Transition to use of SDs after evacuation of CSDHs

# Transition of a clinical practice to use of subdural drains after burr-hole evacuation of chronic subdural haematomas: The Helsinki experience

## Abstract

**Background** A number of randomised controlled trials have shown the benefit of drain in operative treatment of chronic subdural haematomas (CSDHs). However, few reports describe real life result when adopting the drain placement into clinical practice. We report the results following a change in practice at Helsinki University Hospital from no drain to subdural drain (SD) placement after burr-hole craniostomies for CSDHs.

**Methods** We conducted a retrospective observational study including consecutive patients undergoing burr-hole craniostomies for CSDHs. We compared outcomes between a six-month time period when the SD placement was arbitrary (July to December 2015) and a time period when SD placement for 48 h was routine (July to December 2017). Our primary outcome of interest was recurrences requiring reoperation within six months. Furthermore, patient outcome, infections and other complications were assessed.

**Results** A total of 161 patients were included, of which 71 (44%) were in the SD group and 90 (56%) in the non-drain group. There were no differences in age, comorbidities, history of trauma or use of antithrombotic medication between the groups ( $p>0.05$ ). Recurrences within six months occurred in 18% of patients in the non-drain group compared to 6% in the SD group ( $p=0.028$ ; OR 0.28; 95% CI 0.09-0.87). There were no differences in neurological outcome ( $p=0.72$ ), mortality rate ( $p=0.55$ ), infection rate ( $p=0.96$ ) or other complications ( $p=0.20$ ).

**Conclusions** The change in practice from no drain to SD after burr-hole craniostomies for CSDHs effectively reduced the six-month recurrence rate without any effect on patient outcome, infections or other complications.

Transition to use of SDs after evacuation of CSDHs

ACCEPTED MANUSCRIPT

## Introduction

The incidence of chronic subdural haematomas (CSDHs) ranges from 1.7 to 18 per 100,000 people. In patients older than 65 years, this rate increases to 58 per 100,000 people, making CSDHs one of the most common neurosurgical conditions.<sup>1,2</sup> Most physicians would agree that nonsurgical treatment is recommendable with asymptomatic patients who have small CSDHs.<sup>3</sup> For symptomatic CSDHs, burr-hole evacuation has become the most preferred treatment method,<sup>4,5</sup> as it results in rapid resolution of the symptoms and a short period of hospitalisation. Other surgical options, such as using two burr-holes, twist drill craniostomy or even craniotomy in selected patient population have been used to treat CSDHs.<sup>2,3</sup>

Up to date, there is a lack of consensus regarding the most optimal surgical technique.<sup>6</sup> Even among Scandinavian centres, surgical techniques differ.<sup>7</sup> The recurrence rates vary from 3% to 33% and may depend on both treatment- and patient-related factors.<sup>8-11</sup> Many studies indicate that the recurrence rate is most effectively reduced by placing either a subdural or subgaleal drain.<sup>12-16</sup> In a randomised controlled trial (RCT) by Santarius et al.,<sup>16</sup> the placement of a subdural drain (SD) after burr-hole evacuation reduced the rate of recurrence from 24% to 9%.

Although the use of a drain has been reported to reduce recurrence rates, some studies still dispute this.<sup>11,17</sup> However, numerous questionnaire surveys indicate that there is an evidence-practice gap in the usage of drains, as not all neurosurgeons place them regularly.<sup>4,18-22</sup> Despite reported evidence supporting the benefits of drain placement, drain usage in everyday practice within the neurosurgical department of Helsinki University Hospital was arbitrary until, on April 1, 2017, consistent management of CSDHs with subdural drains was established in our clinic.

Due to the stricter inclusion and exclusion criteria of RCTs, the benefits of drain usage as shown by such trials may not necessarily reflect the real clinical setting.<sup>23</sup> Still, there is a need for real-life observational studies to confirm results from RCTs.<sup>24</sup> Thus, our aim was to assess whether the change of clinical practice to start using subdural drains had translated into a lower recurrence rate. Specifically, our primary goal was to confirm if patients treated with postoperative drains experienced lower recurrence rates compared to patients not receiving

drains. The secondary aim was to compare the changes in haematoma size, complications and patient outcome.

