22 ABSTRACT

23 Chemical changes in leaf input to forest soils have been reported to affect decay processes.

In this work, litter mass loss and decomposition constants (k) during 200 days in solid-state 24 25 fermentation of the native tree *Celtis tala* and the exotic one *Ligustrum lucidum* with three common litter saprotrophic basidiomycetes were compared. Alterations in litter quality 26 were characterized by solid-state ¹³C NMR spectroscopy, pH, soluble sugars, ammonium, 27 proteins and phenol content determination, and were associated with extracellular 28 lignocellulolytic enzyme production. Differences in substrate decomposition related to litter 29 type were observed for *Leratiomyces ceres*, achieving a higher k in the exotic L. lucidum 30 litter, which might be attributed to the induction of Manganese peroxidase activity. 31 Substrate preference for alkyl C and more degradation of lignified compounds were found 32 33 in such substrate. Although no statistical differences in mass loss were observed for the rest of the fungi assayed, we detected changes in several of the parameters evaluated. This 34 suggests that exotic invasions may alter ecosystem functioning by accelerating 35 36 decomposition processes through an increased fungal ligninolytic activity.

40 Introduction

Invasion of exotic plants in pristine terrestrial ecosystems is a major environmental 41 42 problem due to alterations in the vegetal community with the consequent detrimental impact on the activity of resident organisms (Pyšek et al. 2012). Plant-litter provides the main contribution 43 of biomass and energy in several environments such as forests, where the substrate quality 44 45 strongly influences microbial composition and its related activity in soils (Hättenschwiler et al. 2005; Wardle et al. 2004). Nevertheless, there are scarce data about the effect of the input of 46 senescent leaves from invasive plants on decomposition and humification processes associated 47 with enzyme activity in soils. 48

Different decay rates among organic matter kept under identical environmental 49 50 conditions are mostly associated with changes in the content of its major chemical constituents such as nitrogen, lignin and polyphenol, as well as the relative contribution of carbon: nitrogen 51 and lignin: nitrogen (Wardle et al. 2004). Leaf litter consists mainly of polysaccharides cellulose 52 and hemicellulose and aromatic polymer lignin, the latter being considered as the most 53 54 recalcitrant. Fungi are the dominant decomposers in temperate and boreal forest soils (Hättenschwiler et al. 2005) and among fungi, saprotrophic basidiomycetes are capable of 55 producing a wide variety of extracellular oxidoreductases and hydrolytic enzymes that allow 56 them to degrade all these three litter components (Purahong et al. 2014). This study was carried 57 58 out with the aim of comparing the abilities of saprotrophic basidiomycetes in decomposition of leaf-litter of both native and invasive plants, based on the hypothesis that litter quality modifies 59 the lignocellulolytic activity of these fungi and may greatly influence litter decomposition rates. 60

Pereyra Iraola Park is a Biosphere Reserve declared as such by UNESCO in 2007,
located in Buenos Aires Province, Argentina. It constitutes the largest green space (10,248)

hectares) of the metropolitan area of the City of Buenos Aires and La Plata, acting as a "green 63 64 lung" for the urban conglomerate. The area has mixed zones belonging to relictual patches of 65 marginal forest, locally known as Selva Marginal, and forested sites with a noteworthy introduction of exotic species. The former is confined to the coastal strip of the De la Plata river 66 and is considered as a reservoir of an extensive spectrum of biodiversity, on the southern limit of 67 68 distribution of subtropical forests in South America (Kalesnik et al. 2013). While Celtis tala Gill. ex Planch. (Cannabaceae) is a typical native tree in the Reserve, Ligustrum lucidum Ait. 69 (Oleaceae), also known as Glossy privet, it is in fact a monodominant canopy tree native to 70 China, which has increased its coverage in the region since it was imported for ornamental 71 purposes. In heavily invaded stands, L. lucidum can exceed 80% of the tree cover, while 72 elsewhere, it is distributed as solitary individuals adjacent to native trees (Aragón and Groom 73 2003; Gavier-Pizarro et al. 2012). L. lucidum is tolerant to a wide range of soils and light 74 75 conditions and, in addition to vegetative reproduction it produces a large number of seeds, which 76 are readily dispersed by birds. These features contribute to making L. lucidum a successful invader with a broad representation at ecosystem level (Marano et al. 2013). Previous studies 77 indicated that it influences the species composition and reduces the diversity in invaded plant 78 79 communities (Lichstein et al. 2004). The aggressive invasion of L. lucidum was reported to be an important issue in other countries such as Australia and New Zealand (Cronk and Fuller 1995). 80 81 However, the influence of L. lucidum senescent leaves on the decomposing activity of litter 82 saprotrophic basidiomycetes and their role in litter degradation are still unraveled.

The objectives of this work were (i) to evaluate how chemical composition of leaf litter affects mass loss and production of lignocellulolytic enzymes by litter saprotrophic basidiomycete's cultures during solid-state fermentation (SSF) and (ii) to assess if fungi have a substrate preference for decomposing native *Celtis tala* or exotic *Ligustrum lucidum* litter by
comparing their decomposition constants under SSF.

