Abstract

Septic cardiomyopathy is a life-threatening organ dysfunction caused by sepsis. Ribonuclease 1 (RNase 1) belongs to a group of host-defense peptides that specifically cleave extracellular RNA (eRNA). The activity of RNase1 is inhibited by ribonuclease-inhibitor 1 (RNH1). The role of RNase 1 in septic cardiomyopathy and associated cardiac apoptosis, however, is completely unknown. Here, we showed that sepsis resulted in a significant increase in RNH1 and eRNA serum levels compared to those of healthy subjects ($p < 0.05$). Treatment with RNase 1 resulted in a significant decrease of apoptosis, induced by the intrinsic pathway, and TNF expression in murine cardiomyocytes exposed to either necrotic cardiomyocytes or serum of septic patients for 16 h ($p < 0.05$). Furthermore, treatment of septic mice with RNase 1 resulted in a reduction in cardiac apoptosis, TNF expression and septic cardiomyopathy ($p < 0.05$). These data demonstrate that eRNA plays a crucial role in the pathophysiology of the organ (cardiac) dysfunction in sepsis and RNase and RNH1 may be new therapeutic targets/strategies to reduce the cardiac injury and dysfunction caused by sepsis.

Introduction

Sepsis is one of the most common causes of death on intensive care units and is defined as a life-threatening organ dysfunction secondary to an infection (1, 2). In addition to respiratory failure, septic cardiomyopathy is a common organ dysfunction in septic shock and is clearly associated with prolonged hospital stays and increased mortality (3, 4). Septic cardiomyopathy is a functional restriction of the heart that results in a ventricular dilation and reduced contractility (5, 6). To date, however, no specific therapeutic strategies are available.

The tissue injury associated with sepsis results in the release of a variety of damage-associated molecular patterns (DAMPs) (7, 8). Extracellular RNA (eRNA) belongs to this heterogeneous group of DAMPs and includes several types of RNA present in the extracellular environment including micro RNA (miRNA), transfer RNA (tRNA), small interfering RNA (siRNA), and long non-coding RNA (lncRNA). The eRNA is released as a result of tissue injury and necrotic cell death from a variety of cells including cardiomyocytes (9) and may play a role in differentiation, chromatin modification, inflammation as well as tissue injury and repair (10-14). It is, however, not known whether eRNA plays a role in septic cardiomyopathy and cardiac apoptosis. Playing a decisive role in septic cardiomyopathy (15), apoptosis represents a programmed, caspase-mediated cell death that is triggered by intrinsic or extrinsic signaling pathways.

In 1988, Steven Benner described eRNA as an intercellular “communicator” and hypothesized that their activity is modulated by endogenous ribonucleases (RNases) (16). RNases belong to a group of host-defense peptides, which are ubiquitously expressed in several tissues and body fluids. As a part of the innate immune system, RNases modulate local and systemic inflammatory responses induced by exogenous pathogens and endogenous danger molecules (17). Specifically, RNase 1 cleaves eRNA and, hence, modulates/limits the levels of circulating

eRNA (17). As an endogenous modulator of RNase 1, the human ribonuclease-inhibitor 1 (RNH1) is ubiquitously expressed in a variety of tissues and binds to and inactivates RNase 1 with a high affinity (18, 19). RNH1 and RNase 1 have complementary structures (20). Primarily induced by oxidative stress (20), RNH1 regulates the activity of RNases and, thus, plays a crucial role in the immunomodulatory and host-defense functions of RNases (21). The respective roles of RNase 1 and RNH1 in septic cardiomyopathy and cardiac apoptosis, however, are completely unknown.

The aim of this reverse-translational study was to investigate a) the levels and kinetics of RNH1 and the eRNA profile in the serum of patients with sepsis and healthy subjects (control), b) the potential of RNase 1 to reduce apoptosis in cardiomyocytes and c) whether the application of RNase 1 attenuates septic cardiomyopathy and cardiac apoptosis in a murine model of polymicrobial sepsis.

Results

RNH1 is elevated in serum of septic patients

We recently reported that serum levels of RNase 1 are significantly elevated in the early phase of sepsis (22). As RNH1 inhibits the enzymatic activity of RNase 1, we have now investigated the serum levels of RNH1 in septic patients (n = 21) on the day of diagnosis and three days after diagnosis. Moreover, we analyzed serum levels of RNH1 in healthy subjects (n = 10) matched in age and gender. The characteristics of the study population according to the groups are shown in Table 1 in the supplemental material. In healthy subjects, the RNH1 concentrations were below the detection limit of the ELISA used (1.563 ng/ml; n = 10; Figure 1A). In contrast, a mean concentration of 4.22 ± 1.00 ng/ml RNH1 was detected in the serum of septic patients at time of diagnosis (Figure 1A), which rose further to 5.29 ± 1.36 ng/ml at three days after diagnosis of sepsis ($p < 0.05$ when compared to healthy subjects; Figure 1A).

Levels of eRNA are elevated in serum of septic patients

Having discovered elevated serum levels of RNase 1 and of its inhibitor RNH1 in patients with sepsis, we then measured the levels of eRNA in serum of septic patients three days after diagnosis (n = 21) and healthy volunteers (n = 10). Furthermore, we investigated the different sizes of eRNA presented in serum of septic patients and healthy volunteers. A mean concentration of 59.64 ± 4.92 ng/ μ l eRNA was measured in healthy subjects. In contrast, in serum of septic patients three days after diagnosis a significantly increased mean concentration of 105.6 ± 4.85 ng/ μ l eRNA was detected ($p < 0.05$ when compared to healthy subjects; Figure 1B). The electropherograms from serum of septic patients three days after diagnosis (n = 21) showed a higher variety of eRNA compared to healthy subjects (n = 10; Figure 1C). In healthy volunteers, a more uniform eRNA size distribution was observed, with the highest sample

intensity in the serum of healthy volunteers lying between 100 and 500 nt. In contrast, the serum of septic patients showed a much higher variance in eRNA size distribution and a much higher sample intensity, which is caused by the higher concentration of eRNA in the serum of septic patients (Figure 1C).

RNase 1 reduces the caspase 3 activation and apoptosis induced by necrotic cardiomyocytes

Septic cardiomyopathy is associated with cardiac apoptosis and necrotic cell death (23, 24). We investigated the potential induction of apoptosis by eRNA released from necrotic cardiomyocytes by exposing murine cardiomyocytes to necrotic cardiomyocytes. We also investigated whether RNase 1 reduces the degree of apoptosis caused by the eRNA released from necrotic cardiomyocytes. Cardiomyocytes exposed to necrotic cardiomyocytes, in the absence of RNase 1 treatment, showed a significant increase of cleaved/activated caspase 3 when compared to unstimulated cells as measured by immunofluorescence ($p < 0.01$; Figure 2A and B). Treatment with RNase 1, however, resulted in a decrease in caspase 3 activation ($p < 0.05$; Figure 2A and B). As eRNA leads to an increased expression of tumor necrosis factor alpha (TNF) via binding to toll-like receptor (TLR) 3 and 7 (23-25), we investigated TNF mRNA expression in this setting. Indeed, we found that cardiomyocytes stimulated with necrotic cardiomyocytes in the presence of RNase 1 showed a significant reduction in the expression of TNF mRNA when compared to cardiomyocytes challenged with necrotic cardiomyocytes in the absence of RNase 1 ($p < 0.05$; Figure 2C). Furthermore, we investigated the amount of the total eRNA released from 10^5 NC/ml and from the cell supernatants of unstimulated/stimulated cardiomyocytes. In cell supernatant of untreated cardiomyocytes, the mean concentration of eRNA was 0.85 ± 0.07 ng/ml. In contrast, we found significantly increased eRNA concentrations in the supernatant of cardiomyocytes exposed to necrotic cardiomyocytes for 16 h (1.17 ± 0.03 ng/ml) as well as in 10^5 necrotic cells/ml (1.15 ± 0.07 ng/ml; $p < 0.05$; Figure 2D).