## Material and methods

### Ethical considerations

The ethics committee of Helsinki University Hospital approved the study and waived the need for informed consent (HUS 1799/2018).

### Study setting and data collection

On April 1, 2017, the use of subdural drain after burr-hole craniostomy for CSDH evacuation became routine at our clinic. Thus, to assess the effect of subdural drain usage on six-month recurrence risk, we chose time periods to represent the pre-drain era (July to December 2015) and the drain era (July to December 2017). During these time periods, we assessed all patients who underwent operations for CSDHs at the Department of Neurosurgery at Helsinki University Hospital. The non-drain group included patients from the pre-drain era and from this group, we excluded all patients that were treated with a drain. The subdural drain group included patients from the drain era and from this group, we excluded those not treated with a subdural drain and those treated with another type of drain than a subdural drain. We excluded patients who had undergone previous intracranial operations for any reason, as well as those with shunts for cerebrospinal fluid diversion or subdural haematomas treated with other methods (subgaleal drain or IRRFlow catheter). (**Figure 1**)

All data concerning patients' medical history, imaging and treatment is stored in Helsinki University Hospital's electronic health records (EHRs). We retrospectively reviewed and analysed patients' EHRs and their pre- and postoperative head computerised tomography (CT) scans or brain magnetic resonance images (MRIs). From EHRs, we obtained patients' baseline and follow-up data concerning mobility and morbidity, history of head trauma during the preceding 12 months, most prominent symptom causing disability to the patient, modified Rankin scale (mRS) scores,<sup>25</sup> medical history and existence of limb weakness or dysphasia. To ensure coherency, a single investigator assessed all clinical data.

Two senior neurosurgeons analysed all the imaging data from CT and MRI scans. We defined the subdural collection as predominantly hypodense, isodense or mixed by comparing the density of the collection to the adjacent brain.<sup>26</sup> We also measured the maximum transition of the anatomical midline structures from the midline and determined the midline shift. On bilaterally operated haematomas, we recorded which side caused the midline shift. Further, we measured the width, length and height of the collection and, using formula  $ABC/2$ ,<sup>27</sup> assessed the volume of the haematoma. The CSDH volume reduction was analysed by comparing pre- and postoperative CT or MRI images. We also recorded the extent of basal cistern effacement, patency of cortical sulci and presence of contusions.

## Burr-hole craniostomy procedure

As a routine, all burr-hole craniostomies at Helsinki University Hospital are performed under local anaesthesia, often combined with intravenous sedation with benzodiazepines and/or opioids during the operation. Here, general anaesthesia is used only if the neurosurgeon or the anaesthesiologist considers it unsafe to perform the procedure under local anaesthesia (applicable to only one patient in the current cohort). Typically, the surgeon drills one 14-mm burr-hole over the maximum convexity of the haematoma. In the case of an expansive bilateral haematoma, the surgeon operates on both sides. After opening the dura, the surgeon washes the subdural collection with warm (body temperature) Ringer's lactate saline until rinsing appears clear. The operating surgeon decides whether or not to insert a subdural drain. The subdural drain used in this study was Spiegelberg Ventricular Catheter 10F (NeoNordic, Odense, Denmark), made of radiopaque polyurethane (length 270 mm, inner diameter 1.9 mm and outer diameter 3.3 mm). The surgeon tunnels the drain under subgaleal skin approximately 5 cm from the incision, and it is linked to a ventricular drainage bag with a connector. The drainage bag is positioned at bed level and routinely removed after 48 h. We do not use postoperative prophylactic antibiotics routinely.

In 2015, drain usage was not mandatory in our clinic, and the use of subdural and subgaleal drains was sporadic. At the beginning of 2017, a new administrative guideline was enforced, and usage of subdural drains became a requirement except in cases where the surgeon believes drain usage would compromise the patient's safety. Subdural drains are routinely left in place for 48 h. We allow patient mobilisation during drain treatment.