88 Materials and Methods

89 Fungal isolates and identification

90 Fresh basidiomata were collected in the Natural Reserve Pereyra Iraola Park in Buenos Aires Province, Argentina (34°84'S 58°10'W), during the summer of 2014. Marasmiellus 91 92 candidus, Leratiomyces ceres and Marasmius haematocephalus were classified based on the 93 morphological characteristics of their basidiomata. These fungi were selected because they were frequently found in both litter assayed (Mallerman 2017). To confirm the identities of fungal 94 isolates, total DNA was extracted from agar cultures with the Microbial DNA Kit (MoBio, USA) 95 and then used for PCR amplification (ABI 3130xl Genetic Analyzer). Amplification reactions 96 used the universal fungal-primers ITS1 (5'- TCCGTAGGTGAACCTGCGG -3') and ITS4 (5'-97 TCCTCCGCTTATTGATATGC -3') for the ribosomal DNA region (White et al. 1990). The 98 PCR products separated through electrophoresis in 1.5% agarose gel were sent to a sequencing 99 100 facility (University of Buenos Aires). Sequences obtained were analyzed using BLAST, 101 compared for homologous NCBI-GenBank database and deposited under the accession numbers: KX423791 (Leratiomyces ceres), KX423792 (Marasmius haematocephalus) and KX423793 102 (Marasmiellus candidus). For fungal isolation, a sterile piece of mushroom tissue was collected 103 104 from the interior of each basidiomata, transferred onto Petri dishes containing 20 mL of malt extract agar medium (MEA: malt extract 1.2%, glucose 1% and agar 2%) and grown at 25°C, in 105 106 darkness. Strains were maintained at 4°C on MEA slants by periodic transfers and specimens 107 were preserved in the culture collection of Natural and Exact Science Faculty, University of 108 Buenos Aires, Argentina (BAFCcult).

109

Litter decomposition under SSF conditions

110 Ligustrum lucidum and Celtis tala senescent leaves (just before abscission) were 111 collected from several individuals in the studied area during the summer of 2014. Litter was air-112 dried at room temperature and stored at 4°C before use. At the beginning of the experiment, leaves were cut into smaller pieces (size > 20 mm) and approx. 2.5 g were placed in 125 mL 113 114 Erlenmeyer flasks. To calculate the initial litter dry mass, flasks were oven-dried at 80°C until constant weight. The litter was moistened with 20 mL of distilled water, autoclaved for 20 min at 115 120°C, and inoculated with two 0.6-cm diameter MEA mycelial plugs, taken from the margin of 116 an actively growing colony. Cultures were incubated at 25°C in darkness, sampling them every 117 30 days, performing the last on day 200. Non-inoculated flasks served as controls and to estimate 118 water loss during the incubation period, in which sterile water was replenished every time a 119 sample was taken. Three replicates per treatment were conducted (3 fungi and 1 control x 2 litter 120 x 3 replicates x 6 sampling times). Decomposition constant (k) was estimated by calculating the 121 122 percentage of dry mass remaining after each culture incubation period (percentage reduction of inoculated litter in relation to the uninoculated one), using a single exponential decay model 123 (Olson 1963): $M_t = M_0 \cdot e^{-kt}$; where M_0 is the initial dry mass, M_t is the dry mass remaining at 124 time t, k is the decomposition constant and t is time. 125

Chemical composition of the water soluble and solid fractions from litter 126

127 On each sampling time, a water soluble fraction (WSF) and a solid fraction (SF) were 128 obtained from both uninoculated and fungal transformed litter, according to Saparrat et al. 129 (2008). For this, the content of each flask was mixed on a rotary shaker at 150 ppm for 1 h with 20 mL of distilled water, filtered through gauze and centrifuged for 10 min at 5000 × g, 4°C. 130 Supernatants conformed the WSF, while the SF consisted of the resulting pellet collected 131

together with the material retained in the gauze. Dry mass content was measured in the SF by
oven-drying at 80°C until constant mass (Saparrat *et al.* 2008).

In the WSF, the extracellular proteins were assessed using the Bradford (1976) method with the BioRad protein assay reagent (Bio-Rad, Hercules, CA) and bovine serum albumin (BSA) as standard protein. Ammonium-N was determined following the protocols of Beecher and Whitten (1970). Free phenolic water-soluble compounds were extracted according to Box (1983) and Folin-Ciocalteu reagent was used for analysis of total phenolic content, being results expressed as phenol equivalents.

The chemical composition of the SF was analyzed by Cross-Polarization Magic-Angle 140 Spinning ¹³C Nuclear Magnetic Resonance (¹³C CPMAS NMR) procedure. The ¹³C CPMAS 141 NMR spectra were obtained using a 7T Bruker Avance II-300 spectrometer (Bruker Instruments 142 Inc., Germany). Litter samples were dried and ground by a 4-mm zirconium rotor and spun at 143 magic angle at 10 kHz. All the solid-state NMR experiments were performed at room 144 temperature. ¹³C CPMAS NMR was performed with a ramped ¹H pulse during a contact time of 145 3 ms to obtain the best signal-to-noise ratio. ¹H decoupling was performed during the acquisition 146 with a TPPM15 sequence to improve the resolution. Recording 1 K transients with a recycle time 147 of 3 s represented standard conditions. The operating frequencies for protons and carbons were 148 300.13 and 75.46MHz, respectively. Glycine was used as an external reference for the 13 C 149 spectra and to set the Hartmann-Hahn matching condition in the cross-polarization experiments. 150 Because of the substantial amount of instrument time required, only samples of the initial and 151 ending decomposition time (200 days) were analyzed. Relative areas were calculated as the 152 percentage of total intensity from the integral curves of the following carbon chemical-shift 153 regions: alkyl C (0-45 ppm), O-alkyl C (45-110 ppm), methoxyl C (50-60 ppm), aromatic C 154

