Abstract

Aim To present results, 1 year postimplementation at primary care level, of an integrated diabetes care programme including systemic changes, education, registry (clinical, metabolic, and therapeutic indicators), and disease management (DIAPREM).

Methods We randomly selected and trained 15 physicians and 15 nurses from primary care units of La Matanza County (intervention—IG) and another 15 physicians/nurses to participate as controls (control—CG). Each physician–nurse team controlled and followed up 10 patients with type 2 diabetes for 1 year; both groups used structured medical records. Patients in IG had quarterly clinical appointments, whereas those in CG received traditional care. Statistical data analysis included parametric/

nonparametric tests according to data distribution profile and Chi-squared test for proportions.

Results After 12 months, the dropout rate was significantly lower in IG than in CG. Whereas in IG HbA1c, blood pressure and lipid profile levels significantly decreased, no changes were recorded in CG. Drug prescriptions showed no significant changes in IG except a decrease in oral monotherapy.

Conclusions DIAPREM is an expedient and simple multistrategic model to implement at the primary care level in order to decrease patient dropout and improve control and treatment adherence, and quality of care of people with diabetes.

Keywords Quality of care · Therapeutic education · Medical data registry · Diabetes primary care · Treatment adherence · Disease management

Introduction

Despite available evidence supporting the concept that appropriate control of blood glucose and associated cardiovascular risk factors (CVRFs) can reduce diabetes complications—the major cause of morbidity, mortality, and costs of the disease [1–7]—these preventive strategies have not been widely incorporated into clinical practice [8]. Consequently, care received by people with diabetes is frequently far from optimal [9–15].

Several factors contribute to this disappointing situation such as a) inadequate knowledge and experience of healthcare providers [12], b) inadequate provider attitude towards application of guidelines [16, 17], c) limited patient access to care, d) poor adherence with self-care and treatment, and e) scant attention given patient education [8, 17]. Lack of continuous evaluation and systematic registry of medical outcomes with concomitant treatment adjustments close the vicious circle that leads to poor care outcomes [9, 11, 18]. Therefore, inappropriate control/treatment is the final common path leading to the high morbimortality of the disease.

Effective models of diabetes care which include systemic changes and patient and/or physician education help to overcome most of the above-mentioned problems. Systemic changes most widely implemented included provision of specific care guidelines and reminders, improved access to care by reduction in financial/administrative barriers to care, and patient/provider feedback to monitor care outcomes. Indeed, a review of educational interventions in disease management programmes of chronic diseases, including diabetes, concluded that most programmes directed at providers and patients improved care outcomes [19]).

In Argentina, there are three health sectors (public health, social security, and private). The social security and private sectors cover around 48 and 10% of the population, respectively, and the extent of health coverage is determined by law in the Mandatory Medical Program (PMO). The public health sector provides universal access to free health care to almost half of the population (mostly unemployed and low-income population not insured by social security or private sector) through primary care units (PCU) and public hospitals. PCUs include different types of disease management programmes for ambulatory treatment of chronic diseases such as diabetes, providing a free supply of drugs such as human insulin, some oral drugs, and a limited number of strips to self-monitor blood glucose (SMBG).

We attempted to improve quality of diabetes care at the primary care level and consequently improve treatment outcomes by implementing at that level of the public health

sector, an integrated diabetes care programme that includes systemic changes, education, registry (clinical, metabolic, and therapeutic indicators), education (physicians and nurses), and disease management (DIAPREM: *DI*abetes *P*rietary care, *R*egistry, *E*ducation and *M*anagement) [20]. Here, we describe the clinical and metabolic outcomes after a 1-year follow-up of patients in the intervention group, comparing them to those who received customary care.

Methods

Study design

Detailed description of the DIAPREM strategy has been already reported [20]. Consequently, we now briefly describe its background and contents.