## Follow-up and outcome measures

Approximately four to six weeks postoperatively, follow-ups were completed with all operated patients in the Helsinki Metropolitan Area at an outpatient clinic. For patients living outside of this area, a recommendation for follow-up was made to their local hospitals. For the follow-up, a routine head CT was recommended. If the residual haematoma or the patient's symptoms required further assessment, the patient was invited monthly for further follow-ups until the collection or symptoms resolved.

Our primary outcome was CSDH recurrence requiring reoperation within six months. Since no other institution performs intracranial operations in the catchment area of Helsinki University Hospital, all patients requiring reoperation are referred to this hospital. We consider reoperation in the case of a new CT scan-verified CSDH, with recurrent neurological symptoms or with a recurrent haematoma of similar or larger size compared to the primary CSDH.

Our secondary outcomes included neurological outcome within seven days and at six months after the primary operation (measured by the mRS), 30-day and six-month mortality, length of stay in the neurosurgical ward, postoperative infections and other complications. A favourable postoperative neurological outcome was defined as mRS 0 to 3, and an unfavourable outcome as mRS 4 to 6. We also recorded all postoperative complications and determined whether they were related to the operation. Further, we obtained dates of deaths through the Finnish Population Registry (available to all Finnish citizens).

## Statistical analyses

We compared categorical variables by using a chi-square test, adjusting the Bonferroni method when appropriate and using Fisher's exact test when appropriate. We tested continuous variables for normality with the Shapiro-Wilk test and thereafter used the Mann-Whitney U test to compare nonparametric data and a t-test to compare normally distributed data. Testing was also completed to find any differences in baseline characteristics between patients in the subdural drain and non-drain groups. To identify associations between variables and the risk of recurrence within six months, binary logistic regression analysis was employed, with adjustments made for differences in baseline characteristics between the

groups (reported as odds ratios [OR] and 95% confidence intervals [CI]). We used Kaplan-Meier curves to show differences in time to recurrence within six months between patients treated with a subdural drain and those treated with no drain. We considered p-values under 0.05 to be statistically significant. We also performed a post-hoc logistic regression analysis assessing the association between drain and recurrence within six months, adjusting for age, sex, preoperative neurological deficit and use of antithrombotic medication. All analyses were done using SPSS 25.0 for macOS (IBM Corp, Armonk, NY, USA).

## Results

### Baseline characteristics

We included a total of 161 patients in our study (**Figure 1**). There were no significant differences in baseline characteristics between patients treated with subdural drains and those treated with no drain (**Table 1**). Similarly, no substantial differences could be observed between patients treated in 2017 with subdural drains and those treated in 2017 without drains (**Supplementary table 1**). The only significant baseline finding was that patients in the subdural drain group had thicker haematomas (median 23 mm vs. 20 mm;  $p=0.007$ ) (**Table 2**).

The reasons for not inserting a subdural drain in 2017 were immediate brain expansion (N=11), membrane loculations (N=3), antithrombotic treatment (N=2), infection (N=1), head wound operation (N=1) and a surgeon's statement that inserting a drain would be unsafe (N=1).

The main presenting symptoms are shown in **Figure 2**. Altogether, 53% of patients had a motor deficit presented as gait disturbance or limb weakness.

### Recurrence rate of CSDHs

The six-month recurrence rate of CSDHs was 6% (N=4/71) in the subdural drain group and 18% (N=16/90) in the non-drain group ( $p=0.028$ ). As there were no differences in patient baseline characteristics between the groups, we assessed the association between use of drain and risk of recurrence within six months using univariable logistic regression analyses.