155 (110-140 ppm), phenolic C (140-160 ppm), and carboxyl C (160-190 ppm). Deconvolution method of the NMR spectra was performed using the DmFit software (Massiot et al. 2002). The 156 degree of humification was calculated as the ratio between the corresponding areas (A) of the 157 spectra alkyl C to O-alkyl C (Baldock et al. 1997). The alkyl C to carboxyl C ratio was 158 calculated according to Knicker *et al.* (2000). The aromaticity index (AI) was considered as AI =159 160 100 (A (110-160 ppm) /A (0-160 ppm)) (Lorenz et al. 2006). Finally, the lignin content was estimated according to Haw et al. (1984) as: % lignin = (100%) (183/9.92) 1' lig / ((183/9.92) 1' 161 lig + (162/6) l' carb). The weighting element in this calculation is the ratio of formula weights 162 for lignin and carbohydrate fractions to the number of carbon atoms in the average formulas 163 assumed for their repeating units [for more details see Haw et al. (1984)]. 164

165 Enzyme activities in the WSF

In order to understand the role of enzymes related to the degradation of the main 166 structural litter components: cellulose, hemicellulose and lignin along time, we evaluated the 167 activity of β -1,4-endoglucanase, β -glucosidase, β -1,4-endoxylanase, laccase and MnP. β -1,4-168 endoglucanase (EC 3.2.1.4), cellobiohydrolase (EC 3.2.1.91) and β -1,4-endoxylanase (E.C. 169 3.2.1.8) activities were estimated by measuring the reducing sugars released from 170 carboxymethylcellulose, crystalline cellulose or beechwood xylan, respectively, as substrates in 171 50 mM sodium acetate buffer, pH 4.8. Liberated reducing sugars were quantified by the DNS 172 method (Miller 1959) using either glucose or xylose as standards. β-glucosidase (E.C 3.2.1.21) 173 activity was determined in 50 mM sodium acetate buffer, pH 4.8, by measuring p-nitrophenol 174 released from p-nitrophenyl-β-D-glucopyranoside (Wood and Bhat 1988). All enzyme activities 175 176 were determined at 50°C. Laccase (EC 1.10.3.2) activity was measured by the oxidation of 5 mM 2,6-dimethoxyphenol (DMP) in 0.1 M sodium acetate buffer (pH 3.6), assessing the increase in 177

absorbance at 469 nm ($\varepsilon = 27.5/\text{mM}$ cm) (Ben Younes *et al.* 2007). The MnP activity (EC 1.11.1.13) was assayed by the oxidation of phenol red in 0.2 M sodium succinate buffer pH 4.5, with hydrogen peroxide and manganese sulfate at 610 nm ($\varepsilon = 22/\text{mM}$ cm) according to Paszczynski *et al.* (1988). Both ligninolytic activities were measured at 30°C. International enzymatic units (U) were used (µmol product/min). Results were expressed in units per gram of dry litter (U/g dry litter). For all spectrophotometric measurements, three technical replicates were performed.

185 Statistical analysis

Decomposition constants (k) among treatments were analyzed using two-way ANOVA, 186 with litter and fungal species as main factors. Data was logarithmically transformed before 187 188 analysis to meet the necessary assumptions for parametric testing of normality (Shapiro-Wilks test) and equality of variances (Levene's test). All post hoc comparisons were accomplished with 189 a Tukey's test and $\alpha = 0.05$ was used for testing statistical significance. When mass loss was 190 compared in a fungus over time, a one-way ANOVA followed by a Tukey's test was performed. 191 The shifts of individual carbon fractions, ratios and indexes calculated in the ¹³C CPMAS NMR 192 analysis were compared between initial fresh litter types using a pair t test. A one-way ANOVA 193 followed by the Tukey's test was used to compare the chemical categories among fresh and 194 decomposed litter within each litter type. Statistical analyses were performed using Statistica 7.0 195 software package (Stat-Soft, USA). The correlation structure among chemical variables (based 196 on analytical determinations in the WSF and NMR spectra of the SF from fungal-litter samples 197 at the end of the SSF) and the enzyme activities (detected in the WSF of the same samples) was 198 199 determined by calculating pairwise Pearson's correlation coefficients. Also, the common structure of these two data tables was examined by Coinertia analysis (CoiA) (Dray et al. 2003), 200

201 previously used in litter decomposition (Alarcón-Gutiérrez et al. 2009). CoiA was performed 202 using the ade4 package in the R environment (R Development Core Team 2008). Principal 203 Component Analysis (PCA) was used as an ordination method in the two data sets and CoiA projected the two PCAs into the same graphical space, in order to visualize variations in 204 individual chemical components among litter types and fungi in relation to enzyme activities. As 205 206 we had some zero values, a Detrended Correspondence Analysis (DCA) -using vegan package in 207 R- was performed first. Because the ordination axes or "gradient lengths" were shorter than two 208 units, the data were linear, and a CoiA with PCA was appropriate for the analysis (Ter Braak 209 1998). The co-linearity was tested using the vif function with *fmsb* package in R. All variables above a threshold of five were excluded from the analyses. In order to identify which factors 210 significantly corresponded to overall enzyme activities, we used the function envfit in *vegan* 211 package in R. The significant variables were analyzed for variance partitioning with varpart 212 function in vegan. 213

214 **Results**

215 Litter decomposition under SSF

Litter fungal strains Marasmiellus candidus, Leratiomyces ceres and Marasmius 216 haematocephalus were able to grow and colonize native Celtis tala and exotic Ligustrum 217 lucidum litter, using them as only substrate source in SSF conditions. The percentages of dry 218 219 mass remaining after each sampling time are shown in Fig. 1. Litter decay rates varied according 220 to the fungus employed in the SSF. In the native litter, fungal degradation began faster than in 221 the exotic one, excepting litter treated by L. ceres, a treatment that, however, showed a 222 significant mass loss after 90 days (P < 0.01). In the native litter, Marasmiellus candidus, Leratiomyces ceres and Marasmius haematocephalus caused dry mass loss of $10.97 \pm 1.12\%$, 223

