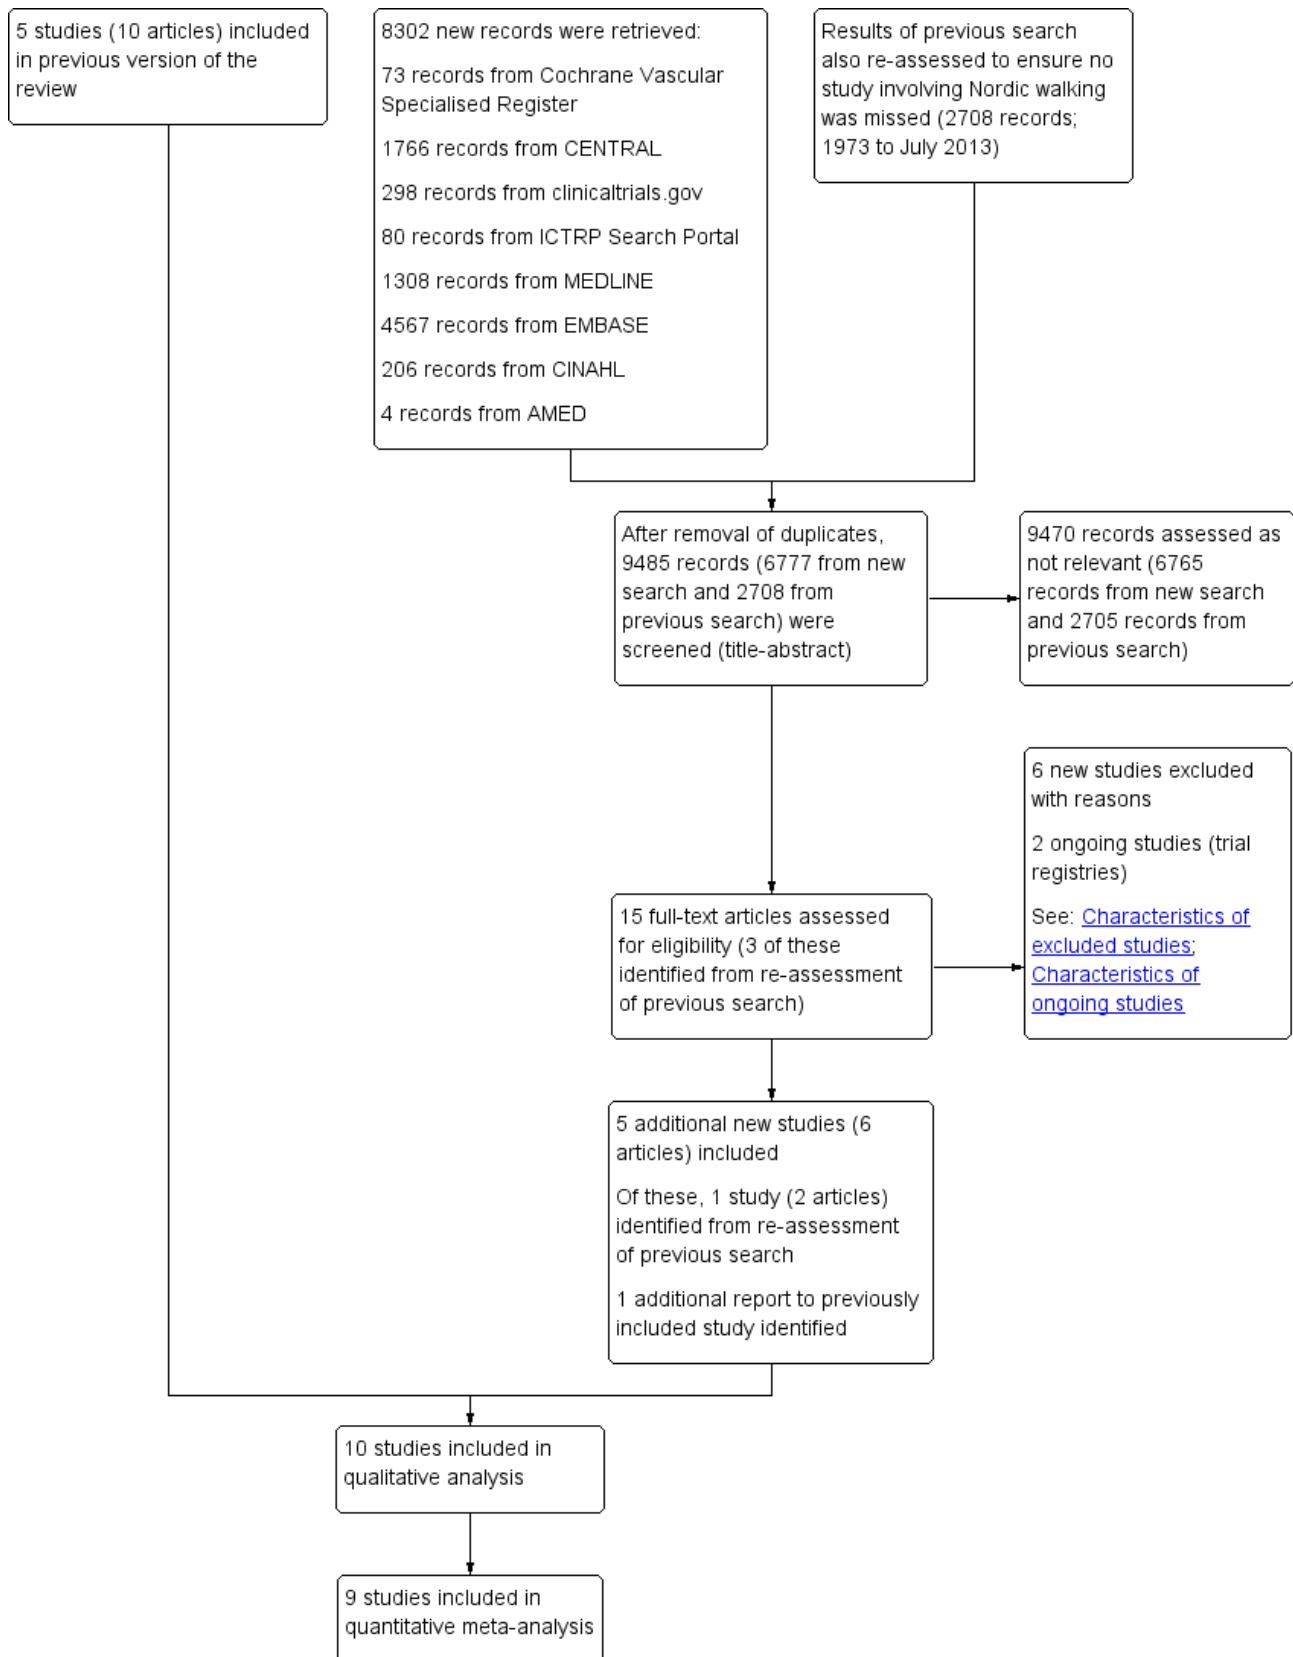

Description of studies

See: [Characteristics of included studies](#); [Characteristics of excluded studies](#); [Characteristics of ongoing studies](#).

Results of the search

See [Figure 1](#).

Figure 1. Study flow diagram

For this update, the updated electronic searches identified 6777 new records (after removal of duplicates), of which four new studies were included in the review (Bulinska 2016; Delaney 2015; Kropielnicka 2018; Szymczak 2016). We also re-evaluated the 2708 records identified in the first review published in 2014, according to the updated inclusion criteria (inclusion of Nordic walking as an alternative mode of exercise). This resulted in the inclusion of one additional study (Collins 2012). Two new ongoing studies were identified (ACTRN12616000243415; NCT03837639); and six new studies were excluded (Delaney 2014; EXERT Study 2018; Kao 2012; Oakley 2008; Parmenter 2013; Van Schaardenburgh 2017).

Included studies

For this update, five additional studies were included (Bulinska 2016; Collins 2012; Delaney 2015; Kropielnicka 2018; Szymczak 2016), making a total of 10 included studies (Bulinska 2016; Collins 2012; Delaney 2015; Kropielnicka 2018; McDermott 2009; Regensteiner 1996; Ritta-Dias 2010; Sanderson 2006; Szymczak 2016; Treat-Jacobson 2009). A summary of included studies is provided in the [Characteristics of included studies](#) tables. In these 10 studies, a total of 527 participants with intermittent claudication (IC) were randomised, of which 488 participants were randomised to the treatment arms that were relevant to this review. One study was relatively small involving fewer than 30 participants (Regensteiner 1996), six studies included more than 30 but fewer than 70 participants (Delaney 2015; McDermott 2009; Ritta-Dias 2010; Sanderson 2006; Szymczak 2016; Treat-Jacobson 2009); and three studies included 70 or more participants (Bulinska 2016; Collins 2012; Kropielnicka 2018). The mean age of the participants in the included studies varied between 62.0 and 73.4 years. All studies included both men and women, with the percentages of female participants ranging from 7% to 54%. The studies were conducted in Australia (2), Brazil (1), Poland (3) and the United States (4). Nine studies compared supervised walking exercise to a single alternative mode of exercise, which was lower-extremity resistance training in four studies (McDermott 2009; Regensteiner 1996; Ritta-Dias 2010; Szymczak 2016), Nordic walking in three studies (Bulinska 2016; Collins 2012; Kropielnicka 2018), cycling (Sanderson 2006) and arm ergometry (Treat-Jacobson 2009). Four studies compared walking exercise to combination treatment, consisting of walking and lower-extremity resistance training (Delaney 2015; Regensteiner 1996), walking and arm ergometry (Treat-Jacobson 2009) and Nordic walking and lower extremity resistance training (Kropielnicka 2018).

Enrolment criteria were relatively homogeneous. In all studies, participants were included if a decrease in ankle brachial index (ABI) was present together with limiting or disabling symptoms of IC. Two studies (Collins 2012; McDermott 2009) assessed claudication symptoms by a questionnaire (Edinburgh Claudication Questionnaire and San Diego Claudication Questionnaire, respectively). McDermott 2009 included both symptomatic and asymptomatic patients with PAD, however only the data of participants with IC were included in this review. Delaney 2015 only included participants with radiographic evidence of infra-inguinal disease in the absence of aorta-iliac disease. In all studies, the presence of critical limb ischaemia was an exclusion criterion. Participants were also excluded if the exercise capacity was limited by another factor than IC (e.g. angina, chronic obstructive pulmonary disease, arthrosis) or if they were unable to perform the exercise programme (e.g. unable to walk on a treadmill or with Nordic poles). Szymczak 2016 excluded patients

with diabetes and Kropielnicka 2018 excluded participants with "generally poor health". In four studies, claudication symptoms needed to be stable for three months (Kropielnicka 2018; Regensteiner 1996), six months (Ritta-Dias 2010), or more than 12 months (Sanderson 2006). Four studies excluded participants if a revascularisation procedure was performed in the previous year (Delaney 2015; Regensteiner 1996; Ritta-Dias 2010; Szymczak 2016). Szymczak 2016 excluded participants that suffered from stroke in the prior six months or had cardiac surgery in the prior 12 months. Three studies excluded participants if a coronary or lower-extremity revascularisation procedure was performed within the prior three months (Bulinska 2016; Kropielnicka 2018; Treat-Jacobson 2009). Two studies excluded participants in case of a cardiovascular event in the prior three months (Bulinska 2016); or 12 months (Kropielnicka 2018). One study excluded patients that participated in another exercise programme in the prior three weeks (Collins 2012). The two remaining studies excluded participants if they recently underwent surgery or a cardiovascular event (McDermott 2009; Sanderson 2006). Treatment duration varied between studies ranging from six weeks training (Sanderson 2006), to 12-week training (Bulinska 2016; Delaney 2015; Kropielnicka 2018; Regensteiner 1996; Ritta-Dias 2010; Szymczak 2016; Treat-Jacobson 2009) and 24-week training (Collins 2012; McDermott 2009).

