## Abstract

The infrared and near infrared spectra of acetylacetone, acetylacetone-*d*<sub>8</sub> and hexafluoroacetylacetone are characterized from experiment and computations at different levels. In the fundamental region, the intramolecular hydrogen bonded OH-stretching transition is clearly observed as a very broad band with substantial structure and located at significantly lower frequency compared to common OH-stretching frequencies.

There is no clear evidence for OH-stretching overtone transitions in the near infrared

3 region, which is dominated by the CH-stretching overtones of the methine and methyl  
4 CH bonds. From molecular dynamics (MD) simulations, with a potential energy sur-  
5 face previously validated for tunneling splittings, the infrared spectra are determined  
6 and used in assigning the experimentally measured ones. It is found that the simulated  
7 spectrum in the region associated with the proton transfer mode is exquisitely sensitive  
8 to the height of the barrier for proton transfer. Comparison of the experimental and the  
9 MD simulated spectra establishes that the barrier height is around 2.5 kcal/mol, which  
10 favourably compares with 3.2 kcal/mol obtained from high-level electronic structure  
11 calculations.

## Introduction

Acetylacetone (AcAc) and hexafluoroacetylacetone (HFAA) are  $\beta$ -dicarbonyls which exist in two isomeric forms: the keto and enol tautomers shown in Figure 1a. The greater proportion of the enol form can be attributed to the resonance stabilization of the conjugated double bonds and to the stabilization provided by the intramolecular O–H $\cdots$ O hydrogen bond. Increasing  $\pi$  electron delocalization may transform the H bond from an asymmetric O–H $\cdots$ O pattern with a double well potential, to a symmetric O $\cdots$ H $\cdots$ O single well structure. If the  $\pi$  delocalization is complete, a symmetric  $C_{2v}$  structure is formed in which the C=C and C–C bonds, along with the C–O and C=O bonds, become equivalent and the H atom is shared equally between the two O atoms. A diagram of the interconversion process is shown in Figure 1b.

The thermodynamics of the keto-enol equilibrium of gas phase AcAc has been studied with temperature dependent nuclear magnetic resonance (NMR) spectroscopy.<sup>1</sup> The enol form is predominant with  $\Delta H^\circ(\text{enol} \rightarrow \text{keto}) = 4.66 \pm 0.18$  kcal/mol and  $\Delta S^\circ = 8.3$  cal/mol K<sup>-1</sup>. The hydroxyl proton resonance full width at half maximum is approximately 16.7 Hz at 373 K, which is significantly broader than the  $\sim 2$  Hz line widths typical of the other proton resonances. The extra width of the hydroxyl proton resonance is indicative of its delocalization. The keto isomer was estimated to be about 4.1 to 4.3 kcal/mol higher in energy than the enol isomer from photoelectron<sup>2</sup> and ultraviolet<sup>3</sup> spectra. The gas phase abundance of the enol form of AcAc has been reported at various temperatures: 98% at 298 K from a <sup>1</sup>H NMR study,<sup>1</sup> 95% at 333 K and  $\sim 60\%$  at 503 K from infrared (IR) studies.<sup>4</sup>

AcAc is structurally related to its much more thoroughly characterized cousin malonaldehyde (MA, R=H in Figure 1) through substitution of the symmetrical H-atoms by methyl groups. Given that the methyl torsion can couple to the O–O stretch and hence to the proton transfer (PT) motion along the H–bond, it constitutes a more challenging problem than PT

Figure 1: a) Keto-enol tautomerization in  $\beta$ -dicarbonyls. b) Interconversion of the enol form of a  $\beta$ -dicarbonyl. The transition state shown in the center has  $C_{2v}$  symmetry.

in MA. For MA, a number of IR spectra<sup>5-8</sup> and the ground state tunneling splitting<sup>9,10</sup> have been measured with high accuracy experimentally. A combined IR and Raman spectroscopy study of MA in supersonic jets and rare gas matrices recorded a tunneling splitting of 69  $\text{cm}^{-1}$  with the OH-bend vibrationally excited.<sup>11</sup> Calculations at different levels of theory have been carried out to assign these spectra and to reproduce the splitting. In general, this requires fully dimensional dynamics simulations<sup>12-17</sup> performed on high level potential energy surfaces (PESs).<sup>18</sup>