8

224 $8.78 \pm 3.64\%$ and $24.11 \pm 3.19\%$, respectively, at the end of the fermentation period. In the exotic litter, decay progressed slowly during the first 60 days. Afterwards the rate of substrate 225 decomposition caused by L. ceres and M. haematocephalus increased till the end of the 226 experiment, reaching $22.90 \pm 1.79\%$ and $31.46 \pm 2.15\%$ dry mass loss, respectively. On the 227 contrary, in *M. candidus*, a plateau in decomposition rate was detected from day 90 onwards, 228 229 with 7.52 \pm 1.49% final mass loss. Decomposition constants (k) followed a decreasing order: M. haematocephalus > L. ceres growing in the exotic litter > M. candidus > L. ceres cultivated in 230 the native one (Table 1). Significant differences in k values between litter species were found 231 only for *L. ceres*, causing faster daily decay rate in the exotic litter $(1.39 \times 10^{-3} \text{ day}^{-1})$ than in the 232 native one $(0.52 \text{ x} 10^{-3} \text{ day}^{-1})$. 233

234 Chemical composition of the WSF and SF from litter

The chemical composition of the WSF extracted from native and exotic litter, 235 respectively, was notoriously different. The first one was more alkaline $(8.32 \pm 0.01 \text{ vs. } 5.08 \pm$ 236 0.03; P < 0.0001) and also had a lower sugar content ($4.03 \pm 0.59 \text{ mg/g vs. } 45.07 \pm 1.51 \text{ mg/g}; P$ 237 < 0.0001), proteins (9.48 \pm 0.88 mg/g vs. 11.13 \pm 0.32 mg/g; P < 0.0001), ammonium-N (0.07 \pm 238 0.01 mg/g vs. 0.25 ± 0.02 mg/g; P < 0.0001) and phenolic compounds (4.77 ± 0.31 mg/g vs. 8.30 239 \pm 0.26 mg/g; P < 0.0001). Changes in chemical characteristics of leaf litter WSF over time are 240 presented in Fig. 2. The native litter incubated with Leratiomyces ceres exhibited a slight 241 increase in pH values. In the exotic litter cultures, strong alkalization of the substrate was 242 observed, especially with *Marasmiellus candidus*, which markedly increased pH within the first 243 30 days of the experiment. Sugar content in the native litter showed few changes along the SSF 244 245 with M. candidus and L. ceres, but when decayed by Marasmius haematocephalus, a significant increase was observed after day 60. In the exotic litter, water-soluble sugar content was about 10 246

247 times higher than in the native one, but it was rapidly consumed and almost exhausted within 60 days. Ammonium-N values detected in WSF showed a tendency to increase over time. In the 248 249 case of *Celtis tala* inoculated with *Marasmius haematocephalus* and *Marasmiellus candidus*, the increment occurred in the initial phase of the SSF, and ammonium levels remained constant once 250 maximum values were attained. In L. ceres, a peak at day 90 was detected and after 120 days, 251 252 ammonium concentration started to rise. For Ligustrum lucidum treatments, a first decline in 253 ammonium content was observed. Nevertheless, after 120 days, it started to increase when incubated with Marasmius haematocephalus and Leratiomyces ceres. Water-soluble protein 254 255 levels registered a maximum at day 30 in the treated native litter and in the exotic one inoculated with Marasmiellus candidus as well, although differences were not statistically significant in the 256 257 first case. A major increase in protein levels was recorded in the native litter incubated with M. haematocephalus at initial fermentation stages, remaining constant after day 60. Phenolic 258 compounds in WSF showed no significant changes in the native litter decomposed by L. ceres, 259 while incubation with *M. candidus* increased total phenolics in WSF at day 200. On the contrary, 260 total phenolics showed a drastic decrease in the exotic litter and to a lesser extent in the native 261 one when decayed by M. haematocephalus. 262

¹³C CPMAS NMR spectra shown in Fig. 4 correspond to SF from uninoculated *Celtis tala* and *Ligustrum lucidum* litter (initial litter samples) and litter obtained after 200 days-SSF with each of the saprotrophic fungi evaluated. All spectra exhibited the same pattern, differing in the relative intensity of the various chemical shift regions. Important differences were found in spectra signals among uninoculated litter types in all the regions that were considered for integration and in all the ratios and indexes estimated as well, except for the O-alkyl C region (*P* = 0.15, Table 2, Table 3). A larger proportion of alkyl C was found in *L. lucidum* (33.67%) rather 270 than in C. tala (24.22%) uninoculated litter. The intensity in this region can be attributed to 271 aliphatic components, mostly methylene structures of lipids, cutins and waxes as well as short-272 chains of acids or amino acids. At the end of the SSF, an increase in their relative content was observed in Ligustrum lucidum inoculated with Leratiomyces ceres and Marasmius 273 haematocephalus. Methoxyl carbons, principally of lignin, were detected at 45-60 ppm, although 274 275 around 10% were identified as methoxyl groups in some of the less common monomer units of 276 hemicellulose, specifically the glucuronic acid in xylan (Haw et al. 1984). Methoxyl carbons content in fresh C. tala, was found to be 4 times higher than in L. lucidum. In L. lucidum a 277 278 significant increase in methoxyl carbons content was detected by the end of the SSF, only when litter was inoculated with Leratiomyces ceres. Signal of the O-alkyl C region constituted the 279 largest proportion in fresh litter and was attributed to polysaccharides, comprising 55.60% in C. 280 tala and 48.27% in L. lucidum. Mainly, two dominant peaks were found, a wider one at 70-80 281 282 ppm, an apparent doublet that was reported to correspond to C-2, C-3, and C-5 carbons of cellulose (I) and a peak at 105 ppm that was generally assigned to the C-1 carbon of the 283 anhydroglucose repeating unit of the cellulose (I) (Haw et al. 1984). The relative content 284 declined by the end of the SSF mainly in *Ligustrum lucidum* inoculated with *Leratiomyces ceres* 285 286 (Fig. 1, Table 2). As the decomposition preceded the alkyl C/O-alkyl C ratio, also known as 287 humification degree, it increased in *M. haematocephalus* mainly growing in the exotic but also in 288 the native litter, and in L. ceres it grew in the exotic one. No significant differences in the alkyl 289 C/O-alkyl C index were found in the rest of the fungal-litter combinations (Table 3). The intensity in the spectral region from 110 ppm to 160 ppm was due to the aromatic ring carbons of 290 291 lignin. The phenolic region, between 140 and 160 ppm, characteristic of oxygen-substituted 292 aromatic ring carbons, was negligible in our litter spectra. Almost twice the content of aromatic