Next, we aimed to confirm that apoptosis was the predominant type of cell death in cardiomyocytes exposed to necrotic cardiomyocytes by TUNEL labelling. Unstimulated cardiomyocytes (control) did not show any TUNEL fluorescence (Figure 3A). In cardiomyocytes exposed to necrotic cardiomyocytes for 16 h, however, there was an increased number of TUNEL positive cells (significant increase of a mean 3.58 ± 0.47 relative TUNEL fluorescence compared to unstimulated cells; $p < 0.001$; Figure 3A and B). In contrast, the exposure of cardiomyocytes to necrotic cells in the presence of RNase 1 resulted in a smaller number of TUNEL positive cells (mean 1.91 ± 0.42 relative TUNEL fluorescence compared to cardiomyocytes exposed to necrotic cells in absence of RNase; Figure 3A and B).

The amount of apoptosis was further quantified/confirmed using flow cytometry. Relatively few unstimulated cells were positive for Annexin V ($7.57 \pm 0.36\%$), 7-AAD ($0.97 \pm 0.30\%$) and Annexin V plus 7-AAD ($0.54 \pm 0.12\%$). The main part of the population was represented by living cells (Figure 3C). Cardiomyocytes exposed to 1×10^5 necrotic cardiomyocytes contained $13.36 \pm 2.17\%$ Annexin V, $1.26 \pm 0.12\%$ 7-AAD and $0.51 \pm 0.01\%$ Annexin V and 7-AAD positive cells (Figure 3C). The exposure of necrotic cardiomyocytes in presence of RNase 1, however, resulted in $7.55 \pm 1.09\%$ Annexin V, $0.82 \pm 0.21\%$ 7-AAD and $0.96 \pm 0.77\%$ Annexin V and 7-AAD positive cells (Figure 3C). The amount of Annexin V positive cells significantly increased in cardiomyocytes exposed to necrotic cardiomyocytes compared to unstimulated cells ($p < 0.001$; Figure 3D), which was significantly diminished by the addition of RNase 1 ($p < 0.001$; Figure 3D).

RNase 1 reduces the caspase 3 activation induced by serum of septic patients

Having found that serum levels of RNH1 as well as total eRNA are significantly elevated in serum of septic patients, we investigated caspase 3 activation and TNF mRNA expression in murine cardiomyocytes challenged with serum of septic patients, as a reverse translational

approach. Specifically, we aimed to confirm the potential protective/anti-apoptotic effect of RNase 1 in this setting. When compared to unstimulated cells, cardiomyocytes exposed to serum of septic patients (in the absence of RNase 1) showed a significant increase in the cleavage of caspase 3 as well as an increase in the expression of TNF mRNA ($p < 0.05$; Figure 4A, B and C). In contrast, RNase 1 attenuated the increases in both caspase 3 activation and TNF mRNA expression in cardiomyocytes challenged with serum of septic patients ($p < 0.05$; Figure 4A, B and C).

TLR3 inhibition reduces the caspase 3 activation induced by eRNA

Having shown that apoptosis and TNF expression were induced by necrotic cardiomyocytes and serum of septic patients which both contain eRNA, we next investigated caspase 3 activation in cardiomyocytes challenged with eRNA isolated from cardiomyocytes. We detected a significantly increased relative caspase 3 activation in cardiomyocytes exposed to eRNA, when compared to unstimulated cardiomyocytes (1.26 ± 0.08 ; $p < 0.05$; Figure 4D). Furthermore, we wanted to investigate whether caspase 3 activation in cardiomyocytes exposed to eRNA is caused by binding to TLR3. Indeed, we found a decreased relative caspase 3 activation in cardiomyocytes stimulated with eRNA in presence of a TLR3 inhibitor (CU CPT 4a) compared to cardiomyocytes exposed to eRNA in the absence of the TLR3 inhibitor (1.10 ± 0.11 ; Figure 4D).

Ribonuclease improves the cardiovascular function and reduces cardiac apoptosis in murine polymicrobial sepsis

Having shown that the exposure of murine cardiomyocytes in presence of RNase 1 resulted in reduced apoptosis (when challenged with necrotic cardiomyocytes or serum of septic patients), we next investigated the effect of RNase 1 on cardiac function and cardiac apoptosis in a murine

model of polymicrobial sepsis. When compared to sham-operated mice, CLP-sepsis resulted in a substantial cardiac dysfunction (measured as a reduction of ejection fraction (EF), fractional shortening (FS) and fractional area change (FAC) by echocardiography) (all $p < 0.001$; Figure 5). Treatment with RNase 1, however, significantly attenuated the cardiac dysfunction associated with CLP-sepsis, as indicated by higher values of EF, FS (both $p < 0.001$; Figure 5) and FAC ($p < 0.01$; Figure 5) compared to vehicle-treated CLP-mice (control). In order to analyze the cardiac dysfunction in sepsis and the potential beneficial effects of RNase 1, we further investigated the left ventricular end-diastolic volume (LVEDV), left ventricular end-systolic volume (LVESV) and stroke volume (SV) as well as the cardiac output and the heart rate before echocardiography. Of note, no change in LVEDV was detected between the groups (Figure 5E). In CLP-sepsis, a significant increased LVESV was measured, when compared to sham-operated mice ($p < 0.01$; Figure 5). RNase 1 treatment of CLP-animals, however, resulted in a decrease of LVESV (when compared to vehicle-treated CLP-sepsis). Accordingly, when compared to sham-operated mice, CLP-sepsis resulted in a significant decreased SV, heart rate and cardiac output, which was significantly diminished by RNase 1 treatment (all $p < 0.01$; Figure 5). Sham operated animals treated with RNase 1 showed no changes in any of the above parameters, when compared to sham-operated animals treated with vehicle (Figure 5).