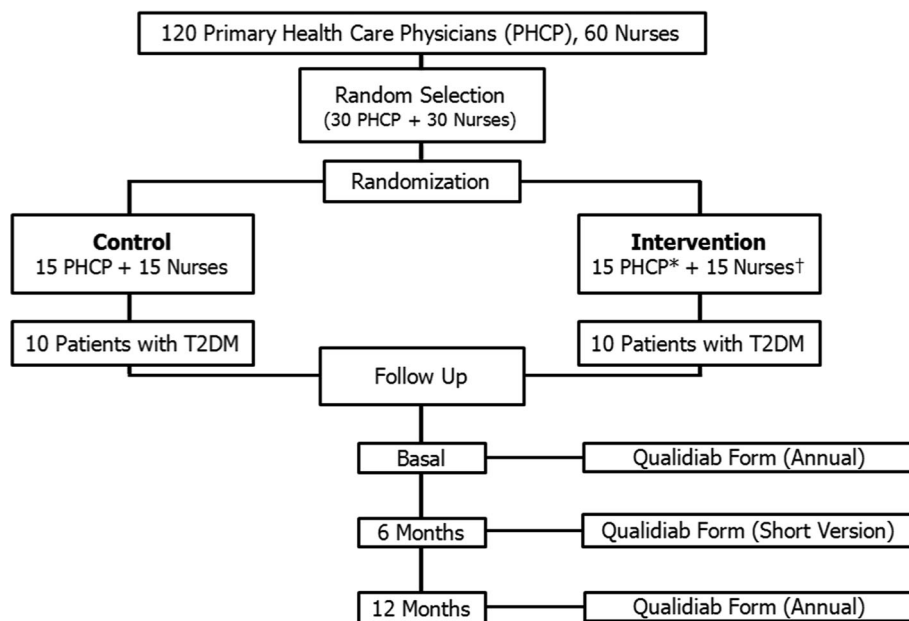

Argentina has 40,117,096 inhabitants (2010 National Census), and 39% of them live in the province of Buenos Aires, of whom 1,775,816 (11%) live in La Matanza County. According to the prevalence defined by the 2009 National Risk Factors Survey [21], our diabetes population is around 2,892,000 people; only about half of them know they have the disease (1,445,973); 70% of those diagnosed are in regular treatment (1,012,181). Half of this population receives free care from the public health system (506,091 people). Of this diabetes population, 4.43% lives in one area (La Matanza) of the city suburbs in the province of Buenos Aires, a low-income population with 34% has unsatisfied basic needs, and only 40% of people have completed their primary education.

Figure 1 shows the DIAPREM design. Of the 40 primary care units (PCU) of La Matanza Health Secretariat, we randomly selected 30 physicians and 30 nurses. Of those, 15 were randomly selected to be trained (IG group), and another group of 15 physicians and nurses from another 15 PCUs were also randomly selected and used as controls (CG group).

Rather than using restrictive patient selection criteria, our criterion was for the patient sample to represent common daily practice in the study area. For this purpose, each physician–nurse team took care of and followed up 10 patients: adults of both genders with type 2 diabetes (T2D) for 1 year; each patient was required to attend clinical appointments at least every 3 months (150 people with T2D in the CG and 150 people in the IG). People with expected short survival (cancer or terminal conditions), different types of addictions or psychiatric disorders, were excluded from the selection.

During the recruitment phase, we had several meetings with local coordinators and authorities from participating organizations to explain the rationale, importance, aims,

Fig. 1 Study design *PHCP received e-learning courses. †Nurses received face-to-face courses

activities, timetable, and methodology selected for the study.

Main outcomes

Changes in HbA1C from baseline to the end of the study were considered the primary outcome variable. Other relevant outcomes were considered secondary: the proportion of patients that attained goals such as HbA1c < 7.0%, glycaemia < 100 mg/dL, blood pressure < 130/80 mmHg, cholesterol < 200 mg/dL, and triglycerides < 150 mg/dL.