Excluded studies

For this update, six additional studies (six publications) were excluded based on full-text assessment (Delaney 2014; EXERT Study 2018; Kao 2012; Oakley 2008; Parmenter 2013; Van Schaardenburgh 2017).

Overall, 23 studies were excluded based on full-text assessment. A summary of excluded studies is available in the [Characteristics of excluded studies](#) table. Three studies were excluded because they were not randomised (or quasi-randomised) controlled trials (Gardner 2011; Kim 2006; Roitman 2010). Five studies were excluded because they were meeting posters with a limited description of the methods and results and no related articles were published or available after contact with the authors (Dedes 2010; Kao 2012; Kuwabara 2010; Ornelas 2011; Treat-Jacobson 2012). Twelve studies were excluded because they did not assess adequately supervised exercise therapy, according to the inclusion criteria of this review (Nawaz 2001; Oakley 2008; Parmenter 2013; Parr 2009; Saxton 2008; Saxton 2011; Van Schaardenburgh 2017; Tebbutt 2011; Treat-Jacobson 2012; Walker 2000; Wang 2008; Zwierska 2005). Six studies did not report the primary and secondary outcome measures of this review (Delaney 2014; Nawaz 2001; Saxton 2008; Saxton 2011; Treat-Jacobson 2011; Walker 2000). One study was excluded because the outcome measures were not clearly described and we did not receive additional information upon request (Jones 1996). The previous version of this review identified the EXERT study as an ongoing study (EXERT Study 2018). Although this study was completed, the original results have not been published. Only one publication was available comparing long-term follow-up (one to four years) to end of study results (24 weeks). Baseline data were not available from the authors, so we have now excluded this study.

Ongoing studies

Two ongoing studies were identified (ACTRN12616000243415; NCT03837639), for which a summary of study protocols is available in the [Characteristics of ongoing studies](#) table. One study

(ACTRN12616000243415) has been completed, but the results have not yet been published or available from the authors (status: preparing the manuscript for submission to a peer-reviewed journal).

Risk of bias in included studies

See [Figure 2](#) and [Figure 3](#).

Figure 2. Risk of bias graph: review authors' judgements about each risk of bias item presented as percentages across all included studies.

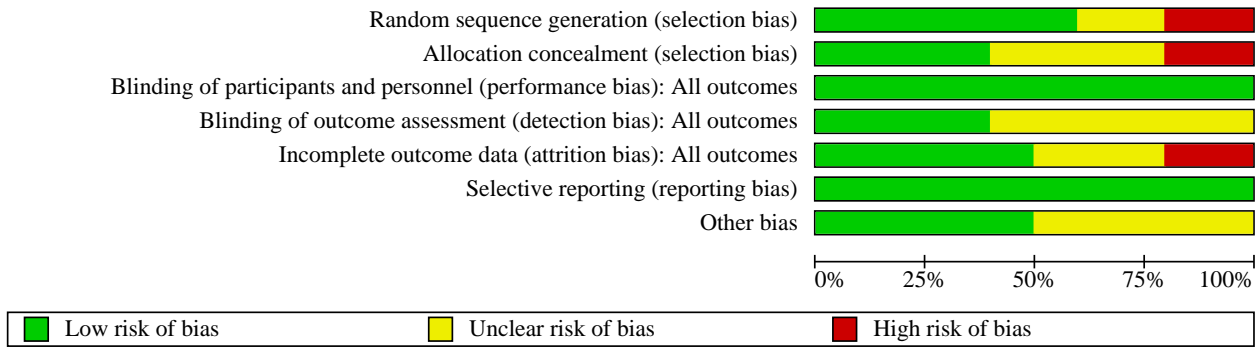

Figure 3. 'Risk of bias' summary: review authors' judgements about each 'Risk of bias' item for each included study

	Random sequence generation (selection bias)	Allocation concealment (selection bias)	Blinding of participants and personnel (performance bias): All outcomes	Blinding of outcome assessment (detection bias): All outcomes	Incomplete outcome data (attrition bias): All outcomes	Selective reporting (reporting bias)	Other bias

Allocation

Four studies described adequate sequence generation and allocation concealment by means of computer randomisation and so were at low risk of selection bias (Collins 2012; Delaney 2015; McDermott 2009; Ritta-Dias 2010). Two studies were judged to be at low risk for randomisation sequence bias but at unclear risk for allocation concealment as they described an adequate sequence generation, but did not describe the allocation concealment (Sanderson 2006; Treat-Jacobson 2009). Two studies were judged to have high risk of bias because they used a pseudorandomisation method in which participants were allocated by the investigators using a fixed block size (Bulinska 2016; Kropielnicka 2018). The two remaining studies did not describe the randomisation process and so were at an unclear risk of selection bias (Regensteiner 1996; Szymczak 2016).

Blinding

In all of the included studies, participants and personnel could not be blinded to the intervention (exercise). For this reason, bias could be introduced. However, since all studies experienced the same limitation, we considered the risk of bias to be low on this domain for all studies. Detection bias can be avoided by blinding the outcome assessors, which was achieved by four studies who were judged to be at low risk of bias (Delaney 2015; McDermott 2009; Ritta-Dias 2010; Treat-Jacobson 2009). The remaining studies did not provide information on blinding of outcome assessors and so were at unclear risk of detection bias (Bulinska 2016; Collins 2012; Kropielnicka 2018; Regensteiner 1996; Sanderson 2006; Szymczak 2016).

Incomplete outcome data

Five studies provided well-described reasons for missing data, which we considered to be plausible and well distributed among the groups and were at low risk of attrition bias (Delaney 2015; Regensteiner 1996; Ritta-Dias 2010; Sanderson 2006; Treat-Jacobson 2009). McDermott 2009 included both symptomatic and asymptomatic participants with PAD. We received the data for participants with IC upon request. Although the article described the missing data, it was unclear to what extent they were related to the group of symptomatic participants. Therefore, we considered the risk of attrition bias to be unclear. Two studies were judged to have high risk of attrition bias because missing data were not balanced across groups and no intention-to-treat analysis was performed (Bulinska 2016; Kropielnicka 2018). Bulinska 2016 did not provide reasons for drop-outs, while in the other study the majority of reasons was directly related to one of the interventions (Kropielnicka 2018). In Collins 2012, the risk of attrition bias was considered to be unclear, as the number of drop-outs was high and not evenly distributed among groups (18 versus 13). Szymczak 2016 did not provide information on incomplete outcome data, and so was also considered to be at an unclear risk of bias.

Selective reporting

We judged all studies to have low risk of reporting bias because published reports included all expected outcomes or because we obtained missing outcomes by contacting the authors (Bulinska 2016; Collins 2012; Delaney 2015; Kropielnicka 2018; McDermott 2009; Regensteiner 1996; Ritta-Dias 2010; Sanderson 2006; Szymczak 2016; Treat-Jacobson 2009).

Other potential sources of bias

Since we included only nine studies in the quantitative analysis, we could not detect publication bias by using a funnel plot. We considered five studies to potentially have other sources of bias and so were judged as 'unclear' (Bulinska 2016; Delaney 2015; Kropielnicka 2018; McDermott 2009; Szymczak 2016). Bulinska 2016 reported significant differences in relevant baseline characteristics (hypertension and degenerative changes of spine and peripheral joints) which might have affected outcomes. Delaney 2015 excluded patients with radiographic aortic-iliac disease, but there is no scientific evidence that confirms a difference in treatment effects of exercise related to the level of disease. Therefore, this was also considered as a potential source of bias. McDermott 2009 included both asymptomatic and symptomatic participants with PAD. Although we only included data of symptomatic participants in this review, the article provided baseline characteristics for the total study population (including asymptomatic participants), which introduces a potential source of bias. In two other studies, baseline characteristics were either not clearly presented (Szymczak 2016) or very limited (Kropielnicka 2018). We identified no other potential sources of bias in the included studies.

Effects of interventions

See: [Summary of findings 1](#) Alternative modes of exercise compared to walking exercise for people with intermittent claudication

Alternative modes of exercise training compared to traditional walking exercise after 12 weeks of training

Maximum walking distance (MWD)

Six studies reported the MWD after 12 weeks of training (Bulinska 2016; Kropielnicka 2018; Regensteiner 1996; Ritta-Dias 2010; Szymczak 2016; Treat-Jacobson 2009), with a total sample size of 274 participants. Overall, there was no clear difference detected between alternative modes of exercise compared to traditional walking (standardised mean difference (SMD) -0.01, 95% CI -0.29 to 0.27; $P = 0.95$; low-certainty evidence; see [Analysis 1.1](#)). Heterogeneity was considered low ($P = 0.28$, $I^2 = 18\%$). See [Summary of findings 1](#). Sensitivity analysis was carried out by removing studies with high risk of bias, as defined in the [Sensitivity analysis](#) section (Bulinska 2016; Kropielnicka 2018; Szymczak 2016), and this had no effect on the SMD.

We investigated different modes of exercise by subgroup analysis (see [Analysis 1.1](#)). These are summarised below. No differences were detected by the test for subgroup differences ($P = 0.16$).

Lower extremity resistance training versus walking exercise

Three studies reported the MWD after 12 weeks of training (Regensteiner 1996; Ritta-Dias 2010; Szymczak 2016), with a sample size of 94 participants. No difference was detected between the resistance and walking exercise groups (SMD -0.02, 95% CI -0.59 to 0.55; $P = 0.94$; [Analysis 1.1](#)). Heterogeneity was considered low ($I^2 = 40\%$; $P = 0.19$) and sensitivity analysis had no significant effect on the SMD.

Nordic walking versus walking exercise

Two studies compared Nordic walking with walking and reported MWD after 12 weeks of training, with a sample size of 88 participants (Bulinska 2016; Kropielnicka 2018). The SMD of 0.31 represented little or no difference (95% CI -0.12 to 0.74; $P = 0.15$; [Analysis 1.1](#)). Heterogeneity was low ($I^2 = 0\%$).

Combination of exercise modes versus walking exercise

Three studies with a sample size of 74 participants compared a combination of exercise modes with walking and reported MWD after 12 weeks of training (Kropielnicka 2018; Regensteiner 1996; Treat-Jacobson 2009). We found no clear difference for MWD (SMD -0.19, 95% CI -0.66 to 0.29; $P = 0.44$; [Analysis 1.1](#)). Heterogeneity was low ($I^2 = 0\%$).

Arm ergometry versus walking exercise

Only one small study investigated arm ergometry compared to walking exercise and no clear differences were detected in MWD between the groups (SMD -0.84, 95% CI -1.87 to 0.19; 18 participants; [Analysis 1.1](#)) (Treat-Jacobson 2009).

Pain-free walking distance (PFWD)

Five studies reported the PFWD after 12 weeks of training (Bulinska 2016; Kropielnicka 2018; Ritta-Dias 2010; Szymczak 2016; Treat-Jacobson 2009), with a sample size of 249 participants. Pooling did not detect a difference in PFWD between alternative modes and walking exercise (SMD -0.01, 95% CI -0.26 to 0.25; $P = 0.97$; low-certainty evidence; see [Analysis 1.2](#)). Heterogeneity was low ($I^2 = 0\%$). We carried out sensitivity analysis by removing studies with a high risk of bias, as defined in the [Sensitivity analysis](#) section

(Bulinska 2016; Kropielnicka 2018; Szymczak 2016), and this had no effect on the SMD.

We investigated different modes of exercise by subgroup analysis (see Analysis 1.2). These are summarised below. No differences were detected by the test for subgroup differences ($P = 0.39$).

Lower extremity resistance training versus walking exercise

Two studies reported the PFWD after 12 weeks of training, with a sample size of 80 participants (Ritta-Dias 2010; Szymczak 2016). There was no clear difference between groups for the pooled PFWD (SMD 0.11, 95% CI -0.32 to 0.55; $P = 0.61$; Analysis 1.2). Heterogeneity was low ($I^2 = 0\%$).