carbons was detected in fresh exotic L. lucidum (4.75%) compared to native C. tala (2.45%), 293 which is consistent with a higher aromaticity and lignin index. Aromatic C content decreased by 294 the end of the decomposition period as a consequence of lignin-degrading fungal activity and 295 maximal chemical shifts were registered in *M. haematocephalus*, which completely delignified 296 all L. lucidum substrate. Finally, signals at 160-190 ppm were attributed to acetate groups known 297 298 to be present in hemicellulose or carbonyl species also existing in hemicellulose (e.g., CO_2H 299 groups of uronic acids). In C. tala inoculated with Marasmius haematocephalus, an increment was observed, while in L. lucidum the content of carboxyl carbons declined when it was 300 301 inoculated with Marasmiellus candidus.

302 Enzyme activities in the WSF

303 Endoglucanase activity was significantly different among substrates in every sample time (Fig. 3A, P < 0.05) with higher values detected when using the exotic litter and *Leratiomyces* 304 ceres being the largest producer $(7.55 \pm 0.99 \text{ U/g})$. In the native litter, Marasmius 305 haematocephalus recorded the highest endoglucanase activity. This treatment also showed a β -306 glucosidase activity that stood out from the rest of fungal-litter combinations, with maximum 307 values of 2.80 U/g approximately recorded upon 120 days (Fig. 3B). Furthermore, M. 308 haematocephalus and L. ceres growing in the exotic litter were the second and third major β -309 glucosidase producers, respectively. Endoxylanase activity showed a peak at day 30 when 310 cultivating *M. haematocephalus* in the native litter (Fig. 3C, 6.09 ± 0.31 U/g); while a constantly 311 increasing activity was detected in the other treatments with maximal enzyme activity at day 200 312 in L. ceres growing in the exotic substrate. Ligninolytic activity was represented mostly by L. 313 314 ceres (Fig. 3D, Fig. 3E). When cultivated in the exotic litter, MnP activity was remarkably higher than in the rest of fungal-litter treatments while laccase activity was detected as a first 315

peak produced at day 30. In the native litter, laccase production was greater but the uppermostvalues were detected at advanced stages of fermentation.

318 Coinertia Analysis (CoiA)

Some of the chemical variables evaluated at the end of the SSF were highly correlated 319 with the enzyme activities (Supplementary Table S1¹). The alkyl C/O-alkyl C ratio (humification 320 degree) positively correlated with endoglucanase (r = 0.82; P < 0.01), endoxylanase (r = 0.65; P 321 < 0.05) and MnP activities (r = 0.62; P < 0.05). The last activity was sensitive to this index 322 despite no significant correlations were observed for its individual components. Endoglucanase 323 (r = -0.76; P < 0.01) and MnP (r = -0.84; P < 0.001) activities were also correlated with pH, with 324 greater activities in the acidic values. β -glucosidase activity was strongly correlated with the 325 326 content of ammonium in the WSF (r = 0.87; P < 0.001). Nevertheless, laccase activity did not correlate with any of the chemical variables measured. As there was multicollinearity among 327 chemical variables, we decided to select only the non-collinear and "representative" ones to 328 reduce the complexity of the variable matrix for the coinertia analysis. From them, the envfit 329 analysis showed that O-alkyl C proportion, alkyl C/carboxyl C ratio, remaining mass degree, pH, 330 content of phenolics and proteins were the variables that significantly corresponded to overall 331 enzyme activities (Supplementary Table S2). The projected inertia with two axes (Fig. 5A, Ax1 332 and Ax2) represented 90.86% of the total covariance (Fig. 5C). The first axis separated 333 Leratiomyces ceres growing on the exotic litter from all the other treatments and responded to a 334 high alkyl C/carboxyl C ratio, more acidic conditions and a major decrease in the phenolic 335 compounds content, principally due to the activities of endoenzymes and MnP (Fig 5B, Fig. 5D). 336 337 The second axis separated the other fungal species, with Marasmius haematocephalus and *Marasmiellus candidus* having opposite scores. *M. haematocephalus* correlated well with β -338

glucosidase activity and protein content and showed greater mass loss, while *M. candidus* was
associated with high chemical scores and low mass loss. Seventy-six percent of the variability
was explained jointly by the two sets of variables (Supplementary Fig. S1).