Contrary to MA, less information about activation barriers, structures and possible tunneling splittings in AcAc is available. Even the question whether its ground state assumes an asymmetric ( $C_s$ ) or a symmetric ( $C_{2v}$ ) structure is still debated.<sup>19-24</sup> Neutron crystallography predicts that the ground state of AcAc has  $C_s$  symmetry.<sup>19</sup> Results from electron diffraction experiments are contradictory, suggesting either a  $C_s$ <sup>20,21</sup> or a  $C_{2v}$  structure.<sup>23</sup> The most recent study performed with ultrafast electron diffraction concluded that the lowest energy form of AcAc has  $C_s$  symmetry.<sup>22</sup> In general, electronic structure calculations find an asymmetric minimum energy structure with  $C_s$  symmetry for AcAc on the PESs excluding zero-point corrections,<sup>25-30</sup> while correcting for zero point vibrational energy lead to a slight preference of the  $C_{2v}$  minimum energy structure at the MP2/D95++\*\* (for energies) and scaled HF/D95++\*\* (for vibrations) level of theory<sup>30</sup> which can, however, not be compared

6

7  
8 Conversely, high-resolution rotational spectra of AcAc and its singly substituted <sup>13</sup>C-isotopologues  
9 in the frequency ranges 2–26.5 GHz ( $\sim 0.1$ – $1$  cm<sup>-1</sup>) and 60–80 GHz ( $\sim 2$ – $3$  cm<sup>-1</sup>) lead to a  
10 structure with *C*<sub>2v</sub> symmetry<sup>24</sup> possibly due to zero point vibration of the proton in systems  
11 with strong hydrogen bonds.<sup>31–33</sup> The double well potential in AcAc due to PT from one  
12 oxygen to another is responsible for the tunneling splitting.<sup>34,35</sup> Depending on whether or  
13 not the proton is constrained in the well will have a marked effect on the spectroscopy with  
14 respect to tunneling effects, thus isotopic substitution can be enlightening. To date only  
15 the microwave spectrum of the normal protonated isotopomer has been investigated,<sup>24</sup> and  
16 it would be informative to observe the microwave spectrum of a deuterated isotopomer of  
17 AcAc, where the tunneling splitting will be reduced due to the heavier isotope.

30 Several IR spectroscopic studies of AcAc are available in the vapor phase.<sup>4,36–38</sup> The OH–  
31 stretching transition is very broad, however is typically assigned in the region from 2750  
32 cm<sup>-1</sup> to 2800 cm<sup>-1</sup>.<sup>36,38</sup> The only near infrared (NIR) investigation of AcAc was performed  
33 in the liquid phase in 1929 as part of a study regarding carbonyl overtones.<sup>39</sup> Other than  
34 a tentative assignment of a carbonyl overtone at 1.91 μm, no further transitions for AcAc  
35 were assigned.

44 Various experimental studies of hexafluoroacetylacetone (HFAA) have been performed in-  
45 cluding electron diffraction,<sup>40,41</sup> and IR spectroscopy<sup>36,37</sup> and microwave spectroscopy.<sup>42</sup> The  
46 microwave data shows that HFAA exists in a ‘rigid’ enolic *C*<sub>s</sub> form, and it lacks doubling  
47 of rotational lines, indicating high effective barriers to the internal motions,<sup>42</sup> while the re-  
48 lated molecule trifluoroacetylacetone exhibits intermediate internal dynamics between AcAc  
49 and HFAA.<sup>43</sup> From gas phase electron diffraction studies it was concluded that HFAA exists  
50 as an enol tautomer with a planar symmetric ring and an O–H···O angle close to 180°. <sup>40,41</sup>