Walking versus Nordic walking versus walking exercise

Two studies reported PFWD after 12 weeks of training, with a sample size of 88 participants (Bulinska 2016; Kropielnicka 2018). No clear difference was detected between groups (SMD 0.14, 95% CI -0.28 to 0.57; $P = 0.51$; Analysis 1.2). Studies were considered homogeneous ($I^2 = 0\%$).

Combination of exercise modes versus walking exercise

Two studies reported PFWD after 12 weeks of training, with a sample size of 63 participants (Kropielnicka 2018; Treat-Jacobson 2009). Little to no difference was found between groups (SMD -0.22,

95% CI -0.74 to 0.30; $P = 0.40$; Analysis 1.2). Included studies were considered homogeneous ($I^2 = 0\%$).

Arm ergometry versus walking exercise

Only one small study investigated arm ergometry compared to walking exercise and no clear differences were detected in PFWD between the groups (SMD -0.65, 95% CI -1.66 to 0.36; 18 participants; Analysis 1.2) (Treat-Jacobson 2009).

Alternative modes of exercise training compared to traditional walking exercise at end of training

Maximum walking distance (MWD)

Nine studies reported the MWD at the end of training with a total sample size of 412 participants (Bulinska 2016; Collins 2012; Kropielnicka 2018; McDermott 2009; Regensteiner 1996; Ritta-Dias 2010; Sanderson 2006; Szymczak 2016; Treat-Jacobson 2009). The duration of exercise programmes varied from 6 to 24 weeks. Pooling detected no clear difference between groups (SMD -0.11, 95% CI -0.33 to 0.11; $P = 0.32$; low-certainty evidence, see Analysis 2.1). The impact of heterogeneity was considered to be low ($P = 0.30$; $I^2 = 15\%$). Sensitivity analysis was carried out by removing studies at risk of bias (Bulinska 2016; Kropielnicka 2018; Szymczak 2016), and resulted in a small to moderate effect on MWD in favour of walking exercise, with a SMD of -0.36 (95% CI -0.63 to -0.10; $P = 0.008$; $I^2 = 0\%$) (Figure 4).

Figure 4. Alternative modes of exercise training compared to traditional walking exercise at end of training: maximum walking distance (MWD). Sensitivity analysis: excluding studies at risk of bias (Bulinska 2016; Kropielnicka 2018; Szymczak 2016)

We investigated different modes of exercise by subgroup analysis (see Analysis 2.1). These are summarised below. No clear differences were detected by the test for subgroup differences (P = 0.62).

Lower extremity resistance training versus walking exercise

Four studies reported the MWD at the end of training with a sample size of 127 participants (McDermott 2009; Regensteiner 1996; Ritta-Dias 2010; Szymczak 2016). The duration of exercise programmes varied from 12 to 24 weeks. There was no clear difference in MWD (SMD -0.06, 95% CI -0.48 to 0.35; P = 0.77; Analysis 2.1). Heterogeneity was considered low (P = 0.27; I² = 24%) and sensitivity analysis had no significant effect on the SMD.

Nordic walking versus walking exercise

Three studies reported MWD at the end of training, with a sample size of 165 participants and programme duration varying from 12 to 24 weeks (Bulinska 2016; Collins 2012; Kropielnicka 2018). No clear difference was found (SMD 0.04, 95% CI -0.47 to 0.54; P = 0.88; Analysis 2.1). The moderate heterogeneity (P = 0.08, I² = 60%)

seemed largely due to one study (Collins 2012). Sensitivity analysis to exclude this trial did result in statistical homogeneity, but did not significantly alter the SMD.

Combination of exercise modes versus walking exercise

Three studies compared combination of exercise modes with walking exercise (Kropielnicka 2018; Regensteiner 1996; Treat-Jacobson 2009). As all three studies had a training duration of 12 weeks, results are reported above (Analysis 1.1).

Arm ergometry versus walking exercise

Only Treat-Jacobson 2009 compared arm ergometry with walking exercise. As the training duration was 12 weeks, results are reported above (Analysis 1.1).

Cycling versus walking exercise

Only one small study with 28 participants compared cycling to walking exercise and no differences were detected in MWD between the groups (SMD -0.31, 95% CI -1.06 to 0.43; P = 0.41; Analysis 2.1) (Sanderson 2006).

Pain-free walking distance (SMDs)

Eight studies reported the PFWD at the end of training with a sample size of 382 participants (Bulinska 2016; Collins 2012; Kropielnicka 2018; McDermott 2009; Ritta-Dias 2010; Sanderson 2006; Szymczak 2016; Treat-Jacobson 2009). The duration of exercise programmes varied from 6 to 24 weeks. There was no clear difference between groups with a small SMD of -0.06 (95% CI -0.30 to 0.17; $P = 0.59$; low-certainty evidence, see Analysis 2.2). The heterogeneity of included studies was considered low ($P = 0.24$, $I^2 = 22\%$). Sensitivity analysis by removing studies with a risk of bias did not alter the SMD (Bulinska 2016; Kropielnicka 2018; Szymczak 2016).

We investigated different modes of exercise by subgroup analysis (see Analysis 2.2). These are summarised below. The test for subgroup differences detected a difference ($P = 0.04$, $I^2 = 60.4\%$), which seemed to be caused by the cycling subgroup that included only one study (Sanderson 2006). After removing this study, no subgroup differences were detected ($P = 0.27$, $I^2 = 23.5\%$).

Lower extremity resistance training versus walking exercise

Three studies reported PFWD at the end of training, with a sample size of 108 participants (McDermott 2009; Ritta-Dias 2010; Szymczak 2016). The duration of exercise programmes varied from 12 to 24 weeks. There was no clear difference between groups (SMD 0.01; 95% CI -0.37 to 0.38; $P = 0.98$; Analysis 2.2). The included studies were considered homogeneous ($I^2 = 0\%$) and sensitivity analyses had no important effect on the SMD.

Nordic walking versus walking exercise

Three studies reported PFWD at the end of training, with a sample size of 165 participants and programme duration varying from 12 to 24 weeks (Bulinska 2016; Collins 2012; Kropielnicka 2018). The SMD of 0.21 represented little to no difference between groups (95% CI -0.10 to 0.52; $P = 0.19$). Studies were considered homogeneous ($I^2 = 0\%$).

Combination of exercise modes versus walking exercise

Two studies compared combination of exercise modes with walking exercise (Kropielnicka 2018; Treat-Jacobson 2009). As these had a training duration of 12 weeks, results are reported above (Analysis 1.2).

Arm ergometry versus walking exercise

Only Treat-Jacobson 2009 compared arm ergometry with walking exercise. As the training duration was 12 weeks, results are reported above (Analysis 1.2).

Cycling versus walking exercise

Only one small study with 28 participants investigated cycling compared to walking exercise and a possible benefit from walking exercise may be seen in PFWD between the groups (SMD -1.01, 95% CI -1.81 to -0.22; $P = 0.01$; Analysis 2.2) (Sanderson 2006).

Health-related quality of life (HR-QoL)

Four studies described HR-QoL (Collins 2012; Delaney 2015; McDermott 2009; Regensteiner 1996). Two studies reported the physical functioning score of the SF-36 (Collins 2012; McDermott 2009). Because of the skewed data of one of the studies (McDermott 2009), with relatively small sample size, we did not perform

a meta-analysis. Both studies found an improvement in both exercise groups. In McDermott 2009, the physical functioning score improved to a median score of 50.0 (interquartile range 40.0 to 60.0) after 24 weeks of treadmill walking ($n = 17$) and to a median score of 60.0 (interquartile range 35.0 to 70.0) after strength training ($n = 14$, $P = 0.811$). In Collins 2012, the mean score was 60.42 (SD 21.75) after 24 weeks of treadmill walking ($n = 43$) and 55.51 (SD 21.27) after Nordic walking ($n = 34$, $P = 0.22$).

Regensteiner 1996, with a sample size of 25 participants, used the Medical Outcomes Study (MOS) SF-20, which consists of five domain scores: physical functioning score, social functioning score, role functioning score, overall health score, and well-being score. After 12 weeks of training, the physical functioning scores improved by 24% for the walking group (95% CI 9 to 39), and the well-being scores increased by 9% (95% CI 2 to 16) for the lower-extremity resistance training group. No improvement in the other MOS domains was detected. In the combined group, no improvement in MOS scores was seen.

Delaney 2015 used the Australian Vascular Quality of Life Index, in which a lower score represents higher quality of life. It found an improved HR-QoL in both the treadmill walking group ($n = 15$) and the combination exercise group ($n = 12$), with a mean decrease of 1.6 points (SD 2.4) and 3.3 points (SD 3.9), respectively ($P = 0.18$).

Self-reported functional impairment

Three studies used the WIQ to measure functional impairment (Collins 2012; McDermott 2009; Regensteiner 1996). All three studies reported the speed and stair-climbing scores (McDermott 2009; Regensteiner 1996). One study had relatively small sample size and a non-normal distribution of outcomes (McDermott 2009). Therefore, it was considered inappropriate to transform these skewed data to enable pooling. Meta-analysis of the two remaining studies, with a sample size of 96 participants, showed little or no difference between the study arms, with a mean difference of -5.52 (95% CI -17.41 to 6.36, $P = 0.36$; low-certainty evidence; see Analysis 2.3). The included studies were considered homogeneous ($I^2 = 0\%$).

In McDermott 2009, the WIQ distance score improved in both the strength ($n = 15$) and treadmill walking group ($n = 15$), with a median of, respectively, 14.0 points (interquartile range = 1.56 to 26.6) and 7.46 points (interquartile range = -0.36 to 25.0; $P = 0.431$). WIQ speed score improved in both the strength ($n = 15$) and treadmill walking group ($n = 16$), with a median of, respectively, 3.26 points (interquartile range = -7.61 to 26.1) and 1.63 points (interquartile range = -3.80 to 28.8; $P = 0.736$). WIQ stair-climbing score improved in the strength training group ($n = 15$), with a median of, respectively, 12.5 points (interquartile range = 4.17 to 25.0), while no improvement was seen in the median score in the treadmill walking group ($n = 16$, median score of 0.00 points, interquartile range = 0.00 to 14.6; $P = 0.136$). Finally, the remaining study (Regensteiner 1996), showed little or no difference in the WIQ speed score with an effect size of -4.50% (95% CI -27.34 to 18.34; $P = 0.70$) and a decreased WIQ stair-climbing score with an effect size of -29.50% (95% CI -51.65 to -7.35, $P = 0.009$), both in favour of alternative exercise.

DISCUSSION

Summary of main results

See [Summary of findings 1](#).

In this update, five additional studies were included, making a total of 10 studies that randomised a total of 527 participants. The alternative modes of exercise therapy included cycling, lower-extremity resistance training, upper-arm ergometry, Nordic walking, and combinations of exercise modes. Besides randomised controlled trials, two quasi-randomised trials were included. Our assessment of the overall risk of bias of included studies varied from high to low risk of bias. Using the GRADE criteria, the certainty of evidence was judged to be low due to the relatively small sample sizes, clinical inconsistency, and inclusion of three studies with risk of bias concerns.

Overall, no clear differences were detected between alternative exercise modes and walking exercise for mean walking distance (MWD) at 12 weeks (standardised mean difference (SMD) -0.01, 95% CI -0.29 to 0.27; $P = 0.95$; 6 studies; 274 participants; low-certainty evidence); or at the end of training (SMD -0.11, 95% CI -0.33 to 0.11; $P = 0.32$; 9 studies; 412 participants; low-certainty evidence). Similarly, no clear differences were detected for PFWD at 12 weeks (SMD -0.01, 95% CI -0.26 to 0.25; $P = 0.97$; 5 studies; 249 participants; low-certainty evidence) or at the end of training (SMD -0.06, 95% CI -0.30 to 0.17; $P = 0.59$; 8 studies; 382 participants; low-certainty evidence).

Four studies reported on HR-QoL and three studies reported on functional impairment. However, meta-analysis was only possible for the WIQ distance score, which demonstrated little or no important difference between study groups (MD -5.52, 95% CI -17.41 to 6.36; $P = 0.36$; 2 studies; 96 participants; low-certainty evidence).