344 Discussion

Below-ground litter decomposition is hierarchically controlled by climate, chemical 345 composition of the substrate and by soil biota (Swift et al. 1979; Coûteaux et al. 1995; Cadish 346 and Giller 1997; Hättenschwiler et al. 2005). In our study, species-specific responses in litter 347 decomposition as a function of litter chemistry could be detected, because species were 348 separately analyzed in environmentally controlled conditions. Litter decomposition rates varied 349 according to the fungus employed in the SSF and only for *Leratiomyces ceres*, significant 350 differences were observed depending on the litter employed, with higher degradation of the 351 352 exotic Ligustrum lucidum litter.

Previous studies recording *Ligustrum lucidum* decomposition detected a k of 11.20×10^{-3} 353 day⁻¹ in a natural lowland stream from Buenos Aires (Marano et al. 2013). This value exceeded 354 355 the k value of the native *Pouteria salicifolia* leaf litter, and it was related to the better quality of 356 the substrate (less lignin and phenolic compounds, lower L:N ratio, similar C:N and higher C:L 357 proportion). Aragón et al. (2014) proved that in a native secondary forest L. lucidum litter 358 decomposed faster than the litter from the native species Ocotea porphyria and Cupania *vernalis*, reaching a k mean value of 3.018 year⁻¹ (8.26 x10⁻³ day⁻¹). Moreover, Fernandez *et al.* 359 (2017) suggested that L. Lucidum invasion altered the abundance and composition of fungal 360 decomposers associated with the secondary forest mentioned. Several studies proposed that alien 361

Page 17 of 42

362 species possess common litter traits that allow them to decompose faster than the native species 363 co-occurring with them, promoting invasion and nutrient cycling (Allison and Vitousek 2004; 364 Liao et al. 2008). However, taking into account that other studies showed opposite results (Godoy et al. 2010; Knight et al. 2007), generalizations concerning the comparative 365 decomposition of native and exotic litters cannot be made. As far as we know, there are no 366 367 reports on *Celtis tala* decomposition rates and only its degradation by ascomycetes was investigated (Saparrat et al. 2008). In comparison, our k for L. lucidum was considerably lower 368 than k values obtained in other studies in natural environments. Such differences are expected 369 370 since in our experimental approach, degradation was the result of the activity of a single fungus in axenic conditions. In this work, mass loss obtained at day 200 in SSF ranged from 7.50 up to 371 31.50% (Fig. 1), but reached around 20% after 120 days with some litter/fungus combinations i.e 372 Marasmius haematocephalus growing in C. tala litter and Leratiomyces ceres cultivated in 373 374 Ligustrum lucidum litter. An average of 16.60% mass loss was reported for Chamaecyparis 375 *obtuse* needle litter degradation by several litter saprotrophic basidiomycetes after 18 weeks in a pure-culture test (Osono et al. 2006). Also a mass loss of 16 to 34% was caused by Hypholoma 376 fasciculare growing in different litter types for 12 weeks under SSF (Voříšková et al. 2011). 377

It is assumed that at early stages of decomposition, mass loss is dominated by the degradation of soluble substances and holocellulose that is not protected by lignin (Berg and McClaugherty 2014). A considerable fraction of soluble substances is also leached to the soils. Concurrently, the sugar content in WSF (resulting from easily degradable C compounds) was 10 times higher in the exotic *Ligustrum lucidum* than in the native *Celtis tala* (Fig. 2). This larger content of sugars may have supported the initial growth in *L. lucidum* (higher endoglucanase activities responsible for cellulose degradation were detected as well). At the same time, initial 385 degradation rates are positively affected by an increase in the levels of key nutrients such as S, P 386 and N (Berg 2014), the latter one considered a critical element for litter-decomposing 387 basidiomycetes. Simultaneously, low values of C:N have been generally associated with fast decomposition (Lambers et al. 2008). N content in C. tala was reported to be around 1% and 388 C:N ratio equal to 27 (Saparrat et al. 2008), while Aragón et al. (2014) informed 0.82% N 389 390 content for L. lucidum and a C:N ratio of 53.72. During fungal cultivation on L. lucidum, 391 ammonium was not detected in the WSF [excluding the end of SSF by *M. haematocephalus* (Fig. 2)] suggesting no net mineralization of the N initially present in the litter (in the form of amino 392 393 acids and proteins) or a net N immobilization in fungal biomass. It was reported that when C:N is high, a substantial fraction of initial nutrients from organic matter can be immobilized into 394 fungal hyphae and converted to growth (Swift et al. 1979). The differences in ammonium-N 395 levels detected may indicate a differential availability of N depending on the type of substrate 396 and therefore, N can be considered limiting in L. lucidum compared to C. tala. This is in 397 agreement with a greater mass loss in C. tala at early stages of SSF. In advanced stages of 398 decomposition, mass loss is more limited and involves the degradation of lignin and lignified 399 compounds (Berg 2014). L. lucidum litter showed higher values of relative area of aromatic and 400 401 aliphatic compounds than C. tala as well as a higher content of water-soluble phenolic compounds (Table 2, Fig. 2), compounds that are recalcitrant and are known to delay the decay 402 403 process (De Marco et al. 2012). Lignin, aromaticity indexes and phenolic compounds content of 404 the WSF decreased by the end of culture period in L. lucidum, revealing the activity of lignin-405 degrading fungi (Table 3, Fig. 2). Thus, mass loss was higher in L. lucidum during the final 406 stages of SSF. Ammonium detected in C. tala at the end of the SSF, derived from organic-N Page 19 of 42

407

408

degradation, could affect lignin degradation and decay rate in this substrate. Some litter fungi are known to repress the expression of ligninolytic enzymes when labile N is present (Berg 2014).