2  
3 The O...O distance was determined to be 2.551 Å<sup>40</sup> or 2.606 Å.<sup>41</sup> The symmetric ring  
4 conclusion has been refuted,<sup>44</sup> because such a structure having a nearly linear O-H...O  
5 angle should have only one minimum for its potential energy well and a smaller O...O dis-  
6 tance of 2.3 Å is more likely (see, e.g., Ref.<sup>45</sup>). Alternatively, the symmetric structure based  
7 on the electron diffraction data has been interpreted as a superposition of two asymmetric  
8 structures.<sup>46</sup> High level electronic structure calculations on HFAA are demanding due to  
9 the extra computational cost associated with the six fluorine atoms and investigations have  
10 been limited.<sup>26,44,46</sup> The theoretical calculations yield structures analogous to AcAc, with an  
11 asymmetric  $C_s$  enol form as the most stable conformation.

48

49 The IR spectra of gaseous AcAc, AcAc- $d_8$  and HFAA were recorded at 1 cm<sup>-1</sup> resolution on  
50 a Perkin Elmer Spectrum BX FTIR spectrometer. Samples were contained in a 10 cm path  
51 length cell equipped with KBr windows. Both, the AcAc and AcAc- $d_8$  spectra were taken  
52 at 7 Torr vapour pressure and HFAA 10 Torr. The AcAc, AcAc- $d_8$  and HFAA spectra were  
53 measured at 291 K, 294 K and 295 K, respectively.

5 The conventional NIR spectra of AcAc and AcAc- $d_8$  were recorded with a Varian Cary 500  
6 spectrophotometer which incorporated a 4.8 m path length White cell (Infrared Analysis,  
7 Inc.) fitted with Infrasil quartz windows. The spectrum of each sample was measured at  
8 6 Torr vapor pressure and at 293 K. The spectrum of HFAA was recorded under the same  
9 conditions except at a pressure of 20 Torr. Background scans with an evacuated cell were  
10 subtracted from the sample spectra. A 0.2 OD neutral density filter was used as an attenu-  
11 ator in the reference beam path of the Cary 500.

21 AcAc and AcAc- $d_8$  were recorded with a photoacoustic spectrometer at pressures of 7 Torr  
22 and 8 Torr, respectively. Our photoacoustic spectrometer and the spectral calibration process  
23 has been described previously.<sup>50,51</sup> Briefly, a Coherent Innova Sabre argon ion laser running  
24 at all lines was used to pump a Coherent 890 titanium:sapphire laser. The wavelength is  
25 tuned with a three-plate birefringent filter which yields a laser line width of approximately 1  
26  $\text{cm}^{-1}$ . The photoacoustic cell contained a Knowles EK3133 microphone for detection of the  
27 photoacoustic signal. The corrosive nature of HFAA necessitated a low sample pressure in  
28 the photoacoustic cell to prevent damage to the microphone. The photoacoustic spectra of  
29 HFAA were recorded with a sample pressure of approximately 0.5 Torr. The photoacoustic  
30 signal of HFAA was enhanced by the addition of a buffer gas of 227 Torr argon to the pho-  
31 toacoustic cell.<sup>52,53</sup> All photoacoustic spectra were measured at 293 K.

## 49 Computational Methods

50  
51 *Anharmonic local mode calculations:* The  $C_2$  and  $C_{2v}$  structures of AcAc were optimized with  
52 the MP2/6-311++G(d,p) and CCSD(T)/cc-pVTZ methods using Gaussian09 and MOL-  
53 PRO, respectively.<sup>54,55</sup> For the OH-stretching vibrations of AcAc and HFAA an anharmonic  
54 oscillator local mode model was used.<sup>47,48</sup> As usual, the OH-stretching oscillator is modelled  
55  
56  
57  
58  
59  
60

as a Morse oscillator.<sup>49</sup> The 1-dimensional PES and dipole moment surface for the OH-stretching coordinate were calculated at the CCSD(T)/cc-pVTZ level. The details of this model are given elsewhere.<sup>49</sup>