We carried out subgroup analyses by type of alternative exercise mode (cycling, lower-extremity resistance training, upper-arm ergometry, Nordic walking, and combinations of exercise modes) for the main outcomes of MWD and PFWD at 12 weeks and end of training. No differences were detected by the test for subgroup differences in MWD or PFWD at 12 weeks ($P = 0.16$; $P = 0.39$; respectively). At the end of training, no difference was detected between the subgroups for MWD ($P = 0.62$); but a difference was detected in PFWD ($P = 0.04$), which seemed to be caused by the cycling subgroup that included only one study with 28 participants ([Sanderson 2006](#)). After removing this study, no subgroup differences were detected ($P = 0.27$, $I^2 = 23.5\%$).

Sensitivity analysis did not significantly alter the results, except for the primary comparison of MWD at the end of training. In this comparison, excluding studies with apparent risk of bias resulted in a small to moderate effect on MWD in favour of walking exercise (SMD -0.36, 95% CI -0.63 to -0.10; $P = 0.0008$; 5 studies; 230 participants; low-certainty evidence). This might suggest that, in the absence of the influence of bias, walking exercise interventions provide more benefit for MWD at the end of intervention compared to alternative modes of exercise. The use of SMDs makes it difficult to determine whether the difference was clinically relevant. Interpretation is further complicated by the fact that the alternative exercise group includes different types of exercises. Moreover, our level of certainty regarding this evidence is low considering it was

from a small number of studies with relatively small sample size. Future research is likely to have a relevant impact on our confidence in the estimate of effect.

Overall completeness and applicability of evidence

Although the subject of this review is increasing in interest, only five new studies could be included since the previous search of July 2013. In addition to this, we have identified some possible factors which may limit the completeness and applicability of the evidence presented:

Participants

The enrolment criteria were relatively homogeneous among included studies. All studies excluded participants if the exercise capacity was limited by comorbidity. However, comorbidity is common among patients with IC, as they are mostly elderly. Therefore, excluding participants with comorbidity probably affects the generalisability of the observed effects.

Interventions

The vast majority of studies met the guidelines' recommendations for a minimum programme duration of 12 weeks, with durations ranging from six weeks ([Sanderson 2006](#)), to 12 weeks ([Bulinska 2016](#); [Delaney 2015](#); [Kropielnicka 2018](#); [Regensteiner 1996](#); [Ritta-Dias 2010](#); [Szymczak 2016](#); [Treat-Jacobson 2009](#)), and 24 weeks ([Collins 2012](#), [McDermott 2009](#)). The included studies reported outcomes on five alternative modes of exercise, namely cycling ([Sanderson 2006](#)), lower-extremity resistance training ([McDermott 2009](#); [Regensteiner 1996](#); [Ritta-Dias 2010](#); [Szymczak 2016](#)), upper-arm ergometry ([Treat-Jacobson 2009](#)), Nordic walking ([Bulinska 2016](#); [Collins 2012](#); [Kropielnicka 2018](#)), and combinations of exercise modes ([Kropielnicka 2018](#); [Regensteiner 1996](#); [Treat-Jacobson 2009](#)). Subgroup analysis was carried out with the available data but each subgroup included a small number of studies. Overall, more studies are needed to make meaningful comparisons between each alternative exercise mode and the current standard of walking exercise.

Outcomes

Only a few studies reported HR-QoL ([Collins 2012](#); [Delaney 2015](#); [McDermott 2009](#); [Regensteiner 1996](#)), using different measuring instruments, and self-reported functional impairment ([Collins 2012](#); [McDermott 2009](#); [Regensteiner 1996](#)). Meta-analysis was only possible for one of the WIQ subscores. Therefore, more studies are needed to make meaningful comparisons for these outcomes.

Applicability

For the overall meta-analysis, the sample size seemed sufficient, but the results should be interpreted with caution because of the risk of bias ranging from high to low and heterogeneity due to the different types of alternative interventions included and the different units of outcomes across studies. Participant numbers for the subgroup analyses were limited. The SMDs were not back-transformed to metres or seconds, because this could be misleading and there is no consensus in the literature on a minimum clinically relevant difference in metres. Using the rules of thumb for effect sizes might simplify interpretation of the results (SMD of 0.2 represents a small effect, 0.5 a moderate effect, and 0.8 a large effect).

The approach chosen in this review has two main limitations that need to be considered. Different types of interventions were lumped together given that our primary aim was to compare alternative modes of exercise to traditional treadmill walking, and the small number of studies looking at different modes of exercises complicated subanalysis. Furthermore, a non-inferiority approach would have been ideal, but this was not feasible due to the mixed alternative modes of exercise group and the impossibility of predetermining a substantiated non-inferiority margin. Despite these limitations, this updated review provides valuable information.

This review focused on treadmill walking distances. However, treadmill walking does not necessarily correlate to walking ability in daily life (Gommans 2016), nor does an increased treadmill walking distance always lead to more walking (Fokkenrood 2015). Additionally, a possible training effect of treadmill walking might affect treadmill testing, which probably causes an underestimation of the effect of alternative exercise modes. Because of these aspects, focusing on treadmill walking capacity alone probably has limited value in optimising the treatment of IC. Moreover, improving physical fitness and reducing cardiovascular risk, e.g. by increasing physical activity, are important treatment goals in IC. Therefore, objective measurements of functional impairment, physical activity, and physical condition might be interesting, provided that they are measured with validated measuring instruments. Unfortunately, the current lack of consensus and availability of reliable instruments leads to a high heterogeneity with regard to the use of measuring instruments and outcomes.

Quality of the evidence

The risk of bias of included studies varied from high to low and three studies were considered to have risk of bias concerns (Bulinska 2016; Kropielnicka 2018; Szymczak 2016) (see Figure 2 and Figure 3). This review demonstrates that alternative modes of exercise therapy seem to yield similar results to walking therapy and may be considered useful when supervised walking exercise is not an option for the patient. The certainty of the evidence according to the GRADE criteria was low for the overall comparison of alternative exercise modes versus walking exercise (Summary of findings 1). The certainty was downgraded due to the relatively small sample sizes, clinical inconsistency, and concerns over risk of bias. Furthermore, we could not investigate possible publication bias, because the limited number of studies did not allow for assessment of asymmetry in funnel plots.

Potential biases in the review process

We used the SMD as a summary statistic to reduce potential heterogeneity due to the use of different treadmill protocols between studies. Furthermore, we performed subgroup analyses if data were available. It was not possible to conduct a formal analysis of possible publication bias by using a funnel plot owing to the limited number of studies included in the meta-analysis. Several studies were excluded, solely because they did not report the correct outcome measures. Although we carefully ascertained that relevant outcomes were not available because they were not measured rather than not reported, this could introduce bias in the review process. In future updates, we will pay further attention to this potential source of bias.

Many studies were excluded in the title-abstract screening, because they were not RCTs, examined nonsupervised programmes or compared alternative modes of exercise to a non-exercise control group. Furthermore, this review only included supervised exercise programmes, thus excluding home-based or partially supervised programmes comparing walking exercise to alternative modes of exercise. However, considering the findings of other studies, this did not substantially alter results (see [Agreements and disagreements with other studies or reviews](#)).

Agreements and disagreements with other studies or reviews

The findings of this update are in line with the findings of the previous version of this review (Lauret 2014), as well as findings of several other systematic reviews. One previously published systematic review (Parmenter 2011), which included unsupervised exercise programmes and RCTs with a non-exercise control group, found no clear difference between alternative aerobic exercise modes and walking exercise for IC. The data on resistance training were considered insufficient to make clinical recommendations and further research was needed. A systematic review and meta-analysis on Nordic walking (Golledge 2018) suggested that Nordic walking might be more effective in improving cardiovascular fitness than standard walking. However, no benefit of Nordic walking was found compared to standard walking, including unsupervised and supervised settings. A subgroup analysis of completely supervised programmes also demonstrated similar improvements in MWD (SMD -0.79; 95% CI -2.81 to 1.24; P = 0.446). Furthermore, a recent statement from the American Heart Association (Treat-Jacobson 2019), was based on a systematic review, which included the comparison of treatment modalities. Evidence for each of the alternative exercise modes was summarised separately, and the authors concluded that modalities other than supervised treadmill exercise, including arm ergometry, cycling, and possibly resistance training, can also improve relevant outcomes. In summary, our findings agree with currently available evidence that alternative exercise modes are as effective as standard walking, however, more evidence is needed.

AUTHORS' CONCLUSIONS

Implications for practice

Overall, this review demonstrates that there is no clear difference between alternative modes of exercise and supervised walking exercise regarding maximum and pain-free walking distance in patients with intermittent claudication, which means that both interventions yield similar improvements. The certainty of this evidence was judged to be low, mainly due to the small sample size and risk of bias concerns. The findings of this review indicate that alternative exercise modes may be useful when supervised walking exercise is not an option. This is consistent with current international guidelines (Aboyans 2018; Gerhard-Herman 2017).

Implications for research

Although this update included five additional studies, the overall sample size was relatively small. More RCTs with adequate methodological quality and sufficient power are needed to provide more robust evidence for comparisons between each alternative exercise mode and the current standard of supervised treadmill walking. Those RCTs should preferably investigate

exercise programmes with a minimum of three sessions a week for a consecutive 12 weeks, as this is recommended based on currently available evidence (Treat-Jacobson 2019). Walking capacity should not solely be measured with treadmill tests, as this might result in an underestimation of the effect of alternative exercise modes and probably does not represent 'daily life' walking. Future studies should investigate functional outcome measures on walking behaviour, physical activity, cardiovascular risk, and HR-QoL, using standardised testing methods and reporting of outcomes to allow meaningful comparison across studies. Furthermore, studies should include patients with comorbidity in order to be more representative of the PAD population. Finally, research is needed to explore possibilities to optimise exercise programmes, taking into account the personal preferences, therapy compliance, and long-term effects. It is thought that more varied and personalised programmes will possibly improve therapy adherence. Furthermore, this might lead to better compliance with the recommendations for physical activity, because combinations

of aerobic and muscle-strengthening activities are preferable, according to the Physical Activity Guidelines (Piercy 2018).

ACKNOWLEDGEMENTS

We acknowledge the support provided by Dr Marlene Stewart, Managing Editor of Cochrane Vascular, Dr Cathryn Broderick, Assistant Managing Editor of Cochrane Vascular, and Ms Candida Fenton, Cochrane Vascular Information Specialist, in updating this review. We would also like to thank the previous authors for their contributions to the previous version of this review: Professor Hunink and Dr Spronk. The review authors, and the Cochrane Vascular editorial base, wish to thank the following peer reviewers for their input as well as the reviewer who opted to remain anonymous: Dr Ralph G DePalma, Uniformed Services University of the Health Sciences, Washington and Department of Veteran Affairs, Washington, US; Associate Professor Anthony Leicht, James Cook University, Australia; Dr Jonathan Moran, Trinity College Dublin, Ireland; LeAnne Lovett-Floom, DNP, MSN, RN, PHN-BC, US.

CHARACTERISTICS OF STUDIES
Characteristics of included studies [ordered by study ID]
Bulinska 2016
Study characteristics

Methods	RCT
Participants	The number of eligible patients was not described, 70 participants were randomised and 52 participants completed follow-up (4 drop-outs in group 1 and 14 in group 2)
Interventions	Group 1: 12 weeks of supervised treadmill exercise Group 2: 12 weeks of supervised Nordic walking
Outcomes	Claudication distance, MWD, 6-minute walking test, heart rate, blood pressure, and rating of perceived exertion
Notes	-

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	High risk	Pseudorandomisation method was used in which recruited participants were allocated by the investigators using a fixed block size.
Allocation concealment (selection bias)	High risk	Pseudorandomisation method was used in which recruited participants were allocated by the investigators using a fixed block size.
Blinding of participants and personnel (performance bias) All outcomes	Low risk	In all of the included studies, participants and direct personnel could not be blinded to the intervention (exercise). For this reason, bias could be introduced. However, since all studies experienced the same limitation, we considered the risk of bias to be low for all studies.
Blinding of outcome assessment (detection bias) All outcomes	Unclear risk	No information provided
Incomplete outcome data (attrition bias)	High risk	The authors reported 18 drop-outs (4 in group 1 and 14 in group 2), without providing clear reasons ("The main reasons for dropouts from the training pro-

Modes of exercise training for intermittent claudication (Review)

Bulinska 2016 (Continued)

All outcomes		grammes were personal problems and health disturbances"). The risk of bias was considered high as the number of drop-outs was high and not evenly distributed, and no intention-to-treat analysis was performed.
Selective reporting (reporting bias)	Low risk	All relevant outcomes were described in the study results.
Other bias	Unclear risk	Significant differences in baseline characteristics were reported for hypertension and degenerative changes of spine and peripheral joints. These characteristics might affect outcomes. We identified no other forms of bias.