409 During the course of decomposition of soil organic matter, a rise in the alkyl C/O-alkyl C ratio has been proposed, as O-alkyl C is converted to alkyl C (Baldock et al. 1997). In this work, 410 the index shown to be a reliable predictor as a substantial increment was observed at the end of 411 412 the SSF in those treatments that recorded the highest percentages of degradation, namely Marasmius haematocephalus in both substrates and Leratiomyces ceres in the exotic litter (Table 413 3). No significant changes in the alkyl C/O-alkyl C ratio were found in the rest of treatments with 414 415 respect to the uninoculated litter. Since a loss in the O-alkyl C region is mainly associated to cellulose and/or hemicellulose degradation, our results suggest that at least *M. haematocephalus* 416 and L. ceres were active degraders of holocellulose, being the former less selective of substrate 417 type. Therefore, these fungi could have a role in humification due to the increase in the alkyl C 418 419 domain, which is mostly linked to the accumulation of recalcitrant structural components present in plant litter such as that of waxes, cutin, suberin, lipids and amino acids (Kögel-Knabner et al. 420 1992). 421

Changes in the activity of the extracellular enzymes that degrade the main components of 422 423 soil organic matter have been associated to variations in rates of decomposition and soil carbon 424 storage (Sinsabaugh et al. 2008). Extracellular enzyme activities are also sensitive indicators of 425 the effort directed by microorganisms towards obtaining carbon, nitrogen, or phosphorus from 426 specific sources (Veres *et al.* 2015). In our work, we detected a noteworthy difference in β glucosidase production by Marasmius haematocephalus with high titers when growing on Celtis 427 428 tala but not on Ligustrum lucidum (Fig. 3). The reducing sugars content in the WSF of L. 429 *lucidum* at initial SSF stages may suggest a byproduct inhibition mechanism of the β -glucosidase 430 activity in this substrate (Xiao et al. 2004) since when sugar levels declined, at the end of culture 431 period, β -glucosidase activity started to rise. The low levels of sugars present in C. tala leaf litter 432 may have allowed *M*. haematocephalus to produce a significant amount of β -glucosidase (high protein levels in the WSF) with a consequent increase in glucose levels after 60 days of 433 cultivation. Accordingly, these variables significantly correlated at the end of the SSF (r = 0.69, 434 435 Table S1). Saparrat *et al.* (2008) found that β -glucosidase activity was correlated with *C. tala* 436 leaf litter decomposition. On the other hand, while in *M. haematocephalus* cultures developing on C. tala, delignification was not significant, this fungus caused a complete delignification on L. 437 438 *lucidum* substrate, which could compensate k and mass loss values between both litter types. Because laccase and MnP activities were negligible, lignin degradation could involve other 439 440 peroxidases found, expressed by litter decomposing fungi such as the dye-decolorizing peroxidase (DyP, EC 1.11.1.19) and the unspecific peroxygenase (UPO, EC 1.11.2.1) (Kellner et 441 442 al. 2014) or other mechanisms such as Fenton reaction, in which degradation involves the 443 generation of low molecular highly oxidizing species (Regalado et al. 1999). MnP production by Leratiomyces ceres increased only when the fungus was growing on Ligustrum lucidum litter 444 (Fig. 5). Considering that MnP is one of the key oxidative enzymes in litter degradation and 445 446 lignin content is the component most often identified as a limiting factor in decomposition (Purahong et al. 2014), MnP activity found in this treatment could possibly explain the important 447 448 mass loss values, as it is shown in the coinertia analysis. Laccase activity could be detected as 449 well, being higher in the native litter than in the exotic one. Laccases are only considered as lignin-modifying enzymes because their redox potential is lower than that of peroxidases, and are 450 451 thought to be involved in polymerization-depolymerization processes of lignin, melanin and 452 humic substances (Liers et al. 2011). Since no specific pattern related with degradation was Page 21 of 42

observed in our study, the detected activity could be associated with other functions adjudicated
to laccase, such as its role in the morphogenesis and differentiation of sporulating and resting
structures in basidiomycetes, pigment formation and detoxification (Mayer and Staples 2002).

Environmental pH affects fungal growth and enzyme activity, with the majority of fungi 456 having pH optima in the acidic values (Dix and Webster 1995). Nevertheless, some prefer 457 458 neutral to slightly alkaline conditions, i.e. some Coprinus species. Initial pH of Celtis tala was 459 8.32 and values remained alkaline throughout all SSF. Fungi growing on Ligustrum lucidum 460 started with an acidic initial pH of 5.08 but a general tendency to alkalization was observed, 461 mainly by Marasmius haematocephalus and Marasmiellus candidus, the latter raised the pH to 8.27 within the first 30 days (Fig. 2). Our results suggest that the enzyme system of some of 462 these fungi was highly active even at alkaline pHs. Thus, the stability of *M. haematocephalus* β -463 glucosidase growing in C. tala was tested in a pH range of 4.8-9, retaining more than 50% of its 464 relative activity after 12 h of incubation (Mallerman 2017). Conversely, Leratiomyces ceres 465 466 might be sensitive to alkaline pHs and favored by the introduction of *Ligustrum lucidum*, which provides a lower pH. In agreement a strong correlation between pH and MnP activity was 467 detected, mainly associated with this fungus (r = -0.84, Table S1). Resistant enzymes adapted to 468 469 alkaline pHs, such of the one found in *M. haematocephalus*, have great potential for basic research and industrial applications. The present work explores the lignocellulolytic abilities of 470 471 species scarcely investigated until now.