To gain a better understanding of the underlying signaling events involved in the observed beneficial effects of RNase 1 on sepsis-associated cardiomyopathy, we investigated the relevant apoptosis pathways in cardiac tissue at 24 h after onset of sepsis (e.g. the time point at which cardiac function was evaluated). When compared to sham-operated animals, CLP-sepsis resulted in a significant increase in Bax levels as well as caspase 9 and caspase 3 activation ($p < 0.001$; $p < 0.01$; $p < 0.01$; Figure 6). In contrast to vehicle-treated animals, the treatment of CLP-mice with RNase 1, however, significantly attenuated the increases in Bax levels and the associated activation of caspase 9 and caspase 3 associated with sepsis ($p < 0.01$; $p < 0.01$; $p <$

0.05; Figure 6). Furthermore, CLP-sepsis resulted in a decrease in Bcl-2 levels in the heart ($p < 0.05$; Figure 6), an effect which was also significantly attenuated by RNase 1 treatment ($p < 0.01$; Figure 6). To confirm that apoptosis is induced by CLP in the heart, we analyzed the number of apoptotic cells in heart tissue by TUNEL labelling. When compared to sham-operated animals, CLP-sepsis resulted in an increase in relative TUNEL fluorescence (mean 2.73 ± 0.71 relative TUNEL fluorescence; Figure 6E and F). The treatment of CLP-sepsis with RNase 1 resulted in a decreased of relative TUNEL fluorescence compared to vehicle-treated CLP-animals (mean 1.45 ± 0.60 relative TUNEL fluorescence; Figure 6E and F). Treatment of sham operated mice with RNase 1 did not result in an increase in TUNEL fluorescence (mean 0.64 ± 0.26 relative TUNEL fluorescence; Figure 6E and F).

Having discovered elevated serum levels of RNH1 and total eRNA in patients with sepsis, we also investigated the serum levels of RNase 1, RNH1 and total eRNA in murine polymicrobial sepsis. We also analyzed the TNF serum levels in CLP-sepsis in order to gain a better understanding of the underlying mechanisms and associations between the eRNA concentration and the pro-inflammatory/pro-apoptotic cardiac response. In sham-operated mice treated with vehicle or RNase 1, RNase 1 serum levels were 236.86 ± 8.11 ng/ml and 287.32 ± 19.37 ng/ml (Figure 7B). In contrast, untreated sepsis (24 hours after CLP-challenge) resulted in significantly decreased RNase 1 serum levels (69.68 ± 27.16 ng/ml RNase 1; $p < 0.05$ when compared to sham operated mice; Figure 7B), while septic mice treated with RNase 1 showed a mean RNase 1 concentration of 108.5 ± 22.70 ng/ml (Figure 7B). In sham-operated mice treated with vehicle, the TNF and RNH1 concentrations were below the detection limit of the ELISA used (31.3 pg/ml and 0.78 ng/ml; Figure 7A and C). CLP-animals showed TNF and RNH1 concentrations of 215.4 ± 57.86 pg/ml and 4.68 ± 0.73 ng/ml, respectively (both $n = 8$; Figure 7A and C). When compared to vehicle-treated animals, the treatment with RNase 1, however, resulted in decrease in the concentrations of TNF (41.1 ± 17.90 pg/ml; $p < 0.05$;

Figure 7A) and RNH1 (3.83 ± 1.15 ng/ml; Figure 7C). In addition, we found a significant correlation between TNF and RNase 1 concentration in CLP-mice treated with vehicle or RNase 1 (both $p < 0.05$; Figure 7F and G). Figure 7D shows the corresponding eRNA levels of the individual groups (Figure 7D). To gain a better understanding of the RNase 1 expression in sepsis, we performed a time course of RNase 1 serum levels in CLP-sepsis (Figure 7E). We detected a significant decrease of RNase 1 serum levels in CLP-sepsis compared to sham operated mice at all time points (all $p < 0.05$; Figure 7E). The highest RNase 1 serum levels in CLP-sepsis could be measured 1 h after sepsis induction by CLP (177.21 ± 62.78). We detected the lowest RNase 1 serum levels at 3 h after surgery (11.43 ± 1.20), with the levels increasing again (52.14 ± 18.59) at 24 h after surgery.

Discussion

Septic cardiomyopathy is a life-threatening organ dysfunction associated with a complicated postoperative course and increased mortality. Despite intense efforts in basic and clinical research, the therapy of this condition is supportive in nature, as no specific therapy is available (5). This urgently necessitates a better understanding of the underlying pathophysiology and most importantly, the identification of new therapeutic targets and strategies. This study provides the first evidence that RNase 1 reduces cardiac apoptosis and attenuates septic cardiomyopathy by reducing the levels of circulating eRNA in a murine model of polymicrobial sepsis.

Specifically, we report here for the first time that the levels of RNH1, the endogenous inhibitor of RNase 1, are significantly elevated on the day of diagnosis and three days after diagnosis of sepsis (Figure 1A). We have also recently reported an increased serum expression of RNase 1 at the onset of sepsis (22). RNH1 specifically binds to RNase 1 and inhibits its activity (20). Based on these findings, we hypothesized that an increase in RNH1 expression results in an increase of eRNA levels, due to inhibition of the enzymatic activity of RNase 1 by RNH1 (Figure 8). Indeed, we found significantly elevated levels of free circulating eRNA in the serum of septic patients (Figure 1B). The tissue injury and cell death in sepsis and septic shock leads to a loss of tissue integrity and subsequently to the release of both cell-free DNA and eRNA into the circulation (26). Although there is good evidence that cell-free DNA plays a crucial role in the crosstalk between tissue injury, inflammation, and coagulation, only very little is known about the physiological and pathophysiological roles of eRNA in sepsis (27). It has been suggested that the negative charge of eRNA builds the structural feature rendering eRNA capable of activating factor XII and, hence, coagulation (28, 29). Moreover, Chen and colleagues report that eRNA contributes to myocardial inflammation via TLR-3-Trif signaling (23). Whether or not eRNA plays a role in cardiac apoptosis, which plays a pivotal role in the

pathophysiology of septic cardiomyopathy, however, was not known. To address this important question, we exposed cardiomyocytes to necrotic cardiomyocytes or serum of septic shock patients (Figure 2, 3 and 5). In line with the work from Chen and colleagues, we used necrotic cardiomyocytes (as our source of eRNA) to stimulate cardiomyocytes with eRNA (23). This approach enabled us to expose cardiomyocytes to the eRNA contained in cardiomyocytes, which contain several types of RNA (e.g. miRNA, tRNA and siRNA) (10). In addition to the free circulating, extracellular RNA, in both stimulants (necrotic cardiomyocytes and serum of septic patients) a part of the RNA may be encapsulated in extracellular vesicles such as exosomes or microvesicles and, thus, be protected from the digestion of RNase 1 (30, 31). Nevertheless, we were able to show that RNase 1 significantly reduces both apoptosis and inflammation in murine cardiomyocytes (Figure 2, 3 and 4). To standardize our model, we first measured the total amount of eRNA in the cell supernatant of cardiomyocytes exposed to necrotic cardiomyocytes (Figure 2D). In fact, we found an increased release of eRNA into the cell supernatant of cardiomyocytes exposed to necrotic cardiomyocytes compared to the cell supernatant of untreated cardiomyocytes (Figure 2D). We further found a significant activation (measured as cleavage) of caspase 3 and consecutive induction of apoptosis by exposing murine cardiomyocytes to either necrotic cardiomyocytes or, of note, serum of septic patients (Figure 2 and 4). Furthermore, to address the question as to whether the observed increase in apoptosis is caused by eRNA, we exposed cardiomyocytes to eRNA isolated from cardiomyocytes. Indeed, we found a significantly increase in caspase 3 activation in cardiomyocytes challenged with eRNA compared to unstimulated cells (Figure 4D). In line to Chen and colleagues, we showed that eRNA contributes to induction of apoptosis (caspase 3 activation) via TLR3 signaling (Figure 4D) (23). Having shown that sepsis is associated with elevated RNH1 levels, we next aimed to investigate the potential protective/therapeutic effects of RNase 1.