Collins 2012
Study characteristics

Methods	RCT
Participants	2296 potential participants were screened for eligibility, 146 were enrolled and 103 were randomised. The authors reported 18 drop-outs in group 1 and 13 in group 2.
Interventions	Group 1: 24 weeks of supervised treadmill exercise Group 2: 24 weeks of supervised Nordic walking
Outcomes	Onset of claudication time, maximum walking time, SF-36 (physical function subscale), WIQ (distance subscale) and tissue oxygenation measured using near-infrared spectroscopy
Notes	-

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Low risk	Randomisation was performed with computer-generated permuted blocks.
Allocation concealment (selection bias)	Low risk	Randomisation was performed with computer-generated permuted blocks.
Blinding of participants and personnel (performance bias) All outcomes	Low risk	In all of the included studies, participants and direct personnel could not be blinded to the intervention (exercise). For this reason, bias could be introduced. However, since all studies experienced the same limitation, we considered the risk of bias to be low for all studies.
Blinding of outcome assessment (detection bias) All outcomes	Unclear risk	No information provided
Incomplete outcome data (attrition bias) All outcomes	Unclear risk	The authors reported 18 drop-outs in group 1 and 13 drop-outs in group 2. The reasons were compliance (10), cardiac (9), peripheral vascular surgery (3), death (1), other medical (7), and moved (1). Although plausible reasons were provided and intention-to-treat analysis was performed, the risk of bias was considered unclear as the number of drop-outs was high and not evenly distributed among groups.

Collins 2012 (Continued)

Selective reporting (re-reporting bias)	Low risk	All relevant outcomes were described in the study results.
Other bias	Low risk	No significant differences in baseline characteristics were found. We identified no other forms of bias.

Delaney 2015
Study characteristics

Methods	RCT
Participants	111 potential participants assessed for eligibility, 35 participants were randomised (18 in group 1 and 17 in group 2). The authors reported 3 drop-outs in group 1 and 5 in group 2.
Interventions	Group 1: 12 weeks of supervised treadmill exercise Group 2: 12 weeks of combination training (supervised treadmill exercise and resistance training)
Outcomes	Australian Vascular QoLIndex, 6-minute walking test, and endothelial function
Notes	-

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Low risk	Randomisation was performed by computer-based random number generation using a 1:1 allocation ratio for block sizes which represented the number of participants recruited within each 3-month interval.
Allocation concealment (selection bias)	Low risk	Randomisation was performed by computer-based random number generation.
Blinding of participants and personnel (performance bias) All outcomes	Low risk	In all of the included studies, participants and direct personnel could not be blinded to the intervention (exercise). For this reason, bias could be introduced. However, since all studies experienced the same limitation, we considered the risk of bias to be low for all studies.
Blinding of outcome assessment (detection bias) All outcomes	Low risk	Outcome assessors were blinded to the allocated intervention.
Incomplete outcome data (attrition bias) All outcomes	Low risk	The authors reported 8 drop-outs: 3 in group 1 due to MI (1), sepsis (1), and lost of interest (1); and 5 in group 2 due to transient ischaemic attack (2), disc prolapse (1), diabetic foot sepsis (1), and lost of interest (1). ITT analysis and per-protocol analysis were performed.
Selective reporting (re-reporting bias)	Low risk	All relevant outcomes were described in the study results.
Other bias	Unclear risk	Participants with radiographic aortic-iliac disease were excluded from the study, but there is no scientific evidence that confirms a difference in treatment effects of exercise related to the level of disease. No significant differ-

Delaney 2015 (Continued)

ences in baseline characteristics were found. We identified no other forms of bias.

Kropielnicka 2018
Study characteristics

Methods	RCT
Participants	219 potentially eligible patients, 144 qualified according to criteria, 95 participants were randomised. The authors reported 15 drop-outs (1 in group 1, 11 in group 2, 3 in group 3), which were excluded from analysis.
Interventions	Group 1: 12 weeks of supervised treadmill exercise Group 2: 12 weeks of supervised Nordic walking Group 3: 12 weeks of supervised combination training (resistance training and Nordic walking)
Outcomes	Initial claudication distance, maximum claudication distance, 6-minute walking test, force-velocity parameters of flexor and extensor muscles in the knee and ankle joints
Notes	We contacted the authors and received relevant outcome data, which were not clearly described in the paper.

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	High risk	Pseudorandomisation method was used in which recruited participants were allocated by the investigators using a fixed block size.
Allocation concealment (selection bias)	High risk	Pseudorandomisation method was used in which recruited participants were allocated by the investigators using a fixed block size.
Blinding of participants and personnel (performance bias) All outcomes	Low risk	In all of the included studies, participants and direct personnel could not be blinded to the intervention (exercise). For this reason, bias could be introduced. However, since all studies experienced the same limitation, we considered the risk of bias to be low for all studies.
Blinding of outcome assessment (detection bias) All outcomes	Unclear risk	No information provided
Incomplete outcome data (attrition bias) All outcomes	High risk	18 participants dropped out after randomisation: 1 in the treadmill group due to deterioration of health and 11 in the Nordic walking group due to distance between place of residence and place of training (6), health concerns for undertaking outdoor training (4), and malaise (1); and 3 in the combination group due to insufficient participation in exercise training (2) and unwillingness to participate in final tests (1). Drop-outs were not evenly distributed and for 10 participants in group 2 the reasons were related to the intervention itself. All drop-outs were excluded from analysis; no intention-to-treat analysis was performed.

Kropielnicka 2018 (Continued)

Selective reporting (reporting bias)	Low risk	Relevant outcome data for this review (initial claudication distance and maximal walking distance) were only presented in a figure; no numerical data were given. However, after contacting the authors, we collected these data.
Other bias	Unclear risk	The presented baseline characteristics were very limited. We identified no other forms of bias.

McDermott 2009
Study characteristics

Methods	RCT
Participants	1009 participants with asymptomatic and symptomatic PAD were assessed for eligibility; 156 participants were randomised; after contacting authors, 33 randomised participants were affected by IC.
Interventions	Group 1: 24 weeks of supervised treadmill walking Group 2: 24 weeks of supervised lower-extremity resistance training Group 3 (control group): 11 nutritional information sessions over 6 months
Outcomes	6-minute walk test, short physical performance battery, brachial artery flow-mediated dilation, physical activity (accelerometry), maximum treadmill walking time, treadmill time to onset of leg symptoms, SF-36 physical functioning score, WIQ, knee extension isometric strength/power, plantar flexion isometric strength
Notes	We contacted the authors for more information regarding study results for the subgroup of participants with intermittent claudication.

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Low risk	Participants were randomised by computer using a randomly permuted block method. Randomisation was stratified by the presence versus absence of intermittent claudication.
Allocation concealment (selection bias)	Low risk	Participants were randomised by computer using a randomly permuted block method.
Blinding of participants and personnel (performance bias) All outcomes	Low risk	In all of the included studies, participants and direct personnel could not be blinded to the intervention (exercise). For this reason, bias could be introduced. However, since all studies experienced the same limitation, we considered the risk of bias to be low for all studies.
Blinding of outcome assessment (detection bias) All outcomes	Low risk	Examiners were blinded to participant group assignment.
Incomplete outcome data (attrition bias) All outcomes	Unclear risk	ITT analyses were performed for drop-outs. Analyses were repeated using multiple imputation for persons who died or dropped out before completing 6-month follow-up testing. However, because of the study setting, it was not clear which participants with IC (instead of asymptomatic PAD) dropped out. The paper stated that missing data at follow-up were more common in more frail participants. On the other hand, the authors performed a sensitivity

Modes of exercise training for intermittent claudication (Review)

McDermott 2009 (Continued)

analysis and showed that the missing data were not likely to have significantly altered the findings.

Selective reporting (reporting bias)	Low risk	All relevant outcomes were described. Although not all secondary outcomes were mentioned in the trial registration, all outcomes mentioned in the study protocol were reported in the final draft of the paper.
Other bias	Unclear risk	Because of the study setting (the study included participants with asymptomatic or symptomatic PAD), the baseline characteristics of the subgroup of participants with IC were not described. We identified no other forms of bias.

Regensteiner 1996
Study characteristics

Methods	RCT
Participants	44 participants evaluated: 15 were excluded before randomisation; 29 participants were enrolled and randomised.
Interventions	<p>Group 1: 12 weeks of supervised walking exercise. Secondly, 12 weeks of additional supervised walking exercise</p> <p>Group 2: 12 weeks of strength training. Secondly, 12 weeks of additional supervised walking exercise</p> <p>Group 3 (control group): no treatment for 12 weeks. Secondly, 12 weeks of a combination of supervised walking exercise and strength training</p>
Outcomes	Peak treadmill walking time, ABI (in rest and after exercise), WIQ score, Physical Activity Recall score, Medical Outcomes Study Questionnaire score, Vitalog activity monitor
Notes	-

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Unclear risk	No information provided
Allocation concealment (selection bias)	Unclear risk	No information provided
Blinding of participants and personnel (performance bias) All outcomes	Low risk	In all of the included studies, participants and direct personnel could not be blinded to the intervention (exercise). For this reason, bias could be introduced. However, since all studies experienced the same limitation, we considered the risk of bias to be low for all studies.
Blinding of outcome assessment (detection bias) All outcomes	Unclear risk	<p>To minimise the potential for bias in the self-evaluation of walking ability and functional status, questionnaires were administered before the treadmill test. Thus, participants' questionnaire responses were not influenced by their treadmill exercise performance. In addition, the interviewer and participant were blinded to previous questionnaire scores.</p> <p>The paper did not describe whether examiners were blinded to participant group assignment.</p>

Regensteiner 1996 (Continued)

Incomplete outcome data (attrition bias) All outcomes	Low risk	Two participants in the control group were not available for follow-up at the 12-week evaluation. They were excluded from further analysis. In the supervised walking and strength training group, no missing outcome data were described.
Selective reporting (reporting bias)	Low risk	All relevant outcomes were described in the study results.
Other bias	Low risk	No significant differences in baseline characteristics were found. We identified no other forms of bias.

Ritta-Dias 2010
Study characteristics

Methods	RCT
Participants	34 participants were randomised; 4 participants did not complete training; 30 participants completed the study protocol (15 per group).
Interventions	Group 1: 12 weeks of supervised treadmill exercise Group 2: 12 weeks of strength training
Outcomes	Initial claudication distance, total walking distance, peak VO ₂ , VO ₂ at the first stage of treadmill test, ischaemic window, leg strength with lower ABI, leg strength with higher ABI
Notes	No ITT analysis

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Low risk	Randomisation was performed by computer random number generation.
Allocation concealment (selection bias)	Low risk	Randomisation was performed by computer random number generation.
Blinding of participants and personnel (performance bias) All outcomes	Low risk	In all of the included studies, participants and direct personnel could not be blinded to the intervention (exercise). For this reason, bias could be introduced. However, since all studies experienced the same limitation, we considered the risk of bias to be low for all studies.
Blinding of outcome assessment (detection bias) All outcomes	Low risk	Participants were evaluated at baseline (pre-training) and after 12 weeks of exercise training (post-training) by a physician who was blinded to the exercise programme performed by participants.
Incomplete outcome data (attrition bias) All outcomes	Low risk	4 participants (2 in the strength training groups and 2 in the walking exercise groups) did not complete the training programmes for the following reasons: inguinal hernia (n = 1), gastrointestinal infection (n = 1), ongoing treatment for lung cancer (n = 1), and diagnosis of abdominal aneurysm (n = 1). Although no ITT analysis was performed, reasons for missing data were plausible and well distributed among intervention groups.