Our study involved a long-term, laboratory, microcosm approach to determine the impact of two sorts of leaf-litter, one native and another exotic, on mass loss and activity of selected lignocellulolytic saprotrophic basidiomycetes. Enzymatic assays were conducted using optimal parameters and reproducible assay conditions that do not occur *in situ* (such as incubation temperature and reaction pH), in order to measure not only the maximum potential enzyme activity (Dick 2011) but also to allow the comparison of enzyme activities among different studies (Nannipieri *et al.* 2012). In addition, the alteration of chemical and physical properties of the litter by autoclaving cannot be ruled out (Berns *et al.* 2008). However, such non-target effects were consistent within a given litter type or fungal culture in our study. Therefore, our findings could not be explained.

482 Litter decay is the result of an active cross-kingdom functional succession and bacteria may also significantly contribute to decomposition (Purahong et al., 2016). Enzymes involved in 483 484 cellulose, hemicellulose, chitin and starch catabolism were detected in litter bacteria proteomes (López-Mondéjar et al., 2016). Lignin degradation appears to be limited when compared with the 485 abilities of saprotrophic fungi, nevertheless Actinobacteria may add to the solubilisation of 486 phenolics (Větrovský *et al.*, 2014). Thus, the lack of bacteria may also contribute to the low k487 488 rates attained in this work. Bacterial-fungal co-culturing could aid in clarifying their possible 489 interacting roles in lignocellulose complex breakdown during plant litter decomposition.

In conclusion, native and exotic litter chemistry differentially affects decomposition rates 490 491 and enzyme production by common lignocellulolytic saprotrophic basidiomycetes. The 492 introduction of *Ligustrum lucidum* to pristine environments could alter the chemical composition 493 of litter input to forest soils. Preliminary data from our *in-vitro* litter degradation study suggests 494 that an impact on litter decomposition rates should be expected, as some common saprotrophic 495 basidiomycetes such as *Leratiomyces ceres* are present, driving to accelerated litter decomposition through an increased ligninolytic activity. Although Marasmius haematocephalus 496 497 and Marasmiellus candidus were less sensitive to alterations in litter quality, the three fungi 498 assayed showed significant changes in their pattern of extracellular lignocellulolytic enzyme 499 production with a concomitant modification in nutrient dynamics. Further research is needed to 500 get a better understanding of the role that basidiomycetous fungi and their extracellular enzyme 501 systems play in degradation of soil organic matter in terrestrial ecosystems, as well as to predict 502 potential effects of plant invasion on ecosystems processes and develop management strategies.

LEGEND TO THE FIGURES

Fig. 1 - Dry mass remaining during 200 days in SSF in (A) *Celtis tala* and (B) *Ligustrum lucidum* litter inoculated with *Marasmiellus candidus* (circles), *Leratiomyces ceres* (squares), and *Marasmius haematocephalus* (triangles). Data are the mean of three replicates, one standard error of the mean is represented.

Fig. 2 - Characterization of the water soluble fraction during 200 days in SSF with *Celtis tala* (dotted lines) or *Ligustrum lucidum* litter (solid lines) and inoculated with *Marasmiellus candidus* (circles), *Leratiomyces ceres* (squares) or *Marasmius haematocephalus* (triangles):
(A) pH (B) Glucose (C) Ammonium-N (D) Proteins (E) Phenolic compounds. Data are the mean of three replicates, one standard error of the mean is represented.

Fig. 3 - Analysis of enzyme activities related to lignocellulose system during 200 days in SSF with *Celtis tala* (dotted lines) or *Ligustrum lucidum* litter (solid lines) and inoculated with *Marasmiellus candidus* (circles), *Leratiomyces ceres* (squares) or *Marasmius haematocephalus* (triangles): (A) Endoglucanase (B) β-glucosidase (C) Endoxylanase (D) Mn Peroxidase (E) Laccase. Data are the mean of three replicates, one standard error of the mean is represented.

Fig. 4 - ¹³C CPMAS NMR spectra of initial litter samples (C.t and L.l) and after 200 days in SSF with the selected basidiomycetous fungi (C.t-M.c, L.I-M.c, C.t-L.c, L.I-L.c, C.t-M.h and L.I-M.h): C.t, *Celtis tala*; L.l, *Ligustrum lucidum*; M.c, *Marasmiellus candidus*; L.c, *Leratiomyces ceres*; M.h, *Marasmius haematocephalus*. Spectra chemical shift range of litter was characterized by the following dominant peaks: alkyl C (0–45 ppm), O-alkyl C

Page 42 of 42

(45–110 ppm), methoxyl C (50–60 ppm), aromatic C (110–140 ppm), phenolic C (140–160 ppm) and carboxyl C (160–190 ppm).

Fig. 5 - Coinertia analysis using PCA-PCA of the chemical parameters (analytical determinations of the WSF and NMR results of the SF) and the lignocellulolytic enzymes in the WSF produced by the selected basidiomycetous fungi after 200 days in SSF. The analysis represents the individual treatments (from 1 to 12; n = 2) corresponding to the substrate (C.t, *Celtis tala;* L.l, *Ligustrum lucidum*) inoculated with the fungal species (M.c, *Marasmiellus candidus*; L.c, *Leratiomyces ceres*; M.h, *Marasmius haematocephalus*). (A) Inertia projection of the chemical and enzymatic parameters (B) Biplot showing the covariance optimization by the coinertia (C) The eigenvalues showing the total variance and the eigenvalues considered in the analysis (D) The Y and X loadings (canonical weights) for PC1 (chemical parameters: Alk.C.Carb.C., Alkyl C/Carboxyl C; Rem. mass, Remaining mass; O. Alk. C, O. Alkyl C; Phen, Phenolic compounds; Prot, Preteins; pH) and PC2 (enzymatic activities: Endo, Endoglucanase; Endoxy, Endoxylanase; b.glu, β glucosidase; MnP, Mn-Peroxidase; Lac, Lacasse).