We report here for the first time that RNase 1 attenuates caspase 3 activation and apoptosis in

cardiomyocytes exposed to either necrotic cardiomyocytes or, as a reverse translational approach, to the serum of septic patients. Previous studies have investigated the therapeutic potential of a reduction/inhibition of apoptosis by direct/specific caspase-inhibition in animal models of cardiomyopathy induced by ischemia/reperfusion and rapid ventricular pacing (32, 33). Cabrera-Fuentes *et al.* reported that RNase 1 treatment reduces the infarct size caused by myocardial ischemia/reperfusion (34). Furthermore, they measured a reduction in necrotic cell death in ischemic hearts treated with RNase 1 compared vehicle-treatment (34). In addition, there is also good evidence that eRNA released from necrotic cells triggers the release of pro-inflammatory cytokines, while RNase1 reduces the formation of cytokines (23, 24), which play a key role in septic cardiomyopathy and cardiac apoptosis (35, 36). We report here that RNase 1 attenuates TNF mRNA expression in cardiomyocytes exposed to either necrotic cardiomyocytes or serum of septic patients. Thus, RNase 1 may attenuate septic cardiomyopathy by reducing both cardiac apoptosis and cytokine production.

In order to gain a better insight into the roles of RNH1, RNase 1 and eRNA in septic cardiomyopathy *in vivo*, we used a murine model of polymicrobial sepsis. Having shown increased serum levels of RNase 1 in patients at the early phase (onset) of sepsis (22), we here detected significantly lower RNase 1 serum levels in CLP-mice (at 24 h after onset of sepsis). The very short half-life of RNase 1 as well as the inhibition of RNase 1 by RNH1 may all be reasons, which either individually or in combination contribute to the differences observed. In line with our findings in human sepsis, we found that the levels of RNH1 are significantly elevated in mice with polymicrobial sepsis (Figure 7C). Based on these findings, we propose that an increase in RNH1 expression results in a decreased RNase 1 expression/enzymatic activity, which results in an increase in circulating eRNA leading to a release of pro-inflammatory cytokines (Figure 8). To substantiate this hypothesis, we have investigated the effect of RNase 1 as a therapeutic target on the cardiac dysfunction associated with sepsis. We

confirm that the model of polymicrobial sepsis used here, indeed, results in a significant cardiac dysfunction defined by a significant decrease in ejection fraction, fractional shortening and fraction area change (Figure 5). Stieger *et al.* reported a significant increase of fractional shortening in mice treated with RNase 1 (50 µg/kg) compared to mice treated with saline 24 h after myocardial infarction (37). In line, we detected a significant reduction in left ventricular cardiac dysfunction in CLP-mice treated with RNase 1 as determined by a significant increase in ejection fraction, fractional shortening, fraction area change and cardiac output (Figure 5). Moreover, we detected a significant reduction in the release of TNF in CLP-mice treated with RNase 1 when compared with CLP-mice treated with vehicle (Figure 7A). Additionally, we found a negative correlation between the RNase 1 and TNF concentration, higher RNase 1 serum levels were associated with lower TNF levels (Figure 7E and F). These findings support the hypothesis that eRNA released from necrotic cells triggers the release of pro-inflammatory cytokines, while RNase 1 reduces the formation of cytokines by cleaving eRNA (Figure 8). Notably, treatment of CLP-mice with RNase 1 reduced the cardiac dysfunction associated with sepsis.

We also investigated the sepsis-associated degree of cardiac apoptosis in our murine model of polymicrobial sepsis. The induction of apoptosis can be triggered by either the intrinsic or the extrinsic pathway. Several studies have shown that cytochrome C and Apaf-1 form an apoptosome which activates caspase 9 (38), which, in turn, activates caspase 3. Activated caspase 3 then initiates and drives apoptosis. Indeed, we observed a significant activation of the intrinsic apoptosis signaling pathway in murine hearts from mice with polymicrobial sepsis, indicated by a significant increase in Bax levels, activation of caspase 9 and caspase 3 and a decrease of Bcl-2 (Figure 6). Furthermore, we measured increased apoptosis induction in heart tissue by TUNEL-labeling (Figure 6). In line with our findings, Hotchkiss *et al.* reported as early as 1999 that apoptosis in the spleen of septic patients also occurs through the intrinsic

apoptosis pathway (39). Treatment of CLP-mice with RNase 1 resulted in a reduction of the activation of apoptosis in the heart. Most notably, treatment of septic mice with RNase 1 attenuated the rise in cardiac Bax levels, activation of caspase 9 and caspase 3, the decrease in Bcl-2 and TUNEL-positive cells caused by sepsis in the heart (Figure 6). In line with our findings, Stieger *et al.* reported a reduction of apoptosis 24 h after ligation of the left anterior descending artery (LAD) in mice treated with RNase 1 (37). Treatment with RNase 1 in sham operated mice did not show any apoptosis induction (Figure 6). These results indicate that excessive amounts of eRNA drive apoptosis in the heart by activating the intrinsic apoptosis pathway. However, in contrast to the eRNA serum levels of septic patients, we could not detect any difference in eRNA expression in CLP-mice compared to sham operated mice (Figure 7D). One possible reason for the different results may be the different time points of the measurements: While eRNA concentration was measured in patients with sepsis three days after diagnosis, the concentration of eRNA in mice was measured 24 h after CLP-sepsis induction. This hypothesis is also confirmed by Stieger and colleagues, who reported increased eRNA levels within 30 min and maximal eRNA levels at 2 h after ligation of the LAD. However, 4 h after ligation of LAD, the eRNA levels had returned to baseline (37).

In conclusion, our data show for the first time that sepsis results in a significant increase in eRNA and RNH1, the endogenous inhibitor of RNase 1. We found that RNase 1 reduces apoptosis as well as TNF expression in murine cardiomyocytes induced by necrotic cardiomyocytes or serum of septic patients. In addition, treatment with RNase 1 reduces the degree of a) cardiac apoptosis induced by the intrinsic pathway, b) TNF expression and c) the cardiac dysfunction caused by polymicrobial sepsis in mice. Based on these findings we propose that a) eRNA plays a significant role in the pathophysiology of the organ (cardiac) dysfunction in sepsis and b) RNase may be a new therapeutic strategy to reduce the cardiac injury and dysfunction caused by sepsis.