Subdural drain usage was associated with an OR of 0.28 (95% CI 0.09-0.87) for recurrence within six months compared to no drain. Among unilateral CSDHs, the six-month recurrence rate was reduced from 17% (N=12/72) in the non-drain group to 5% (N=3/55) in the drain group (p=0.06). Among bilateral CSDHs, the six-month recurrence rates were 22% in the non-drain group (N=4/18) and 6% in the drain group (N=1/16) (p=0.22). All recurrences were treated by burr-hole craniostomy. (**Table 3**)

The results of our analysis of factors possible associated with six-month recurrence of CSDHs are displayed in **Table 4**. Apart from subdural drain usage, there were no other risk factors significantly associated with recurrence. In the post-hoc logistic regression analysis, adjusting for age, sex, preoperative neurological deficit and use of antithrombotic medication, the use of subdural drain still independently associated with a reduced risk of six-month recurrence (OR 0.27; 95% CI 0.08-0.85; p=0.025).

Prior to the diagnosis of a CSDH, 66% of patients (N=107/161) were on some type of antithrombotic medication. Preoperative use of antithrombotic medication did not associate with recurrent CSDHs. Postoperatively, antithrombotic medication was restarted prior to the first control (four to six weeks after operation) in 28% of patients (N=29/102), 17% (N=5) of which had a recurrent CSDH. Of the five patients, one was treated with a subdural drain and four were treated without one in the primary operation.

**Figure 3** shows a Kaplan-Meier curve of differences in time to six-month recurrence and risk of six-month recurrence between patients in each group. Notably, the risk of recurrence was highest in the first 30 days following the procedure, after which it remained low throughout the follow-up period.

## Secondary outcomes

There were no significant differences between the groups regarding immediate postoperative mRS (p=0.85), six-month mRS (p=0.72), 30-day mortality (p=0.14), six-month mortality (p=0.55), hospital length of stay (p=0.17), need for further care (p=0.56), infections within 30 days (p=0.85) or within six months (p=0.96) or other complications (p=0.20). (**Table 3**) Of all secondary outcomes, only volume reduction differed significantly between the subdural

and non-drain groups (mean volume reduction 70% vs. 50%;  $p=0.005$ ). Postoperative infections and other complications are shown in detail in **Supplementary table 2**. All complications were diagnosed within seven days postoperatively. Noticeably, there were no wound infections, meningitides or intracranial empyemas.

## Discussion

In our study, we showed that the transition to consistent use of subdural drains after burr-hole craniostomies for CSDHs in a real-life clinical setting (Helsinki University Hospital) reduced the six-month recurrence rate from 18% to 6% without any increase in infections or complications. Subdural drain usage did not affect patient outcome, but did correspond with a notable decrease in CSDH volume. Furthermore, we showed that CSDH recurrence often happens within the first 30 days after treatment, following which the risk of recurrence is low. Our findings are well in line with recurrence rate reductions reported in numerous RCTs.<sup>16,28–30</sup>

Our findings indicating the predominance of aged patients and those with a recent history of head trauma (81%), as well as a sex ratio in favour of male (68%), are in line with previous reports.<sup>31–34</sup> CSDHs are common in elderly patients and have a major impact on their independence. Many authors have reported a high rate of functional dependency, even in operated patients.<sup>31,33,35</sup> In a report by Leroy et al., the age threshold of 75 years was associated with an unfavourable functional outcome.<sup>33</sup> In our study, the patients' median age was 78 years in the subdural drain group and 77 years in the non-drain group. Prior to diagnosis, 75% of our patients had been walking independently, and 70% of the drain group and 78% of the non-drain group were living independently. Six months after treatment, only 80% had recovered to walk independently. In our study, we were unable to reproduce the reduction of mortality rate by drain usage reported by Santarius et al.<sup>16</sup> Furthermore, in our study only 64% of patients recovered to good mRS, as compared to 84% reported by Santarius et al. These differences may be due to the fact that the patients in our study were slightly older than in the report by Santarius et al. therefore having more morbidity and a higher need for assistance.

The use of antithrombotic medication is a pressing issue in patients with CSDHs. In recent meta-analysis,<sup>36</sup> both anticoagulation and antiplatelet therapy had higher risks of recurrence.