Statistical power and sample size

Considering 1.7% the standard deviation of change in HbA1c, with a 5% level of significance and 80% power, we needed 93 patients in each group to detect a decrease of 0.5% in the main outcome. Thereafter, we chose to increase the sample size by 50% at the first stage, assuming this would be the rate of dropout or failure to follow-up. This totalled 140 patients for each group. Finally, for that purpose, we decided to recruit at least 10 patients per physician–nurse pair.

Consequently, the programme started with a sample size of 157 patients for CG and 154 for the IG.

Interventions

Diabetes training course for physicians Physicians in the IG attended an online course with 14 compulsory and 12 optional modules, plus 8 h of practical activities completed at a national reference centre. This course was released

through the School of Medicine of the National University of La Plata (Argentina) and Indiana University (USA).

Each participant also received a manual with all the algorithms for diagnosis, control, and treatment of T2D included in the modules [22]. Physicians in the CG did not receive this training.

Nurse education Nurses in the IG attended in person a 5-day full-time intensive theoretical and practical course given at the Bernardo A. Houssay Center (La Plata, Argentina) which also included practical activities in the teaching hospital of the School of Medicine of the National University of La Plata.

Patient follow-up and call centre activities Participants in the IG were seen every three months in a programmed visit; to decrease dropouts, the call centre called them by telephone to remind them of their next appointment. Also, once a year, the call centre gave each patient an appointment for cardiovascular and ophthalmological controls done at the hospital at the same morning. In this way, we tried to facilitate attendance to these controls and minimize the number of work days missed.

Data registry

We used a structured registry form developed and validated by our group (QUALIDIAB) [10] to collect patients' clinical, biochemical, educational, and therapeutic data previous to and after 6 and 12 months of the DIAPREM implementation. QUALIDIAB registry includes clinical, metabolic, and associated CVRF indicators, degree of diabetes education, hospitalization events, and type of treatment prescriptions. These forms were filled in by the

physicians and nurses in both groups who were trained previously to record data properly on the data registry. The QUALIDIAB system also includes a feedback mechanism: physicians and nurses received a form from each patient comparing treatment target values and current values of different clinical and metabolic indicators (HbA1c and the other CVRF); if the patient did not achieve target values, the form suggests the issues the care team should focus on in particular. In this study, feedbacks were not available to the CG.

Data analysis

We used the Statistical Package for Social Sciences version 15 (SPSS Inc, Chicago, IL, USA). Descriptive statistics are presented as percentages and mean \pm standard deviation (SD). Group comparisons for continuous variables were made by a parametric or nonparametric test depending on the data distribution profile. The Chi-squared test was used to estimate differences between proportions. Significance was established at $p \leq 0.05$.

Ethical issues

The study protocol was analysed and approved by the Bioethical Committee of the National University of La Plata. The study was developed according to the Good Practice Recommendations (International Harmonisation Conference) and the ethical guidelines of the Helsinki Declaration. All subjects gave their written informed consent to participate in the study, and it was signed before their inclusion in the study cohort. At the end of the study, the 15 physicians and 15 nurses who were initially in the control group will receive the same training courses received previously by the intervention group.

Results

Dropouts

During the 1-year follow-up, patients who dropped out were significantly fewer in the intervention than in the control group (28 and 48%, respectively; $p < 0.0003$). No significant differences were found between clinical and metabolic characteristics of adherent compared to dropout patients in any of the groups (data not shown).

Clinical and metabolic parameters

Patients in the CG showed no significant improvement of their clinical and metabolic indicators during the 1-year follow-up, except a nonsignificant decrease in total

cholesterol at 12 months and a transitory decrease in LDL-c levels at 6 months (Table 1). Conversely, in the IG, diastolic blood pressure, HbA1c, and all lipid fractions decreased significantly at 6 months with either sustained or further improvement at 12 months (Table 1). This group also showed a small but nonsignificant decrease in BMI values.