Materials and methods

Study Population

The blood samples of septic ICU patients (n = 21) were collected during the first 18 h and three days after diagnosis of sepsis defined by the 2012 Surviving Sepsis Campaign Guidelines using an intravascular catheter (40). Age and gender matched healthy subjects were used as control (n = 10).

Serum sampling

After 10 min of coagulation at room temperature, the serum samples were centrifuged at 2000 g for 10 min and stored at -80 °C (22). The characteristics of the study population are shown in Table 1 according to the groups: healthy subjects, patient with sepsis on the day of diagnosis (Sepsi DD) and patients with sepsis three days after diagnosis (Sepsis D3).

Enzyme-Linked Immunosorbent Assays (ELISA)

The levels of the RNH1 and RNase 1 in human and mice serum were determined using a commercial ELISA kit (LifeSpan BioSciences, Seattle, Washington, USA). According to the manufacturer, no significant cross-reactivity or interference between Ribonuclease A / RNASE1 and analogues is known. Furthermore, the ELISAs do not distinguish between bound RNase 1 and unbound RNase 1 with RNH1. Mouse TNF-alpha DuoSet ELISA kit (R&D Systems, Minneapolis, Minnesota, USA) was used to measure the TNF serum levels in mice. The optical density was measured at 450 nm using a microplate reader (Tecan Group, Männedorf, Switzerland).

Total eRNA analyzation and screening

Total eRNA in serum of healthy subjects (n = 10) and septic patients three days after diagnosis (n = 21) were analyzed using QuantiFlour RNA System and Quantus Fluorometer (Promega, Madison, Wisconsin, USA). For RNA size quantification cell-free RNA was isolated from serum of healthy subjects and patients with sepsis by the Quick-cfRNA Serum & Plasma Kit (Zymo Research, Irvine, Kalifornien, USA). The 4200 TapStation system and the high sensitivity RNA ScreenTape Assay (Agilent, Santa Clara, Californian, USA) was used for analyzing the RNA molecules from 50-6000 nucleotides.

Cell culture

HL-1 cells, a mouse atrial cell line, were provided by Dr. Claycomb (Sigma-Aldrich, Munich, Germany) (41). Briefly, HL-1 cells were cultured on gelatin/fibronectin coated plates and maintained in Claycomb-Medium (Sigma-Aldrich, Munich, Germany) supplemented with 10% fetal calf serum (Biochrom, Berlin, Germany), 0.1 mM norepinephrine (Sigma-Aldrich, Munich, Germany), 2 mM L-glutamine (Sigma-Aldrich, Munich, Germany) and 1% penicillin/streptomycin (Invitrogen, Carlsbad, Californian, USA) under an atmosphere of 5% CO₂ at 37°C (42-45). Cardiomyocytes were exposed to 1x10⁵ necrotic cardiomyocytes per ml medium or to 5% serum of septic patients in the presence or absence of 2.8 U/ml RNase 1 (Invitrogen) for 16 h. Unstimulated cells were used as negative control.

Necrotic Cardiomyocytes

Necrotic cardiomyocytes were generated as described recently, by three circles of freezing at -80°C and thawing at 37°C (23). Necrosis was verified by trypan blue staining. Necrotic cells (1x10⁶ cells/ml) were stored at -80°C.

RNA extraction of cardiomyocytes

HL-1 cells were cultivated as described before and harvested by scraping (45). After three washing cycles with PBS the RNA was isolated using the NucleoSpin RNA Kit (Macherey-Nagel, Düren, Germany).

Cell stimulation

Cardiomyocytes were exposed to 1×10^5 necrotic cardiomyocytes per ml medium or to 5% serum of septic patients in the presence or absence of 2.8 U/ml RNase 1 (Invitrogen) for 16 h. Unstimulated cells were used as negative control. Furthermore, cardiomyocytes were exposed to 100 ng/ml RNA in presence or absence of 2 μ M CU CPT 4a (TLR3 inhibitor, Tocris Bioscience, Bristol, United Kingdom).

Immunofluorescence of cleaved caspase 3

The amount of cleaved caspase 3 was analyzed using immunofluorescence. As described previously (45), HL-1 cells were grown on coverslips and exposed to necrotic cardiomyocytes or serum of septic patients in presence or absence of 2.8 U/ml RNase 1 for 16 h. Afterwards, cells were fixed with 4% formaldehyde (Sigma-Aldrich, Munich, Germany) for 15 min at room temperature. After three times of washing using PBS, cells were blocked with blocking buffer (5% BSA and 0.3% Triton X-100 in PBS) for 1 h. The cardiomyocytes were, then, incubated with a primary antibody directed against cleaved caspase 3 (Cell signaling, Danvers, Massachusetts, USA), diluted 1:200 in antibody dilution buffer (1% BSA and 0.3% Triton X-100 in PBS) over night at 4°C. After three washing cycles, the cardiomyocytes were incubated with a secondary antibody (Invitrogen, Carlsbad, California, USA) diluted 1:1000 in antibody dilution buffer for 2 h at room temperature in the dark. Coverslips were washed as described before and covered with ProLong Gold (Invitrogen, Carlsbad, California, USA) containing 4',6-

diamidino-2-phenylindole (DAPI) for nuclei staining. Immunofluorescence was detected using LSM 710 confocal microscope (Zeiss, Oberkochen, Germany) and quantified by ImageJ software.

TUNEL-labelling

As described previously (45), HL-1 cells were grown in 12-well plates on coverslips coated with gelatin/fibronectin. HL-1 cells were fixed with 4% formaldehyde for 1 h at room temperature after exposure with necrotic cells in presence or absence of RNase 1 for 16 h. After washing, cells were permeabilized with 0.1% Triton X-100 for 2 min on ice. Next, cells were labeled using the *In-Situ* Cell Detection Kit TMR red (Roche, Mannheim, Germany) as described (45). Coverslips were covered with 15 µl ProLong Gold. Unstimulated cells were used as negative control. The paraffin embedded heart tissues were dewaxed by a series of alcohol and washed twice in PBS. The tissues were permeabilized in the microwave with 0.1 M citrate buffer (pH 6.0) for 5 min by 350 W. After cooling down the tissues were labeled also using the *In-Situ* Cell Detection Kit TMR red (Roche, Mannheim, Germany) and covered with ProLong Gold. An LSM 710 confocal microscope (Zeiss, Oberkochen, Germany) and ImageJ software was used to detect and quantify apoptotic cells.

Relative TNF mRNA expression

RNA was isolated using Trizol reagent, as described before (45). The following primers were used to analyze the relative mRNA expression of TNF in the quantitative real-time PCR (StepOnePlus Real-Time PCR System; Thermo Fisher Scientific, MA, USA): TNF 5' TCCCCAAAGGGATGAGAAG 3' (for) and 5' GCACCACTAGTTGGTTGTC 3' (rev), S7 5' GGTGGTCGGAAAGCTATCA 3' (for) and 5' AAGTCCTCAAGGATGGCGT 3' (rev). Relative quantification was performed by using Microsoft Excel (Microsoft, Washington, DC, USA).