In our study, two-thirds of patients were on some sort of antithrombotic medication. We did not find any association between preoperative use of antithrombotic medication and recurrence risk. Further, antithrombotic medication was restarted prior to the first follow-up (four to six weeks postoperatively) in 28% of the users, only 17% of which had a recurrent CSDH requiring reoperation. The number of recurrences in the antithrombotic users was too low to allow for any more detailed statistical analysis. Still, these low numbers suggest that excessive caution regarding restarting of antithrombotic medication after CSDH evacuation may not be as warranted as previously thought. However, more studies are needed on this topic.

Our results were derived from retrospective analysis, which is prone to well-known limitations. Therefore, caution is advised in interpreting them. As mentioned, in the Helsinki catchment area, all patients in need of reoperation are sent to Helsinki University Hospital, since it is the only institution in the region that performs such operations. Therefore, we were able to obtain complete data in terms of six-month recurrence and mortality rates. Furthermore, six months of follow-up data was obtained for 79% of patients in terms of mRS, 76% in terms of mobility and 75% in terms of infection rates.

In the operative management of CSDHs, there are still numerous unsettled intra- and postoperative factors that contribute to the outcome. At Helsinki University Hospital, we routinely perform the procedures under local anaesthesia, while some institutions favour general anaesthesia.<sup>16</sup> We typically use one burr-hole, while some centres prefer two.<sup>37</sup> We use subdural drains rather than other drainage methods, i.e. active subdural drains, drains with continuous irrigation and drainage or subgaleal drains. No one method has been shown to be superior to another.<sup>7,9,15</sup> We use intraoperative irrigation until fluid is clear. Some studies indicate that irrigation results in a better outcome,<sup>9</sup> while others show that there is no disadvantage to placing a drain without irrigation.<sup>5,38,39</sup> We keep the drain in place for 48 h, although elsewhere, the use of 12- to 18-h drainage has been reported.<sup>7</sup> We allow patient mobilisation during drain treatment, while some opt for bed rest.<sup>11,40</sup>

Although we observed a reduction in recurrences within six months after beginning to use subdural drains, it is important to note that there are several factors related to perioperative treatment that may affect the risk of recurrence. Evidence in favour of drain usage is ever

more convincing; however, there is still a need for further research in the field of treatment of CSDHs.

## Conclusions

Subdural drain usage after burr-hole craniostomies for CSDHs has been shown to significantly reduce the risk of recurrence without affecting patient outcome, infections or complications. More research is required to identify other treatment-related factors that might further reduce this risk.

## Compliance with ethical standards

**Funding** This research did not receive any specific grant from funding agencies in the public, commercial or not-for-profit sectors.

**Declarations of interest** None.

**Ethical approval** All procedures performed in studies involving human participants were in accordance with the ethical standards of the institutional and/or national research committee and with the 1964 Helsinki declaration and its later amendments or comparable ethical standards.

**Figure captions**

**Figure 1.** Flow chart displaying the inclusion and exclusion criteria and the formation of study groups

CSDH chronic subdural haematoma, SIH spontaneous intracranial hypotension

**Figure 2.** Most prominent symptom causing disability to the patient

**Figure 3.** Kaplan-Meier curve showing differences in time to six-month recurrence and risk of six-month recurrence between patients in the subdural drain and non-drain groups. Of patients in the non-drain group, 18% had a recurrence, most often occurring within the first 30 days following treatment. Of patients in the subdural drain group, 6% had a recurrence.

Data are n/N (%), median (IQR) or mean (SD). Odds ratios are calculated for binary outcomes using logistic regression. An odds ratio under one indicates that subdural drain is associated with a lower probability for the specific outcome and vice versa. \*Postoperative complications included cerebral infarction, intracerebral haemorrhage, wound bleeding, epileptic seizure, unintended drain removal, cardiac failure, pulmonary embolism and epidural haematoma. †Postoperative infections included urinary tract infection, pneumonia, soft tissue infection, shingles, upper respiratory infection, erysipelas, gastroenteritis and non-specific infection. ‡Excluding patients dying before six months. §Missing for 44/161 (27%) patients. ¶Calculated using a non-parametric Mann-Whitney U test.