*Intermolecular Interactions and Morphing:* A detailed account of the Molecular Mechanics with Proton Transfer (MMPT) method has been given previously.<sup>15,56–58</sup> Briefly, MMPT uses parametrized three-dimensional potential energy surfaces (PESs) fitted to *ab initio* calculations at the MP2/6-311++G(d,p) level to describe the interactions within a general DH–A motif where D is the donor, H is the hydrogen and A is the acceptor atom. Together with a standard force field - here, CHARMM<sup>59</sup> is used - specific rules control how bonded interactions on the donor and acceptor side are switched on and off depending on the position of the transferring H-atom (DH–A or D–HA). To adapt the overall shape of the PES to topologically similar, but energetically different hydrogen bonding patterns - depending on the chemical environment of D and A - the PES can be “morphed”.<sup>60,61</sup> Morphing can be a simple coordinate scaling or a more general coordinate transformation.

Table 1: The geometries of optimized (OPT) and transition state (TS) structures, together with the PT barrier  $\Delta E$  for AcAc and MA calculated at the MP2/aug-cc-pVTZ level, which are used in the PES morphing. See text for details.

	AcAc		MA	
	OPT	TS	OPT	TS
$R(\text{\AA})$	2.53	2.36	2.56	2.36
$r(\text{\AA})$	1.01	1.20	1.00	1.20
$\theta(^{\circ})$	17.9	10.8	19.4	10.6
$\rho$	0.17	0.5	0.15	0.5
$d(\text{\AA})$	0.31	0.22	0.33	0.22
$\Delta E$ (kcal/mol)	2.18		2.74	

For proton transfer in AcAc, the MMPT potential  $V(R, \rho, d)$  depends on  $R$ ,  $\rho = (r \cos \theta - r_{\min}) / (R - 2r_{\min})$  and  $d = r \sin \theta$  where  $R$  is the O<sub>1</sub>–O<sub>2</sub> distance,  $r$  is the O<sub>1</sub>–H distance, and  $\theta$  is the angle between  $\vec{R}$  and  $\vec{r}$  (see Fig. 2). The parameter  $r_{\min} = 0.8 \text{ \AA}$  is in principle

arbitrary but should be sufficiently small to cover the shortest possible D–H separations to ensure  $\rho > 0$ . The MMPT potential for AcAc is generated via PES morphing from that of MA,<sup>15</sup> since the PT motifs in the two molecules experience chemically similar environments. Morphing is achieved by modifying MMPT parameters and thus reshaping the interaction potentials, with reference data such as equilibrium structure and energy barrier provided by electronic structure calculations (Table 1). Different morphing schemes are tested and discussed in detail in the supplementary material. In the present work  $V^{\text{AcAc}}(R, \rho, d)$  and  $V^{\text{MA}}(R, \rho, d)$  are related through the following transformations:

$$V^{\text{AcAc}}(R, \rho, d) = \lambda V^{\text{MA}}(R - R_0, \rho, d) \quad (1)$$

with morphing parameters  $\lambda = \frac{\Delta E^{\text{AcAc}}}{\Delta E^{\text{MA}}} = \frac{2.18 \text{ kcal/mol}}{2.74 \text{ kcal/mol}} = 0.796$  and  $R_0 = R_{\text{opt}}^{\text{MA}} - R_{\text{opt}}^{\text{AcAc}} = 2.56 \text{ \AA} - 2.53 \text{ \AA} = 0.03 \text{ \AA}$  determined from comparing the PT barrier ( $\Delta E$ ) and the equilibrium donor-acceptor distance ( $R_{\text{opt}}$ ) of AcAc and MA computed at the same level of theory (MP2/aug-cc-pVTZ). With such a morphing scheme information concerning the PT barrier height, and partly the PT barrier width as reflected in the O–O distance, are included. The entire set of parameters for  $V(R, \rho, d)$  and comparison with those of MA are listed in the SI (Tables S2 and S3). Other force field parameters for all bonded and non-bonded interactions in AcAc are identical to those for MA, while the substituted methyl and trifluoromethyl groups are treated with existing CHARMM force field parameters.<sup>59</sup>

*Infrared spectra and assignments from MD simulations:* IR and power spectra are computed from suitable time correlation functions from MD simulations. More specifically, the total dipole moment  $\vec{M}(t)$  was recorded along the MD trajectories and correlated over  $2^{14}$  time origins to give the dipole-dipole correlation function  $C(t)$

$$C(t) = \langle \vec{M}(t) \cdot \vec{M}(0) \rangle \quad (2)$$

Figure 2: Equilibrium structure (left) and PT transition state structure (right) of AcAc, computed by MM force field. Atom types and internal coordinates ( $R, r$  and  $\theta$ ) for the MMPT potential are also labeled. See text for more details.