Flow cytometry

The amount of cell death was analyzed as described before by using flow cytometry (45). Stimulated cardiomyocytes were harvested by scraping. After three washing cycles with PBS, the supernatant was discarded and cells were resuspended in binding buffer as described in the APC Annexin V Apoptosis Detection Kit (BD Pharming, New Jersey, USA). Cells were stained with APC Annexin V Apoptosis Detection Kit and analyzed by FACSCanto-II (BD Biosciences, New Jersey, USA).

Caspase 3 activity

To analyze the caspase 3 activity 1.5×10^4 cardiomyocytes/well were seeded in a 96-well white plate. After 24 h the cells were exposed with 100 μ l medium containing RNA in presence and absence of TLR3 inhibitor. Untreated cells were used as negative control. The caspase 3 activity was analyzed by adding 100 μ l of Caspase-Glo® 3/7 Assay reagent (Promega Corporation, Madison, Wisconsin, USA). The luminescence was detected after 30 min of incubation at room temperature using microplate reader (Tecan Group, Männedorf, Switzerland).

Murine polymicrobial sepsis model

For this study, ten-week old, male C57BL/6 mice were used. Cecal ligation and puncture (CLP) was performed to induce polymicrobial sepsis as previously described (46, 47). Surgery was performed under anesthesia by isoflurane (3%) delivered in oxygen at a rate of 1 l/min in an anesthetic chamber and maintained with isoflurane (2%) and oxygen (1 l/min) via a face mask. Buprenorphine (0.05 mg/kg, i.p.) was administered just before starting the surgery to obtain adequate analgesia. Under anesthesia, the abdomen was opened, the cecum was totally ligated below the ileocecal valve and punctured at both opposite ends using an 18-G needle, where a small amount of feces was squeezed out. As control, sham operated mice (without CLP) were

used. For fluid resuscitation, normal saline (0.9% NaCl) was administered into the mouse's abdomen before closure (5 ml/kg) and administered directly after surgery (10 ml/kg s.c.). Antibiotics (Imipenem/Cilastatin; 0.25 mg dissolved in fluid resuscitation 7.5 ml/kg 0.9% NaCl, s.c.) and analgesia (Buprenorphine; 0.05 mg/kg, i.p.) were injected 6 and 18 h after surgery. RNase 1 or its vehicle was administered before sepsis induction (50 µg/kg RNase 1 or 0.9% NaCl, i.v.), directly after surgery (200 µg/100 µl RNase 1 or 100 µl 0.9% NaCl, s.c.) and 4 h after surgery (500 µg/100 µl RNase 1 or 100 µl 0.9% NaCl, s.c.). The surgeon was blinded to vehicle or treatment group. After 24 h, cardiac function was assessed by echocardiography *in vivo*.

Echocardiography

Cardiac function was assessed 24 h after CLP on the Vevo 3100 imaging system (VisualSonics, Toronto, Ontario, Canada). Briefly mice were sedated in an anesthetic chamber with isoflurane (3%) delivered in oxygen at a rate of 1 l/min and then transferred onto a thermoregulatory platform in the supine position, where anesthetic was maintained at: isoflurane (0.5-2.0%) and oxygen (1 l/min). The fur was removed from the chest by Veet® hair removal cream and pre-warmed echo gel was then placed onto the shaven chest, where the following parameters of cardiac function was measured via the MX550D imaging probe: percentage ejection fraction (EF %), percentage fractional shortening (FS %) and percentage fractional area change (FAC %). After sacrifice of the animals, the organs and blood were collected for further experiments. All analysis was conducted offline and blinded.

Protein isolation and Western-Blot

Semi-quantitative Western-Blot analysis of caspase 3, caspase 9, Bax and Bcl-2 was performed in murine heart tissue as described before (48, 49). For protein isolation, the tissue was

homogenized in homogenization buffer (20 mM HEPES (pH 7.9), 1 mM MgCl₂, 0.5 mM EDTA, 1% Nonidet P-40, 1mM EGTA, 1 mM DTT, 0.5 mM PMSF, 1 µl/ml of PIC) and centrifuged by 18800 g for 40 min at 4°C. The protein concentration of the supernatant was determined using the bicinchoninic acid (BCA) protein assay (Thermo Fisher Scientific, MA, USA). Proteins were separated by size using sodium dodecyl sulfate polyacrylamide gel electrophoresis and transferred to polyvinylidene difluoride membrane. Unspecific bonds were blocked by incubating the membrane for one hour in blocking buffer (10% BSA in TBS containing 0.1% Tween). Following, the membrane was incubated with the primary antibody over night at 4°C diluted in 5% BSA in TBS containing 0.1% Tween. After three washing cycles, the membrane was incubated for 30 min with the HRP-conjugated secondary antibody. Protein bands were detected with enhanced chemiluminescent (ECL) detection system. The immunoreactive bands were visualized by autoradiography and the densitometric analysis was performed using Gel Pro Analyzer 4.5, 2000 software (Media Cybernetics, Silver Spring, MD, USA). Results were normalized by using Tubulin as an endogenous control. The following primary antibodies from Cell Signaling were used: caspase-9 (C9) mouse (#9508), Bcl-2 (D17C4) rabbit (#3498), caspase-3 rabbit (#9662), Bax (D3R2M) rabbit (#14796).

Statistical analysis of the measurements

The statistical analysis and the graphs were performed with GraphPad Prism 7 (GraphPad Inc., San Diego, California, USA). A one-way ANOVA followed by Bonferroni test or unpaired t-test (two-tailed) were used for multiple comparisons with a significance level of $p < 0.05$. The data represent the mean \pm SEM of three independent experiments.

Study approval

All serum samples were collected in a study carried out by the Department of Intensive Care and Intermediate Care at University Hospital RWTH Aachen and were stored in the centralized

biomaterial bank (RWTH cBMB) after informed consent of all study participants and approval by the local ethics committee (EK 206/09).

The Animal Welfare Ethics Review Board of the Queen Mary University of London approved the animal experimental protocols used in this study (Procedure Project License: PC5F29685). Animal care was in accordance with the guidelines of the Home Office guidance on Operation of Animals (Scientific Procedures Act 1986) published by Her Majesty's Stationery Office and the Guide for the Care and Use of Laboratory Animals of the National Research Council.

Author contributions

Conception and design: EZ, LM and CT. In vitro experiments and data analyses: EZ, NW, LM, TS, SE and GMN. In vivo experiments and data analyses: CEO, EZ, LS, LM, CT, SMC and BW. eRNA measurements and data analyses: BD, TPS, CS, EZ and LM. Performing western blots and data analyses: FC, DC, MC, EZ, CT and LM. Drafting and/or revising the manuscript for important intellectual content: EZ, GM, LM and CT. All the authors reviewed and finally approved the manuscript.