Ritta-Dias 2010 (Continued)

Selective reporting (reporting bias)	Low risk	All relevant outcomes were described in the study results.
Other bias	Low risk	No significant differences in baseline characteristics were found. We identified no other forms of bias.

Sanderson 2006
Study characteristics

Methods	RCT
Participants	694 participants were assessed for eligibility; 43 participants were randomised.
Interventions	Group 1: 6 weeks of supervised treadmill exercise Group 2: 6 weeks of supervised cycling Group 3 (control group): cardiovascular risk management and exercise advice
Outcomes	Maximum walking time, pain-free walking time, maximum cycling time, pain-free cycling time, submaximal and peak heart rate/ VO_2 /respiratory exchange ratio/minute ventilation
Notes	We contacted the authors and received relevant outcome data, which were not clearly described in the paper.

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Low risk	A closed-envelope system was used to randomise participants from the stratified groups to a control group, a cycle-training group, or a treadmill training group.
Allocation concealment (selection bias)	Unclear risk	No information provided
Blinding of participants and personnel (performance bias) All outcomes	Low risk	In all of the included studies, participants and direct personnel could not be blinded to the intervention (exercise). For this reason, bias could be introduced. However, since all studies experienced the same limitation, we considered the risk of bias to be low for all studies.
Blinding of outcome assessment (detection bias) All outcomes	Unclear risk	No blinding of outcome assessment was described.
Incomplete outcome data (attrition bias) All outcomes	Low risk	One participant in the treadmill training group withdrew after 1 week of training. The baseline data have been omitted.
Selective reporting (reporting bias)	Low risk	Relevant outcome data for this review (maximum and pain-free walking time) were only presented in a figure; no numerical data were given. However, after contacting the authors, we collected these data.
Other bias	Low risk	No significant differences in baseline characteristics were found. We identified no other forms of bias.

Szymczak 2016

Study characteristics

Methods	RCT
Participants	50 participants were randomised; the number of eligible patients and the number of participants that completed follow-up were not provided.
Interventions	Group 1: 12 weeks of supervised treadmill exercise Group 2: 12 weeks of lower limbs resistance training
Outcomes	Initial claudication distance, absolute claudication distance, 6-minute walking test, ABI
Notes	-

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Unclear risk	"Patients were randomly assigned". No further information provided
Allocation concealment (selection bias)	Unclear risk	"Patients were randomly assigned". No further information provided
Blinding of participants and personnel (performance bias) All outcomes	Low risk	In all of the included studies, participants and direct personnel could not be blinded to the intervention (exercise). For this reason, bias could be introduced. However, since all studies experienced the same limitation, we considered the risk of bias to be low for all studies.
Blinding of outcome assessment (detection bias) All outcomes	Unclear risk	No information provided
Incomplete outcome data (attrition bias) All outcomes	Unclear risk	The text did not specify the number of eligible participants or the number of participants that completed follow-up. There was no information about drop-outs or types of analysis (ITT or per-protocol).
Selective reporting (reporting bias)	Low risk	All relevant outcomes were described in the study results.
Other bias	Unclear risk	The baseline characteristics were not clearly presented. According to the text there was a significant difference for baseline ABI between groups. We identified no other forms of bias.

Treat-Jacobson 2009

Study characteristics

Methods	RCT
Participants	102 participants were assessed for eligibility; 45 participants were randomised.
Interventions	Group 1: 12 weeks of arm ergometry

Modes of exercise training for intermittent claudication (Review)

Treat-Jacobson 2009 (Continued)

Group 2: 12 weeks of supervised treadmill walking

Group 3: 12 weeks of a combination of arm ergometry and supervised treadmill walking

Group 4 (control group): usual care (cardiovascular management and exercise advice)

Outcomes	MWD, pain-free walking distance, resting ABI/heart rate/blood pressure, functional capacity (peak VO ₂)
Notes	The study paper mentioned only the change in walking distances. We were not able to retrieve the absolute values at follow-up for the walking distances through contact with the authors.

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Low risk	Eligible participants were randomised by simple randomisation tables to 1 of the 4 study groups.
Allocation concealment (selection bias)	Unclear risk	No information provided
Blinding of participants and personnel (performance bias) All outcomes	Low risk	In all of the included studies, participants and direct personnel could not be blinded to the intervention (exercise). For this reason, bias could be introduced. However, since all studies experienced the same limitation, we considered the risk of bias to be low for all studies.
Blinding of outcome assessment (detection bias) All outcomes	Low risk	The physician supervising the treadmill tests was blinded to treatment group assignment. However, other staff assisting with testing were not blinded. To mitigate for this limitation, care was taken to ensure standardisation of exercise-testing protocols.
Incomplete outcome data (attrition bias) All outcomes	Low risk	Incomplete outcome data are well described and equally distributed among intervention groups. 4 of the 45 participants withdrew from the study before completing exercise training (2 participants in the arm-ergometry group and 2 participants in the treadmill walking group). Therefore, only 41 participants completed the 12-week follow-up. 31 participants completed the 24-week follow-up.
Selective reporting (reporting bias)	Low risk	All relevant outcomes were described in the study results.
Other bias	Low risk	No significant differences in baseline characteristics were found. We identified no other forms of bias.

ABI: ankle brachial index

IC: intermittent claudication

ITT: intention-to-treat

MI: myocardial infarction

MWD: maximal walking distance

PAD: peripheral arterial disease

PFWD: pain-free walking distance

QoL: quality of life

RCT: randomised controlled trial

SET: supervised exercise therapy

SF-36: 36-item Short Form Health Survey

SMM: skeletal muscle mass

 VO₂: pulmonary oxygen uptake

WIQ: Walking Impairment Questionnaire

Characteristics of excluded studies [ordered by study ID]

Study	Reason for exclusion
Dedes 2010	Meeting poster; no journal article available
Delaney 2014	No correct outcome measures
EXERT Study 2018	The original results of the EXERT study are not published. Only one publication is available comparing long-term follow-up (1 to 4 years) to end of study results (24 weeks). Baseline data were not available from the authors.
Gardner 2011	Commentary on other journal article; not an RCT
Jones 1996	Outcome measures unclearly described; no information from authors
Kao 2012	Meeting poster; no article available (authors contacted)
Kim 2006	Commentary on other journal article; not an RCT
Kuwabara 2010	Meeting poster; no article available
Nawaz 2001	No intervention group with adequate supervised walking therapy; no correct outcome measures
Oakley 2008	No intervention group with adequate supervised walking therapy
Ornelas 2011	Meeting poster; no article available
Parmenter 2013	No control group with SET
Parr 2009	No intervention group with adequate supervised walking therapy
Roitman 2010	Editorial; not an RCT
Saxton 2008	No control group with adequate SET; no correct outcome measures
Saxton 2011	No control group with adequate SET; no correct outcome measures (MWD assessed by shuttle-walk test instead of protocolised treadmill test)
Tebbutt 2011	No control group with adequate SET
Treat-Jacobson 2011	No relevant outcome measures for this review assessed and reported
Treat-Jacobson 2012	Meeting poster; no journal article available; no control group with adequate SET
Van Schaardenburgh 2017	No control group with adequate SET
Walker 2000	No control group with adequate SET; no correct outcome measures (no treadmill test)
Wang 2008	No control group with SET
Zwierska 2005	No control group with adequate SET

MWD: maximum walking distance
 RCT: randomised controlled trial
 SET: supervised exercise therapy

Characteristics of ongoing studies [ordered by study ID]

ACTRN12616000243415

Study name	Comparison of the effects of supervised treadmill walking training and supervised walking with poles on the functional capabilities, the function of endothelium and the metabolic cost of walking in patients with IC
Methods	<p>Study type: interventional</p> <p>Study design: RCT</p> <p>Masking: open (no masking used)</p> <p>Primary purpose: treatment</p>
Participants	<p>Recruitment status: completed</p> <p>Number of participants: 90</p> <p>Inclusion criteria:</p> <ul style="list-style-type: none"> • Age: older than 50 years; • Patients with atherosclerosis of lower extremities evaluated according to the Fontaine's classification as degree IIA and IIB; • ABI < 0.9; • No systemic contraindications to undertake the proposed forms of exercise; • Written consent to participate in a clinical trial. <p>Exclusion criteria:</p> <ul style="list-style-type: none"> • Inability to walk on a treadmill at a speed of 2 mph; • Recently completed vascular treatments (less than 6 months); • Changes in pharmacological treatment (less than 6 months); • Symptomatic coronary artery disease, exertional dyspnoea, resting blood pressure higher than 160/100 mmHg, resting tachycardia higher than 100/min, thrombophlebitis, arterial embolism, active cancer, exercise-induced asthma, cardiorespiratory failure (NYHA III)
Interventions	<p>There are three study arms:</p> <ul style="list-style-type: none"> • 12 weeks of supervised treadmill walking three times a week • 12 weeks of supervised walking with poles three times a week • A control group that will be instructed according to standard preventive recommendation and will not undergo walking training
Outcomes	<p>All outcomes will be measured at baseline and after 12 weeks</p> <p>Primary outcome measures:</p> <ul style="list-style-type: none"> • MWD (treadmill test, Gardner protocol) • Vascular endothelial function (flow mediated dilatation) • Metabolic cost of walking determined using oxygen consumption measure (graded treadmill walking test with simultaneous breath-by-breath VO₂ measurements) <p>Secondary outcomes measures:</p> <ul style="list-style-type: none"> • PFWD (treadmill test, Gardner protocol) • Functional walking ability (WIQ)
Starting date	Date of first participant enrolment: April 2016

Notes	We contacted the study authors: the study is completed, but results are not yet published or available.

NCT03837639

Study name	Effects of arm-crank exercise training on cardiovascular function of patients with PAD: an RCT
Methods	Study type: interventional Study design: RCT; parallel assignment Masking: double (investigator, outcome assessor) Primary purpose: treatment
Participants	Estimated enrolment: 45 participants Inclusion criteria: <ul style="list-style-type: none"> • Age 45 to 85 years • PAD stage II • ABI < 0.90 in one or both lower limbs • Women in postmenopause phase without hormone replacement therapy • Not an active smoker • Able to perform exercise training Exclusion criteria: <ul style="list-style-type: none"> • PAD stage I, III and IV • Presence of diabetic neuropathy
Interventions	There are three study arms: <ul style="list-style-type: none"> • 12 weeks of supervised arm-crank exercise twice a week • 12 weeks of supervised treadmill walking twice a week • 12 weeks of active control sessions twice a week (patients will perform manual tasks without exercise component)
Outcomes	All outcomes will be measured at baseline and after 12 weeks Primary outcome measure: <ul style="list-style-type: none"> • Ambulatory blood pressure (systolic, diastolic and mean blood pressure) Secondary outcome measures: <ul style="list-style-type: none"> • Clinical blood pressure (systolic and diastolic blood pressure) • Cardiac autonomic modulation (heart rate monitor) • Arterial stiffness (pulse wave velocity)

Modes of exercise training for intermittent claudication (Review)

NCT03837639 (Continued)

- Vasodilatory capacity (flow mediated dilation)

Other measures (additional information on request, not described in trial registry):

- 6-minute walking test
- Functional capacity (2 questionnaires: Walking Estimated-Limitation Calculated by History (WELCH) and WIQ)

Starting date	Estimated starting date: April 2019
Contact information	Gabriel Cucato, PhD Hospital Israelita Albert Einstein, São Paulo, Brazil, 05652-900
Notes	We contacted Dr Cucato to confirm that functional tests will be performed.