To suppress noise, a Blackman filter was used.<sup>62</sup> Then  $C(\omega)$ , the Fourier-Transform of  $C(t)$ , was weighted with the Boltzmann factors to give the IR spectrum  $A(\omega)$

$$A(\omega) = \omega \{1 - \exp[-\hbar\omega/(k_B T)]\} C(\omega) \quad (3)$$

where  $k_B$  is the Boltzmann constant and  $T$  is the temperature.

MD trajectories also offer the possibility to determine power spectra corresponding to selected internal coordinates  $q$ . Such power spectra can be employed to assign spectroscopic features to motion along these coordinates and to analyze possible couplings between different internal coordinates. For this, the time series  $q(t)$  is used to construct the correlation function  $\langle q(t) \cdot q(0) \rangle$ . The Fourier transform (see above) of this correlation function yields the power spectrum.

## Results and Discussion

### Molecular Geometries and Energies

The fully optimized geometry of the  $C_s$  and the  $C_{2v}$  structures of AcAc at the MP2 and CCSD(T)/cc-pVTZ level are compared with parameters from an electron diffraction (ED) experiment<sup>22</sup> in Table S4 (supporting information). Due to the weak scattering of the hydrogen atom, the O–H and H $\cdots$ O distances and the O–H $\cdots$ O angle were held at the B3LYP calculated values in the ED data.<sup>22</sup> The computed geometries are in good mutual agreement and agree well with experimentally determined structures which show some variation: the O $\cdots$ O distances are 2.592 Å<sup>22</sup> and 2.547 Å respectively,<sup>63</sup> which compares favourably with our CCSD(T)/cc-pVTZ value of 2.55 Å. The  $C_s$  structure is significantly more stable than the  $C_{2v}$  structure by approximately 2.2 kcal/mol and 3.2 kcal/mol at the MP2/aug-cc-pVTZ and the CCSD(T)/cc-pVTZ levels, respectively. The energy differences can be considered as the classical barrier to PT. The relative structural degeneracy of the  $C_s$  and  $C_{2v}$  structures is 2:1, statistically favoring the  $C_s$  structure (Figure 1b) by  $-RT\ln 2$  which is approximately 0.4 kcal/mol at 298 K. Hence, at the MP2 level of theory the  $C_s$  is more stable by  $\approx 2.6$  kcal/mol compared to the  $C_{2v}$  structure. Harmonic frequency calculations at this level of theory yield a zero-point vibrational energy (ZPVE) of 77.7 kcal/mol and 75.3 kcal/mol for the  $C_s$  and  $C_{2v}$  structures, respectively, which is a difference of 2.4 kcal/mol. At the MP2 level of theory it is therefore difficult to unambiguously assign the minimum energy structure to either  $C_s$  and  $C_{2v}$  symmetry, whereas the electronic energy difference of the CCSD(T) calculations favor the  $C_s$  structure, even with inclusion of the MP2 ZPVE difference to the CCSD(T) energies.