OR odds ratio, CI confidence interval, CSDH chronic subdural haematoma, mRS modified Rankin scale, NA not applicable

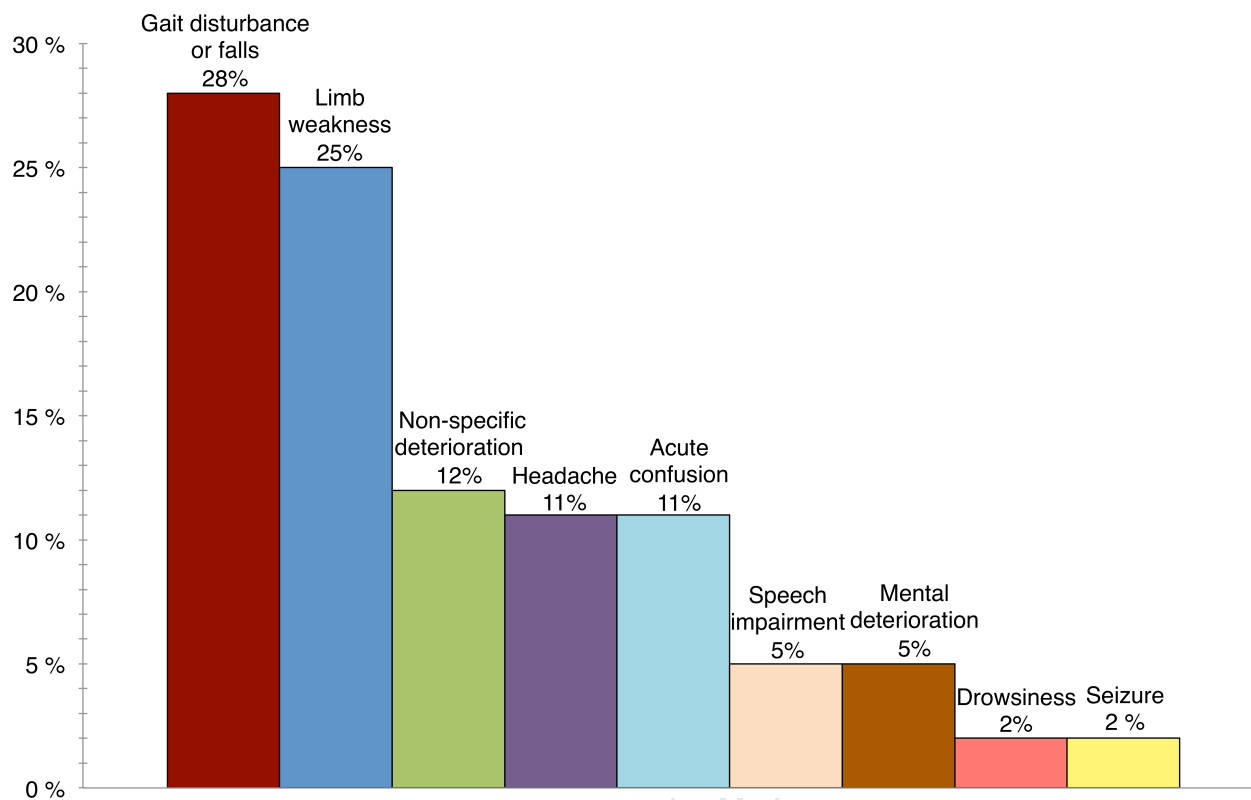

**Table 4** Factors associated with recurrence of chronic subdural haematomas requiring reoperation within six months

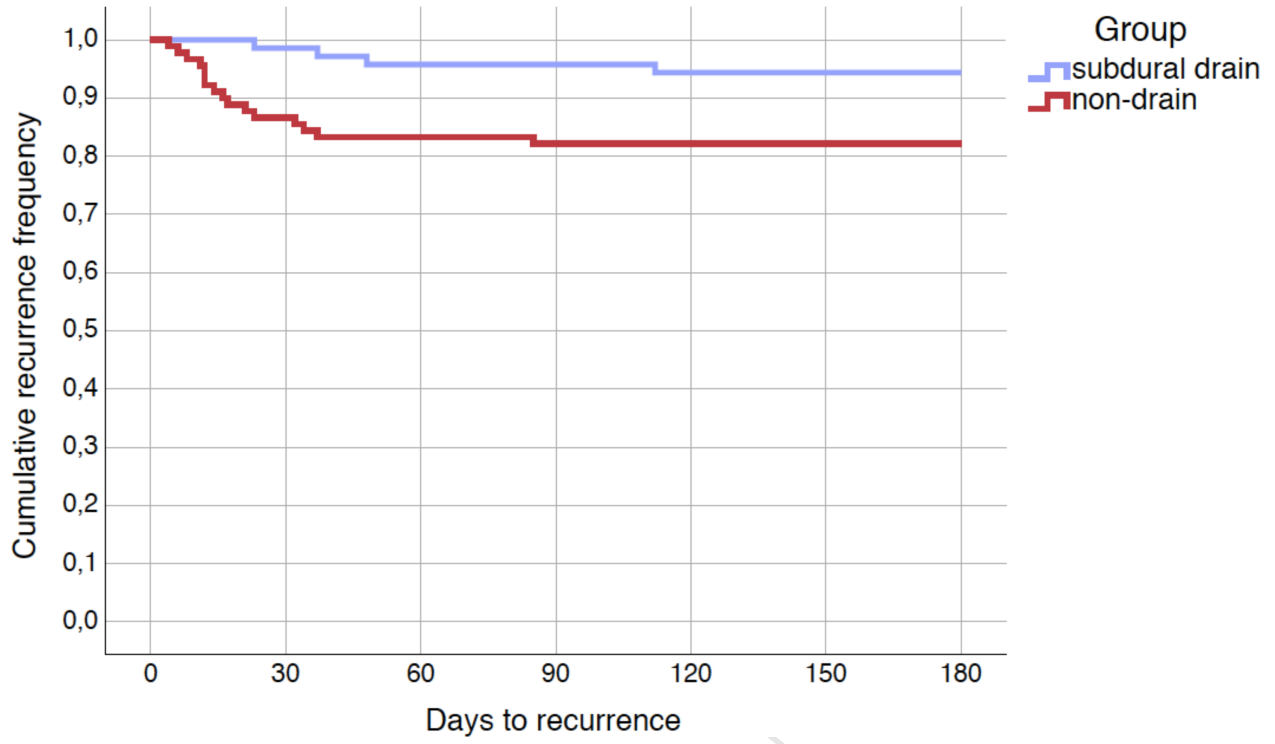

| Variable  | No recurrence<br>(N = 141) | Recurrence<br>(N = 20) | OR (95% CI)      | p-value |
|---|----------------------------|------------------------|------------------|---------|
| Age (years), median (range)                     | 78 (46-95)                 | 77 (56-90)             | 0.98 (0.94-1.02) | 0.33    |
| Neurological deficit (hemiparesis or dysphasia) | 60%                        | 45%                    | 0.54 (0.21-1.38) | 0.20    |

**Article title:** Transition of a clinical practice to use of subdural drains after burr-hole evacuation of chronic s

**Journal name:** World Neurosurgery

**Authors:** Pihla Tommiska, Kimmo Lönnrot, Rahul Raj, Teemu Luostarinen, Riku Kivisaari

**Corresponding author:** Pihla Tommiska; Department of Neurosurgery, University of Helsinki and Helsinki

## Abbreviations and acronyms

**CI** confidence interval

**COPD** chronic obstructive pulmonary disease

**CSDH** chronic subdural haematoma

**CT** computerised tomography

**DOAC** direct oral anticoagulant

**DVT** deep venous thrombosis

**EHR** electronic health record

**LMWH** low-molecular-weight heparin

**MRI** magnetic resonance imaging

**mRS** modified Rankin scale

**OR** odds ratio

**PE** pulmonary embolism

**RCT** randomised controlled trial

**SD** subdural drain