Acknowledgments

This work was supported by an intramural grant to EZ (START 113/17), a grant of the German Research Foundation to LM (DFG, MA 7082/1-1) and a grant of the Federal Ministry of Education and Research, Germany to SMC (BMBF 03Z22JN12, Research Group Translational Septomics, Centre for Innovation Competence Septomics). CT is funded by the Centre for Diabetic Kidney Disease, which is funded by the Barts and London Charity, and the William Harvey Research Foundation (WHRF). This work was supported by the RWTH centralized Biomaterial Database (RWTH cBMB) of the University Hospital RWTH Aachen and by the Confocal Microscopy Unit, a core facility of the Interdisciplinary Center for Clinical Research (IZKF) Aachen within the Faculty of Medicine at RWTH Aachen University. The authors thank Nadine Frank, Daniel Hinkelmann and Oliver Krenkel for excellent technical support.

Figures

Figure 1

RNH1 and total extracellular RNA serum levels

(A) RNH1 levels of healthy subjects (n = 10) and ICU patients with sepsis on the day of diagnosis (Sepsis DD) and three days after diagnosis (Sepsis D3; both n = 21) are displayed. A one-way ANOVA followed by Bonferroni test was used for multiple comparisons. Data are presented as dot plot with the mean \pm SEM. (B) Total eRNA levels from serum of healthy subjects (n = 10) and septic patients three days after diagnosis (n = 21) are demonstrated. An unpaired t-test (two-tailed) was used for statistical analysis. Data are presented as dot plot with the mean \pm SEM. (C) The eRNA size distribution from serum of healthy subjects (n = 10) and septic patients three days after diagnosis (n = 21) are presented in an electropherogram and a gel image. The first peak (between 10 and 100 nt) of the electropherograms represented the ladder. §p < 0.05 vs control/healthy; RNH1 = ribonuclease-inhibitor 1; eRNA = extracellular RNA

Figure 2

RNase 1 treatment results in decrease of cleaved caspase 3 immunofluorescence and TNF mRNA expression in murine cardiomyocytes exposed to necrotic cardiomyocytes

(A) Cardiomyocytes exposed to 10^5 necrotic cardiomyocytes (NC) for 16 h in presence (RNase + NC) or absence of 2.8 U/ml RNase 1 were stained with Phalloidin, DAPI and anti-cleaved caspase 3 and compared to unstimulated cells (control). Phalloidin represents the cytosol (red), DAPI stained the nuclei (blue) and the green immunofluorescence represents the cleaved caspase 3 (cl. caspase 3) expression. Scale bars: 100 μ m. (B) Quantification of cleaved caspase 3 immunofluorescence (all n = 3). A one-way ANOVA followed by Bonferroni test was used for multiple comparisons. Data are presented as dot plot with the mean \pm SEM. (C) Relative TNF mRNA expression of cardiomyocytes exposed to NC in presence of RNase 1 compared to cardiomyocytes stimulated in absence of RNase 1 (both n = 3). An unpaired t-test (two-tailed) was used for statistical analysis. Data are presented as dot plot with the mean \pm SEM. (D) Total extracellular RNA in cell supernatant of cardiomyocytes exposed to NC for 16 h and untreated cells (both n = 3) as well as eRNA level in 10^5 NC/ml (n = 2). A one-way ANOVA followed by Bonferroni test was used for multiple comparisons. Data are presented as dot plot with the mean \pm SEM. [§]*p* < 0.05 vs control; [#]*p* < 0.05 vs NC; DAPI = 4',6-diamidino-2-phenylindole; NC = necrotic cardiomyocytes; RNase = ribonuclease 1

Figure 3

RNase 1 treatment of cardiomyocytes exposed to necrotic cardiomyocytes results in decreased apoptosis

Cardiomyocytes exposed to 10^5 necrotic cardiomyocytes in presence (RNase + NC) or absence (NC) of 2.8 U/ml RNase 1 for 16 h compared to unstimulated cells (control) were analyzed (all $n = 3$). (A) Apoptotic cells were labeled with TUNEL (red) and the nuclei of cardiomyocytes stained with DAPI (blue). Scale bars: 100 μm . (B) Quantification of TUNEL fluorescence. A one-way ANOVA followed by Bonferroni test was used for multiple comparisons. Data are presented as dot plot with the mean \pm SEM. (C) Treated HL-1 cells were stained with Annexin V and 7-AAD and analyzed by flow cytometry. Gate I (lower left) displays the living cells. The Annexin V positive cells are shown in Gate II (top left) and represent the apoptotic cardiomyocytes. The double positive cells are demonstrated in Gate III (top right) and in Gate IV (lower right) the 7-AAD positive or necrotic cells are located. (D) The percentage of Annexin V positive (apoptotic) cells are displayed. A one-way ANOVA followed by Bonferroni test was used for multiple comparisons. Data are presented as dot plot with the mean \pm SEM. [§] $p < 0.05$ vs control; [#] $p < 0.05$ vs NC; NC = necrotic cardiomyocytes; RNase = ribonuclease 1; DAPI = 4',6-diamidino-2-phenylindole; TUNEL = TdT-mediated dUTP-biotin nick end labeling

Figure 4

RNase 1 treatment or TLR3 inhibition results in decrease of caspase 3 activation and TNF expression in murine cardiomyocytes exposed to serum of septic patients or RNA

(A) Cardiomyocytes exposed to 5 % serum of patients with sepsis (SsP) for 16 h in presence (RNase + SsP; n = 4) or absence of 2.8 U/ml RNase 1 (n = 3) were stained with DAPI and anti-cleaved caspase 3 and compared to unstimulated cells (control; n = 3). DAPI stained the nuclei (blue) and the green immunofluorescence represents the cleaved caspase 3 (cl. caspase 3) expression. Scale bars: 50 μ m. (B) Quantification of cleaved caspase 3 immunofluorescence. A one-way ANOVA followed by Bonferroni test was used for multiple comparisons. Data are presented as dot plot with the mean \pm SEM. (C) Relative TNF mRNA expression of cardiomyocytes exposed to SsP in presence of RNase 1 compared to cardiomyocytes stimulated in absence of RNase 1 (both n = 3). An unpaired t-test (two-tailed) was used for statistical analysis. Data are presented as dot plot with the mean \pm SEM. (D) Relative caspase activity was analyzed in cardiomyocytes exposed to 100 ng/ml eRNA and unstimulated cells for 16 h in presence (both n = 3) or absence (both n = 5) of 2 μ M TLR3-Inhibitor using Caspase Glo assay. A one-way ANOVA followed by Bonferroni test was used for multiple comparisons. Data are presented as dot plot with the mean \pm SEM. $^{\$}p < 0.05$ vs control; $^{\#}p < 0.05$ vs SsP; DAPI = 4',6-diamidino-2-phenylindole; SsP = serum of septic patients; RNase = ribonuclease 1