*Methyl Groups:* An evident structural difference between the  $C_s$  and  $C_{2v}$  structures is the orientation of the methyl group with the parent carbon labelled “12” in Figure 2. Hence, the torsion of this methyl group is coupled to the PT coordinate. In the transition state –

1  
2  
3 labelled TS2<sup>28</sup> the methyl groups eclipse one another (see Figure S1).  
4  
5

6  
7 The MP2/aug-cc-pVTZ calculated energy difference between the TS2 and  $C_s$  structure,  
8 *i.e.*, the barrier to the methyl rotation, is 0.13 kcal/mol, in quite good agreement with the  
9 0.27 kcal/mol obtained at the CCSD(T)/cc-pVTZ//MP2(FC)/cc-pVTZ level<sup>28</sup> and with  
10 microwave data at 0.163 kcal/mol.<sup>24</sup> Interestingly, the torsional barrier of the CH<sub>3</sub> group  
11 of acetone is considerably higher (0.76 kcal/mol).<sup>64</sup> Thus, the ring structure in AcAc must  
12 play a role in lowering the barrier to rotation of that methyl group. The  $C_s$  and TS2 enol  
13 forms of AcAc were calculated to have their OH-stretching vibrations separated by  $\approx 500$   
14 cm<sup>-1</sup>, which indicates that methyl torsion could lead to a broad OH-stretching band. In  
15 the force field treatment (vide infra) coupling between the CH<sub>3</sub> rotation and the H-transfer  
16 coordinate is not explicit. Nevertheless, the two degrees of freedom are coupled through  
17 stretching, bending and torsional terms in the overall force field.  
18  
19

20  
21 The barrier for methyl rotation of the C8 methyl group (Figure 2) in AcAc is calculated to be  
22 1.45 kcal/mol at the MP2(FC)/6-311G(d,p) level.<sup>27</sup> Methyl barrier heights of 0.45 kcal/mol  
23 and 1.17 kcal/mol were predicted based on inelastic neutron scattering measurements on  
24 solid AcAc<sup>65</sup> and in the range of 0.44–1.59 kcal/mol in more recent experiments on the enol  
25 tautomer.<sup>19</sup> The potential barriers of the enol tautomer were also sensitive to deuteration  
26 of the nonmethyl protons.<sup>19</sup> This is further indication of the coupling between the methyl  
27 rotation and PT. In contrast, the methyl potential of the keto tautomer was insensitive to  
28 these factors.  
29  
30

31  
32 *Equilibrium structures from the Reactive Force Field:* The minimum and transition state  
33 (TS) structures calculated from the MMPT force field compare favorably with those from  
34 *ab initio* calculations at the MP2/aug-cc-pVTZ level (see Table 2). Differences in bond  
35 lengths and angles are within 0.02 Å and 3°, respectively. The energy difference between

the minimum ( $C_s$ ) and TS ( $C_{2v}$ ) structure is 2.35 kcal/mol, which is in good agreement with the MP2/aug-cc-pVTZ *ab initio* value of 2.17 kcal/mol. Also listed in Table 2 are the conformationally averaged geometries from 5 ns MD simulations in the gas phase. In such an ensemble averaged structure the proton is equally shared by the two oxygen atoms which corresponds to  $C_{2v}$  symmetry. This is not in conflict with a  $C_s$  minimum structure and ultrafast methods may be successful in detecting asymmetric structures.

Table 2: Comparison of selected bond lengths and angles of AcAc minimum and transition state obtained from *ab initio* MP2/aug-cc-pVTZ (QM) and force field (MMPT) optimizations. Also, the ensemble average from 5 ns MD simulations of gas phase AcAc is given.

## Experimental Spectra

*AcAc*: The IR spectra of vapor phase AcAc and AcAc-*d*<sub>8</sub> are shown in Figure 3a. In both spectra the absorbance is low above 1700 cm<sup>-1</sup>, so the absorbance scale in this region has been magnified in the figure to emphasize the structure relating mainly to the OH(OD)- and CH(CD)-stretching transitions. Hydrogen bonding can lead to very broad OH-stretching fundamental ( $\nu_{OH}$ )<sup>66</sup> and overtone bands.<sup>67,68</sup> The intensity of the  $\nu_{OH}$  band of AcAc appears weak, however significant intensity is spread over a wide wavenumber region. The intramolecular H-bond is strong in AcAc and  $\nu_{OH}$  is broad and lower in wavenumber than the  $\nu_{CH}$  transitions. In the literature,  $\nu_{OH}$  is typically assigned in the range of 2750 cm<sup>-1</sup> to 2800 cm<sup>-1</sup>.<sup>36,38</sup> However, we observe several transitions in the 2000–3300 cm<sup>-1</sup> region.