The magnitude of the significant decreases in DBP, glycaemia, HbA1c, total and LDL-cholesterol, and TG levels attained values of -4.6 mmHg, -17.9 mg/dL (-0.99 mmol/L), -14.9 mg/dL (-0.39 mmol/L), -9.2 mg/dL (-0.24 mmol/L), and -25.7 mg/dL (-0.29 mmol/L), respectively.

Both groups showed a significant increase in the percentage of people at the goal for systolic blood pressure and total cholesterol, but this increase was larger in the IG (Table 2).

Pattern of drug prescriptions

The above-mentioned improvement was not associated with significant changes in drug treatment of hyperglycaemia, blood pressure, and dyslipidemia, except a significant decrease in monotherapy with oral antidiabetic agents (Table 3).

A comparable percentage of people with dyslipidemia or hypertension was in treatment in the CG at either the basal or 12-month control (Table 4). A similar prescriptive situation was observed in people with hypertension in the IG. Conversely, at the 12-month control, the percentage of treated patients with dyslipidemia increased significantly in the latter group. This value was significantly higher than the percentage in the CG.

Annual eye and cardiovascular evaluation

Control of micro- and macroangiopathic impact of diabetes improved significantly in the intervention group (around 100%) compared with the control group (75%) (Table 5).

Discussion

In our previous report on DIAPREM, we demonstrated that care provided to our population with T2D and associated CVRF at the primary care level was not effective enough to prevent development and progression of chronic complications of the disease [20]. This concept was based on HbA1c levels and other indicators of clinical and metabolic control, also the annual frequency of chronic complication evaluation, and the absence of systematic clinical records as well as inadequate drug prescription. We assumed that unfortunately, this poor provision of care was a common picture all around the world rather than an isolated problem

occurring at the primary care level of a developing country. Supporting this concept, two recent reviews analysed the situation of attainment of treatment targets in people with T2D and concluded that a large proportion of them failed to reach glycaemic targets due to a combination of factors, mainly poor adherence to treatment prescription and clinical/prescription inertia from healthcare team members [23, 24]. Further, Blondel et al. mentioned that this condition that favours the development and progression of chronic complications results from impaired attitudes, perceptions, and behaviours of healthcare providers, in particular frequent delays in the prescription of appropriate

interventions to achieve glycaemic targets. These authors concluded that a better understanding of these factors would facilitate implementation of suitable strategies to assist healthcare team members to prescribe more timely treatment to control blood glucose level.

On account of the above-mentioned evidences of worldwide and local poor quality of care provided to people with T2D, we call for urgent implementation of effective care strategies to overcome these problems; simultaneously, we have also decided to initiate this implementation at the primary care level and with general practitioners (GPs) and nurses, since they represent the first

scenario that receives people with diabetes and CVRF who request disease management [25]. Outcomes of the 1-year DIAPREM implementation showed that, in the intervention group, we significantly improved faulty diabetes care processes and reversed undesirable care outcomes.

In the intervention group, the dropout rate decreased significantly to almost half the rate recorded in the control group and at the same time also significantly increased the ophthalmological and cardiovascular annual controls. These changes were associated with

significant and sustained improvement in HbA1c, blood pressure values, and serum lipid profile without marked changes in drug prescriptions. Since we have applied a “multistrategic approach to improve quality of care”, all these changes could be ascribed to different factors which we will try to disaggregate in order to provide a reasoned explanation.

One of these factors might be the inclusion of the call centre to remind patients of their programmed control visits; others might be the systematic record of clinical,

metabolic, and treatment data with the corresponding feedback form for the physician–nurse care team. In this regard, Posadzki et al. [26] in their Cochrane revision concluded that appointment reminders sent by telephone can improve attendance rates and adherence to medications or tests. Systematic patient records and feedback have also been shown to exert a positive impact on programme outcomes [27].