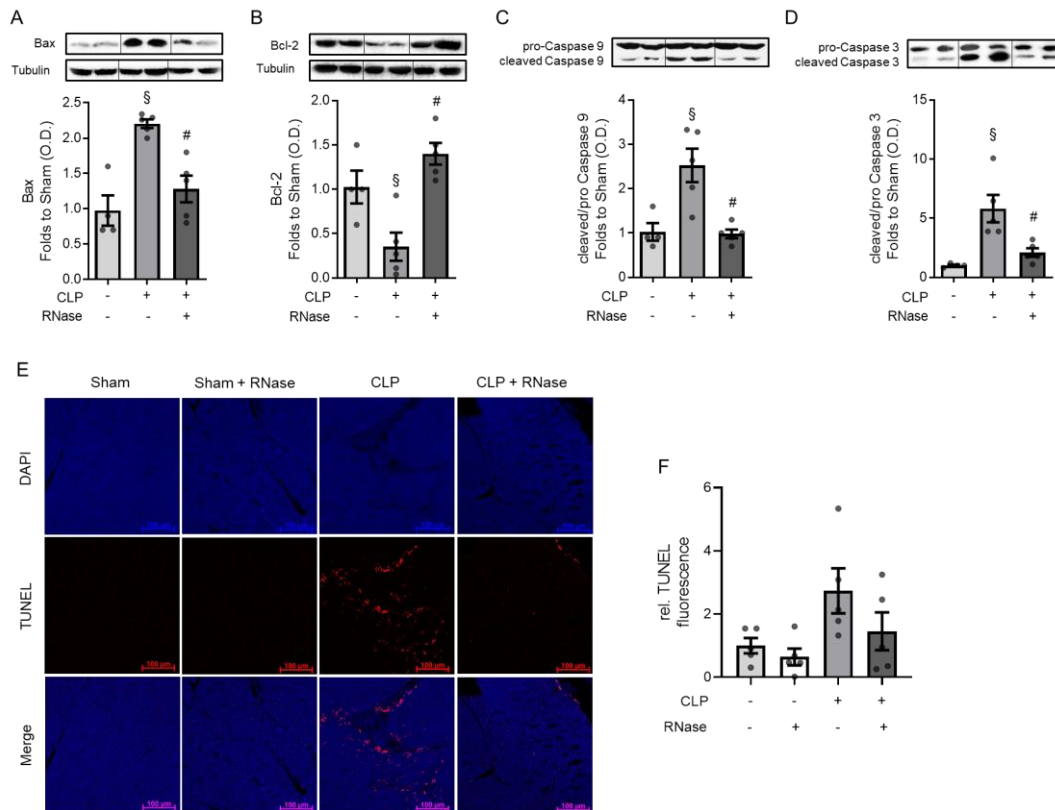

Figure 5

RNase 1 treatment of mice with polymicrobial sepsis resulted in an improved heart function

(A) Representative echocardiography images of each group are shown. (B) The ejection fraction, (C) fractional shortening, (D) fraction area change, (E) left ventricular end-diastolic volume (LVEDV), (F) left ventricular end-systolic volume (LVESV), (G) stroke volume (SV), (H) cardiac output and (I) heart rate before echocardiography of sham operated mice treated with vehicle (n = 12) or RNase 1 (n = 5) and mice with polymicrobial sepsis induced by CLP treated with vehicle or RNase 1 were analyzed (both n = 12). Individual values are plotted as mean \pm SEM. A one-way ANOVA followed by Bonferroni test was used for multiple comparisons (graph B-I). §p < 0.05 vs Sham; #p < 0.05 vs CLP + Vehicle; CLP = cecal ligation and puncture; RNase = ribonuclease 1

Figure 6

RNase 1 treatment of mice with polymicrobial sepsis resulted in a decreased cardiac apoptosis

Heart tissue of sham operated mice (n = 4) or mice with polymicrobial sepsis induced by CLP treated with vehicle or RNase 1 (both n = 5) were analyzed by Western Blot. To analyze the intrinsic apoptosis signaling pathway, (A) Bax and (B) Bcl-2 levels as well as (C) caspase 9 and (D) caspase 3 activation were investigated. A one-way ANOVA followed by Bonferroni test was used for multiple comparisons. Data are presented as dot plot with the mean ± SEM. Representative immunoblots are presented above the bar charts. The quantified OD of bands was corrected for the corresponding tubulin bands and normalized using the related sham band. Heart tissue of sham operated mice treated with vehicle or RNase or mice with polymicrobial sepsis induced by CLP also treated with vehicle or RNase 1 (all n = 5) were analyzed by TUNEL-labelling. (E) Apoptotic cells were labeled with TUNEL (red) and the nuclei of cardiomyocytes stained with DAPI (blue). Scale bars: 100 µm. (F) Quantification of TUNEL fluorescence. A one-way ANOVA followed by Bonferroni test was used for multiple comparisons. Data are presented as dot plot with the mean ± SEM. [§]*p* < 0.05 vs Sham; [#]*p* < 0.05 vs CLP + Vehicle; CLP = cecal ligation and puncture; RNase = ribonuclease 1; Bcl-2 = B-cell lymphoma 2

Figure 7

RNase 1 treatment of mice with polymicrobial sepsis resulted in a decreased TNF expression

(A) TNF, (B) RNase 1 and (C) RNH1 serum levels of sham operated mice treated with vehicle (n = 11) or RNase 1 (n = 5) or mice with polymicrobial sepsis induced by CLP treated with vehicle (n = 8) or RNase 1 (n = 9) were analyzed by ELISA. An unpaired t-test (two-tailed) was used for statistical analysis (graph A and C). In graph B, a one-way ANOVA followed by Bonferroni test was used for multiple comparisons. Data are presented as dot plot with the mean \pm SEM. (D) Total extracellular RNA in serum of mice are demonstrated. A one-way ANOVA followed by Bonferroni test was used for multiple comparisons. Data are presented as dot plot with the mean \pm SEM. (E) RNase 1 serum levels over the time in sham operated mice (n = 3) and mice with polymicrobial sepsis induced by CLP treated with vehicle (n = 4). Correlation of TNF and RNase 1 of mice with polymicrobial sepsis induced by CLP (F) treated with vehicle and (G) treated with RNase 1. § $p < 0.05$ vs Sham; # $p < 0.05$ vs CLP + Vehicle; CLP = cecal ligation and puncture; RNase = ribonuclease 1; RNH1 = ribonuclease-inhibitor 1; TNF = tumor necrosis factor alpha

Figure 8

Proposed pathway and pathophysiologic role of eRNA, RNase 1, and RNH1 in septic cardiomyopathy

eRNA belongs to the heterogeneous group of DAMPs and is released as a result of sepsis-associated tissue injury and necrotic cell death. eRNA binds to the pattern recognition receptors toll-like receptor 3 located on the endosome, which results in the formation of TNF in cardiomyocytes. TNF binds to TNFR and induces pro-apoptotic as well as pro-inflammatory pathways. RNases belong to a group of host-defense peptides secreted from endothelial cells and thereby cleave eRNA. RNH1 binds to RNase 1 and inactivates the host-defense function of RNases, which allows eRNA to bind to TLR. eRNA = extracellular RNA; RNase 1 = ribonuclease 1; RNH1 = ribonuclease-inhibitor 1; TNF = tumor necrosis factor alpha; TLR = toll-like receptor; TNFR = tumor necrosis factor receptor