ABI: ankle brachial index

IC: intermittent claudication

mph: miles per hour

MWD: maximal walking distance

PAD: peripheral arterial disease

PFWD: pain-free walking distance

RCT: randomised controlled trial

WELCH: walking estimated-limitation calculated by history

WIQ: walking impairment questionnaire

DATA AND ANALYSES

Comparison 1. Alternative modes of exercise versus walking exercise at 12 weeks

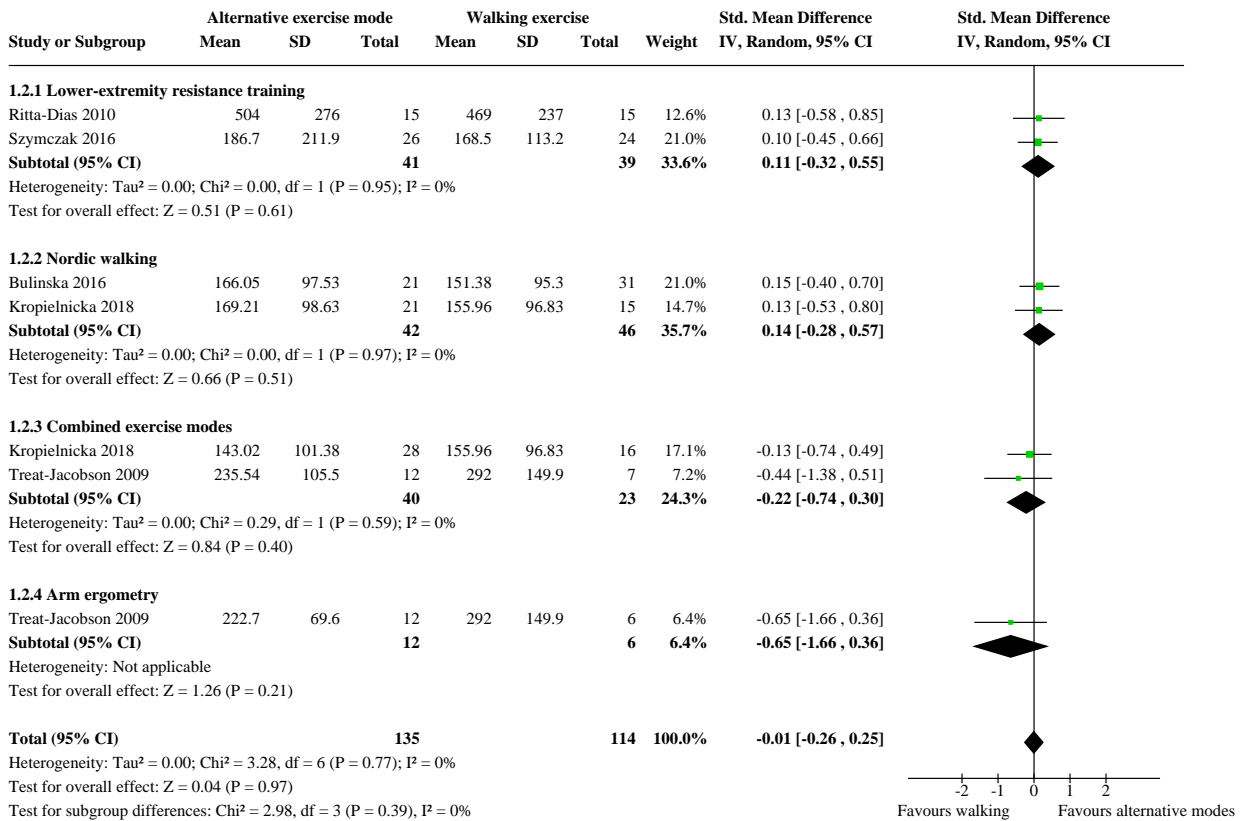

Outcome or subgroup title	No. of studies	No. of participants	Statistical method	Effect size
1.1 Maximum walking distance	6	274	Std. Mean Difference (IV, Random, 95% CI)	-0.01 [-0.29, 0.27]
1.1.1 Lower-extremity resistance training	3	94	Std. Mean Difference (IV, Random, 95% CI)	-0.02 [-0.59, 0.55]
1.1.2 Nordic walking	2	88	Std. Mean Difference (IV, Random, 95% CI)	0.31 [-0.12, 0.74]
1.1.3 Combined exercise modes	3	74	Std. Mean Difference (IV, Random, 95% CI)	-0.19 [-0.66, 0.29]
1.1.4 Arm ergometry	1	18	Std. Mean Difference (IV, Random, 95% CI)	-0.84 [-1.87, 0.19]
1.2 Pain-free walking distance	5	249	Std. Mean Difference (IV, Random, 95% CI)	-0.01 [-0.26, 0.25]
1.2.1 Lower-extremity resistance training	2	80	Std. Mean Difference (IV, Random, 95% CI)	0.11 [-0.32, 0.55]
1.2.2 Nordic walking	2	88	Std. Mean Difference (IV, Random, 95% CI)	0.14 [-0.28, 0.57]
1.2.3 Combined exercise modes	2	63	Std. Mean Difference (IV, Random, 95% CI)	-0.22 [-0.74, 0.30]
1.2.4 Arm ergometry	1	18	Std. Mean Difference (IV, Random, 95% CI)	-0.65 [-1.66, 0.36]

Modes of exercise training for intermittent claudication (Review)

Analysis 1.1. Comparison 1: Alternative modes of exercise versus walking exercise at 12 weeks, Outcome 1: Maximum walking distance

Analysis 1.2. Comparison 1: Alternative modes of exercise versus walking exercise at 12 weeks, Outcome 2: Pain-free walking distance

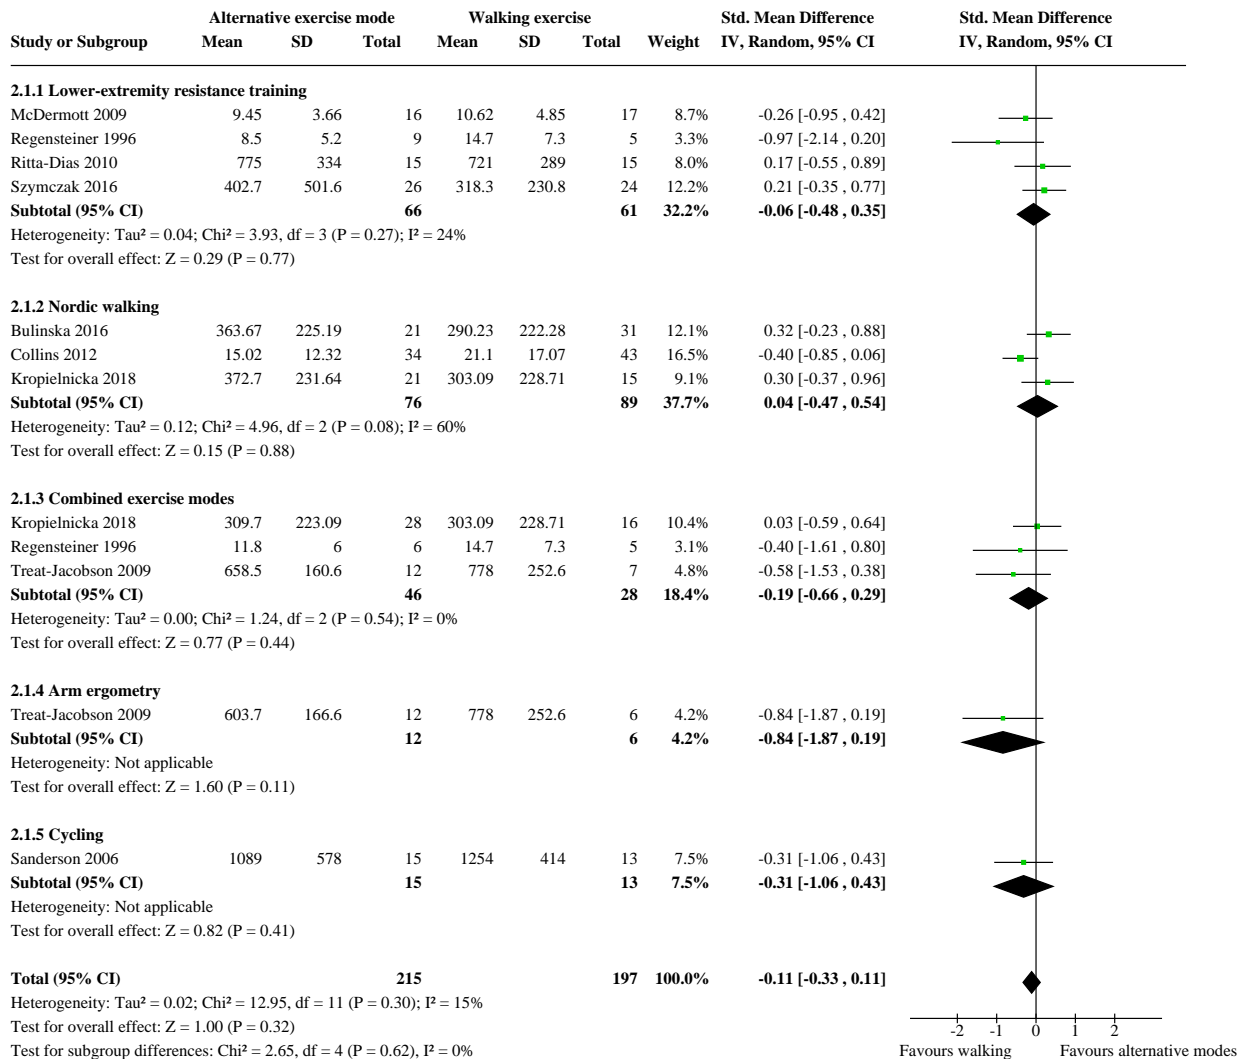

Comparison 2. Alternative modes of exercise versus walking exercise at the end of training

Outcome or subgroup title	No. of studies	No. of participants	Statistical method	Effect size
2.1 Maximum walking distance	9	412	Std. Mean Difference (IV, Random, 95% CI)	-0.11 [-0.33, 0.11]
2.1.1 Lower-extremity resistance training	4	127	Std. Mean Difference (IV, Random, 95% CI)	-0.06 [-0.48, 0.35]
2.1.2 Nordic walking	3	165	Std. Mean Difference (IV, Random, 95% CI)	0.04 [-0.47, 0.54]
2.1.3 Combined exercise modes	3	74	Std. Mean Difference (IV, Random, 95% CI)	-0.19 [-0.66, 0.29]
2.1.4 Arm ergometry	1	18	Std. Mean Difference (IV, Random, 95% CI)	-0.84 [-1.87, 0.19]
2.1.5 Cycling	1	28	Std. Mean Difference (IV, Random, 95% CI)	-0.31 [-1.06, 0.43]
2.2 Pain-free walking distance	8	382	Std. Mean Difference (IV, Random, 95% CI)	-0.06 [-0.30, 0.17]