1  
2  
3  
4 The IR spectrum of AcAc- $d_8$  was closely examined for the small impurity of OH present  
5  
6 in the compound, however no correspondence between the AcAc and AcAc- $d_8$  spectra in  
7  
8 the  $\nu_{\text{OH}}$  region was found. This is in contrast to findings for other examples with hydrogen  
9  
10 impurities.<sup>69</sup> The  $\nu_{\text{OD}}$  transition of AcAc- $d_8$  is more defined and narrower compared to the  
11  
12  $\nu_{\text{OH}}$  band in AcAc.  
13

14  
15  
16 The conventional NIR spectra of vapor phase AcAc and AcAc- $d_8$  are presented in Figure  
17  
18 4a. Relatively strong combination bands are present in the 4000–4600  $\text{cm}^{-1}$  region of both  
19  
20 isotopomers. The far wings of the more intense  $\nu_{\text{CH}}$  transitions contribute to the sloping  
21  
22 baseline at low wavenumber in the AcAc spectrum. The  $\Delta\nu_{\text{CH}} = 2$  region is observed near  
23  
24 6000  $\text{cm}^{-1}$ . The small CH impurities present in the AcAc- $d_8$  sample are apparent in the  
25  
26 spectrum. The  $\Delta\nu_{\text{CH}} = 2$  and 3 regions of AcAc and AcAc- $d_8$  are shown in Figures S2 and  
27  
28 S3 in the supplementary information, respectively.  
29  
30

31  
32 The photoacoustic spectra of AcAc and AcAc- $d_8$  are shown in Figures 5a and 5b, respec-  
33  
34 tively. The slightly overlapping scans shown in each figure correspond to the various optics  
35  
36 used in the Ti:sapphire laser. The intensity axis of each trace presented in the figures has  
37  
38 been expanded to show the transitions clearly. For example, the AcAc  $5\nu_{\text{CH}}$  transition is  
39  
40 approximately an order of magnitude less intense than  $4\nu_{\text{CH}}$ .  
41  
42

43  
44 *HFAA*: The IR spectrum of HFAA is shown in Figure 3b. Like the spectrum of AcAc,  
45  
46 the  $\nu_{\text{OH}}$  transition of HFAA is extremely broad and clearly contains many transitions. The  
47  
48 values for  $\nu_{\text{OH}}$  in HFAA has been given in the literature in the range from 2965  $\text{cm}^{-1}$  to  
49  
50 3000  $\text{cm}^{-1}$ .<sup>36,37</sup> However, just as for AcAc it is not possible to assign only one transition to  
51  
52 the OH-stretching transition. The methine  $\nu_{\text{CH}}$  transition is located at 3134  $\text{cm}^{-1}$ , which is  
53  
54 approximately 40  $\text{cm}^{-1}$  higher than that in AcAc.  
55  
56  
57  
58  
59  
60

1  
2  
3 The conventional NIR spectrum of vapor phase HFAA is shown in Figure 4b. Its NIR spec-  
4 trum is simpler than AcAc because the methyl CH transitions are absent. In the 4000–5000  
5  $\text{cm}^{-1}$  region, there is a quartet of peaks at 4049, 4233, 4405 and 4584  $\text{cm}^{-1}$ . The peaks are  
6 approximately evenly separated by 180  $\text{cm}^{-1}$ , and the intensity of the four peaks progres-  
7 sively drops with increasing wavenumber. In the 7000–8000  $\text{cm}^{-1}$  region, a similar pattern  
8 of peaks is observed, however the spacing between them is not as regular. The pattern could  
9 be due to Fermi resonance, which is common in CH-stretching spectra of compounds such  
10 as  $\text{CF}_3\text{H}$  and  $\text{CF}_3\text{CCH}$ .<sup>70</sup>  
11  
12  
13  
14  
15  
16  
17  
18  
19  
20