In each participating primary care centre of the intervention group, we have also created an interactive, trained physician–nurse team in which each member takes care of a fixed number of patients for their yearly control and treatment follow-up. In this context, combined team approach interventions have been reported to be more effective than single intervention targeting single primary or community care professionals in improving metabolic control of people with diabetes [28]. A team approach in which trained physicians and nurses provide care management to people with diabetes at the primary care level has also been shown to significantly improve care outcomes [29]. Additionally, the sequential physician–nurse duet care increases time devoted to each patient, without affecting total number of patients attendance thus optimizing use of time.

Training of physicians and nurses was certainly an important component of our programme, and current data

support our previous positive experience with its implementation [30, 31].

Our multistrategic approach has facilitated access to regular HbA1c measurement, and this initiative has been shown to improve diabetes management at the primary care level in developing countries such as South Africa [32]. Similar success was reported in remote Australian indigenous communities [33].

Finally, our approach to care of people with T2D and CVRF also included some aspects of the care providing process not frequently considered an important conditioner of its quality, particularly at the primary care level. This specific point is based on the assumption that achieved outcome depends on medical technology but also on whether what is currently known as “good” medical care has been properly applied. We have also considered the structure, administrative, and related processes that support care provision, availability, and adequacy of facilities and equipment; the qualifications of medical staff and their organization as well as the administrative structure and programme operation of our primary care units. A detailed description of all these aspects and their impact on care quality was already published in 2005 by Donabedian [34].

In order to test whether the significant clinical and metabolic changes recorded in the Intervention Group could have clinical significance, we have compared the

magnitude of such changes with data reported in the literature. For that purpose, we took advantage of the systematic review and meta-analysis reported by Tricco et al. [35] on the effectiveness of quality improvement (QI) strategies on diabetes care, particularly assessing its impact on glycosylated haemoglobin (HbA1c), and other cardiovascular risk factors indicators. The result of such comparison showed that except for the changes observed in SBP, every outcome recorded in DIAPREM was larger than those reported in the literature for the 12-month follow-up period. It must be stressed that none of our baseline data was as high as those considered by Tricco et al., to render larger outcomes differences.

In brief, implementation of our multistrategic diabetes care programme—a combination of systemic changes, education, consistent patient registry, and disease management—has significantly improved patient adherence, quality of care, and treatment adherence; these changes were associated with high motivation of the healthcare team participating members, as well as the support of local health authorities. Even though we did not quantify healthcare team members motivation, they continuously manifested such attitude through permanent expressions of their satisfaction with their participation in the DIAPREM programme. All together, they have led to significant improvement in clinical and metabolic care indicators and optimization of human and economic resources regularly available at the primary care level. These simple and low-cost interventions yielded appreciable improvement in diabetes and associated CVRF control. Consequently, healthcare authorities must be aware of these results and endeavour to replicate the model in countries/regions with restricted health budgets in order to alleviate the heavy burden that T2D imposes on the public health budget, the community and, most of all, on the people suffering from this disease.

Acknowledgements DIAPREM implementation was partially supported by a grant provided by the World Diabetes Foundation (WDF12-761). The authors heartily acknowledge the generous cooperation of the La Matanza County health authorities as well as that of the Ministry of Health of the Province of Buenos Aires. The authors also thank Biochem. Cinthia Gonzales, Coordinator of the Municipal Laboratory Network, Ophthalmologist Marcelo Diaz, and administrative staffers Susana Lopez and Gladys Morello for their efficient support. MP is a research fellow of the Comisión de Investigaciones Científicas de la Provincia de Buenos Aires CIC/PBA-UNLP; LG is a UNLP fellow, ER is a CONICET research fellow, and JFE and JGG are CONICET career researchers.

Compliance with ethical standards

Conflict of interest The authors declare that they have no competing interests.

Human and animal rights disclosure All procedures in studies involving human participants were performed according to the ethical standards of the institutional and/or national research committee and

the 1964 Helsinki Declaration and its later amendments or comparable ethical standards. The study protocol was analysed and approved by the Bioethical Committee of the National University of La Plata.

Informed consent Informed consent was given in writing by all individual subjects included in the study.