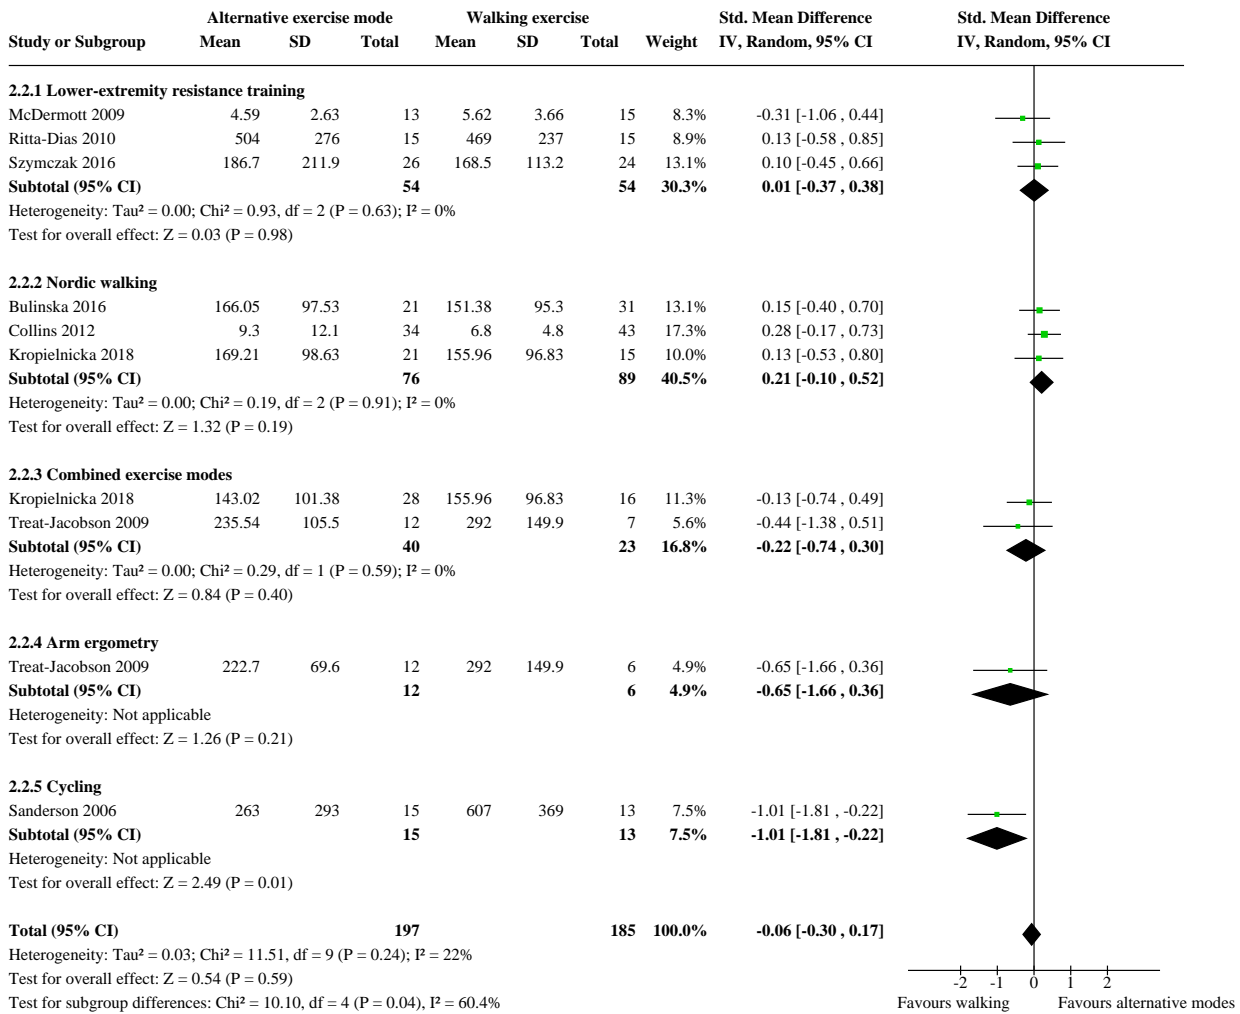

Outcome or subgroup title	No. of studies	No. of participants	Statistical method	Effect size
2.2.1 Lower-extremity resistance training	3	108	Std. Mean Difference (IV, Random, 95% CI)	0.01 [-0.37, 0.38]
2.2.2 Nordic walking	3	165	Std. Mean Difference (IV, Random, 95% CI)	0.21 [-0.10, 0.52]
2.2.3 Combined exercise modes	2	63	Std. Mean Difference (IV, Random, 95% CI)	-0.22 [-0.74, 0.30]
2.2.4 Arm ergometry	1	18	Std. Mean Difference (IV, Random, 95% CI)	-0.65 [-1.66, 0.36]
2.2.5 Cycling	1	28	Std. Mean Difference (IV, Random, 95% CI)	-1.01 [-1.81, -0.22]
2.3 Functional impairment (WIQ distance score)	2	96	Mean Difference (IV, Random, 95% CI)	-5.52 [-17.41, 6.36]
2.3.1 Lower-extremity resistance training	1	19	Mean Difference (IV, Random, 95% CI)	-14.00 [-36.64, 8.64]
2.3.2 Nordic walking	1	77	Mean Difference (IV, Random, 95% CI)	-2.30 [-16.26, 11.66]

Analysis 2.1. Comparison 2: Alternative modes of exercise versus walking exercise at the end of training, Outcome 1: Maximum walking distance

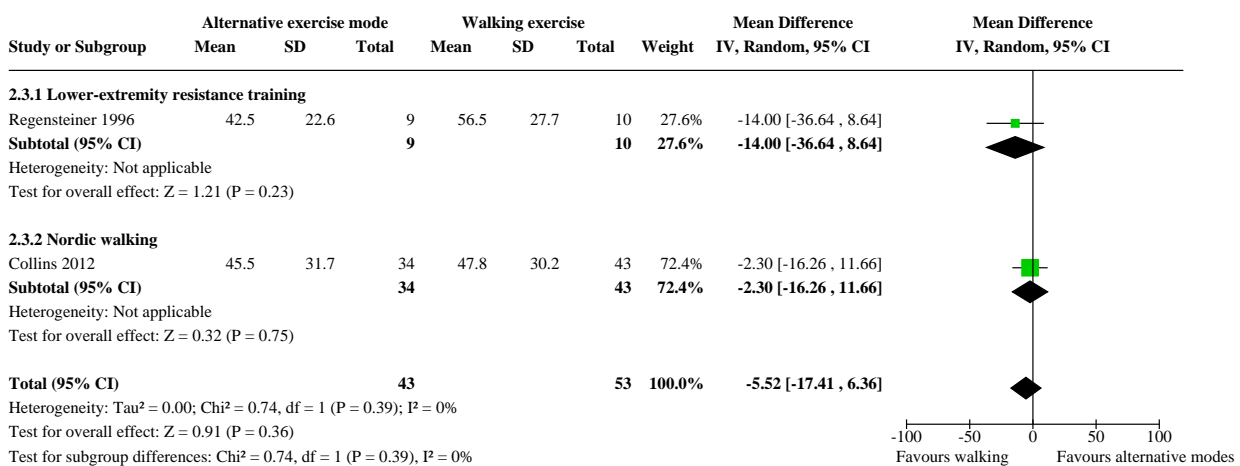

Favours walking Favours alternative modes

Analysis 2.2. Comparison 2: Alternative modes of exercise versus walking exercise at the end of training, Outcome 2: Pain-free walking distance

Analysis 2.3. Comparison 2: Alternative modes of exercise versus walking exercise at the end of training, Outcome 3: Functional impairment (WIQ distance score)

ADDITIONAL TABLES

Table 1. Glossary of abbreviations and definitions

Abbreviations	
CI	Confidence interval
HR-QOL	Health-related quality of life
IC	Intermittent claudication
MD	Mean difference
MWD	Maximum walking distance
PFWD	Pain-free walking distance
PAD	Peripheral arterial disease
RCT	Randomised controlled trial
SD	Standard deviation
SMD	Standardised mean difference
WIQ	Walking impairment questionnaire
Definitions	
Arm-ergometry	Ergometry is a heart rate increasing activity. In arm-ergometry, an arm ergometer is used (also referred to as an arm cycle or arm crank), which is an alternative to the treadmill or leg cycle.
Endothelial and mitochondrial dysfunction	This means that the endothelial cells and mitochondria do not function as well as they should due to a disease or condition. Endothelial cells form a thin layer that line the interior surface of blood vessels. Mitochondria lay within a cell and produce the energy necessary for the cell's survival and functioning.
Endothelial flow-mediated dilatation	Flow-mediated dilatation refers to dilatation (widening) of a blood vessel when blood flow increases in that vessel. This process is primarily regulated by endothelial cells, which form a thin layer that line the interior surface of blood vessels.
Metabolic adaptation	This is the process by which the body (e.g. the skeletal muscle) alters how efficient it is at obtaining energy and this increases capacity.
Pain tolerance	Pain tolerance is the maximum level of pain that a person is able to tolerate.
Vascular angiogenesis	This is the physiological process through which new blood vessels form from pre-existing vessels.

WHAT'S NEW

Date	Event	Description
29 October 2019	New citation required but conclusions have not changed	Searches updated. Five new studies included and two ongoing studies identified. Six new studies excluded. New authors joined team. Text updated to reflect current Cochrane standards including addition of 'Summary of findings' table. No change to conclusions.
29 October 2019	New search has been performed	Searches updated. Five new studies included and two ongoing studies identified. Six new studies excluded.

HISTORY

Protocol first published: Issue 2, 2012

Review first published: Issue 7, 2014

CONTRIBUTIONS OF AUTHORS

SJ: updated the protocol, selected relevant studies, assessed study quality, extracted data, performed data analysis, and wrote the text of this update.

UA: contributed to updating the protocol, selected studies, assessed study quality, extracted data, checked data for accuracy, and contributed to the text of the review.

GJL: contributed to updating the protocol, confirmed suitability of selected studies for inclusion, was consulted where disagreements occurred, checked data for accuracy, and revised the text of the review. In the previous version, he wrote the protocol, selected relevant studies, assessed study quality, extracted data, and wrote the review.

FF: contributed to updating the protocol, confirmed suitability of selected studies for inclusion, and revised the text. In the previous version, he contributed to the protocol, selected relevant studies, assessed study quality, and extracted data.

HF: contributed to updating the protocol, confirmed suitability of selected studies for inclusion, and revised the text. In the previous version, he contributed to the protocol and to the text of the review.

JT: contributed to the protocol, confirmed suitability of selected studies for inclusion, and contributed to the text of the review (both in the updated and previous version of the review).

DECLARATIONS OF INTEREST

SJ: none known

UA: none known

GJL: none known

FF: none known

HF: none known

JT: declares that he is Chairman of ClaudicatioNet, a network of specialised physiotherapists and foundation that implemented SET in the Netherlands

DIFFERENCES BETWEEN PROTOCOL AND REVIEW

For this update, in the [Types of interventions](#) section, 'Nordic walking' was added as an alternative mode of exercise. In the original protocol and review, studies comparing different types of walking exercise were not included, and Nordic walking was considered a different type of walking exercise. Recent publications have led to a different insight, as Nordic walking is different from standard walking because it uses a core-focused walking technique which engages the muscles of the arms and trunk to reduce the load on the legs during walking. Therefore, the criterion for not including studies was changed to 'different settings of walking exercise' (supervised versus unsupervised, community-based versus hospital), and Nordic walking was included as an alternative mode of exercise. In the [Data collection and analysis](#) section, a different method to analyse treatment effect was used in this update. In the case of different treadmill test protocols, the standardised mean difference approach was used for summary statistics. Therefore, it was no longer necessary to convert times or distances to metabolic equivalent of tasks (METs).

In the previous version, we altered the primary outcome from mean change in maximum or pain-free walking distance to a post-intervention maximum or pain-free walking distance. After extracting the data, most of the included trials only reported pre-intervention and post-intervention walking distances and their variances. No data on mean change were reported. Although calculating the mean change in walking distance from the pre-intervention and post-intervention data was possible, calculating a variance (standard deviation) of the mean change without having individual participant data was more challenging. To calculate a variance of the mean change from the reported summary pre-intervention and post-intervention variances, we needed at least the correlation between the pre-intervention and post-intervention variance ([Higgins 2019](#)), which was not reported. Furthermore, as we only included randomised trials and no significant difference in walking distance between the intervention and control group in each trial existed at baseline, we did not have any indication that our main outcome, the mean difference in post-intervention walking distance between the intervention and control group might be biased. We changed the P value that was considered statistically significant in case of heterogeneity from 0.05 in our protocol to 0.10 in our full review. In the [Background](#), we adjusted the description of the systematic review by Parmenter and colleagues ([Parmenter 2011](#)) after they contacted us and added why no meta-analysis was performed in this systematic review.