21 The photoacoustic spectra of HFAA are shown in Figure 5c. In this wavenumber region,  
22 transitions from the OH- and methine CH-stretching oscillator, would be expected to con-  
23 tribute to the observed spectrum. The spectra are very simple, because transitions from the  
24 methyl CH oscillators are absent, and show no sign of an OH-stretching transition. There  
25 is no evidence for a Fermi resonance in the higher wavenumber region as it was in the 4000-  
26 9000  $\text{cm}^{-1}$  region. The methine  $4\nu_{\text{CH}}$  and  $5\nu_{\text{CH}}$  transitions are dominant at 11841  $\text{cm}^{-1}$  and  
27 14527  $\text{cm}^{-1}$ , respectively. The weak CH-stretching/bending combination band,  $4\nu_{\text{CH}} + \delta\nu_{\text{CH}}$   
28 is observed at 12898  $\text{cm}^{-1}$ .  
29  
30  
31  
32  
33  
34  
35  
36  
37  
38  
39

40 Apart from the tentative  $2\nu_{\text{OH}}$  regions shown in Figure S4, higher overtone OH-stretching  
41 transitions were not observed in the photoacoustic spectra of AcAc and HFAA. It is appar-  
42 ent that the detection of the OH-stretching transition is not straightforward because the  
43 linewidth of the OH-stretching transitions is very broad, and the first overtone transition  
44 has a weak intensity.<sup>49</sup>  
45  
46  
47  
48  
49  
50

51  
52 *The Methyl CH-Stretching Regions:* The methyl band profile of the CH-stretching overtone  
53 regions can be used as a guide to estimate the methyl torsional barrier height. If the barrier  
54 to methyl torsion is large, then the methyl group position is effectively fixed on the time  
55  
56  
57  
58  
59  
60

1  
2  
3  
4 scale of the CH vibrations and two transitions are observed in its CH-stretching overtone  
5  
6 spectrum corresponding to the in-plane and out-of-plane CH. If, on the other hand, the  
7  
8 methyl torsional barrier is very low, there is effectively free rotation of the methyl group and  
9  
10 a more complex spectrum is observed.<sup>71-76</sup>

11  
12  
13 The methyl CH-stretching region of AcAc-*d*<sub>8</sub> is much simpler than that of AcAc (see Fig. 4a  
14  
15 and Supporting Information), as expected since in the AcAc-*d*<sub>8</sub> sample, a methyl group is  
16  
17 most likely to have only one proton as an impurity. Thus facile CH coupling in the methyl  
18  
19 group is removed and the spectra are simpler, revealing an in-plane and out-of-plane CH-  
20  
21 stretching transition. The relative intensity of the out-of-plane to in-plane CH-stretching  
22  
23 transitions is approximately 2:1, which to first order reflects the statistical weight of the  
24  
25 oscillators.  
26

27  
28  
29 The *C*<sub>s</sub> structure of AcAc has two nonequivalent methyl groups. Thus the CH-stretching  
30  
31 overtone spectra of the methyl groups will overlap and complicate their interpretation. In  
32  
33 our spectra we are likely observing the transitions of the in- and out-of-plane CH bonds of  
34  
35 the higher torsional barrier methyl group (parent carbon 8 in Figure 2). The lower barrier  
36  
37 methyl group will have less structure in its spectrum and be less distinct.<sup>76</sup>  
38  
39  
40

41  
42 The  $\Delta\nu_{\text{CH}} = 4$  and 5 methyl CH-stretching regions of AcAc, labelled as  $4\nu_{\text{CH}_3}$  and  $5\nu_{\text{CH}_3}$ ,  
43  
44 respectively, are shown in Figure 5a. In both overtone regions, the methyl band profile is es-  
45  
46 sentially a two-peak structure representing the in- and out-of-plane CH oscillators, and based  
47  
48 on this observation, we would expect that the methyl torsional barrier height is greater than  
49  
50 0.7 kcal/mol.<sup>76</sup> Our finding is in fair agreement with previously determined barrier heights  
51  
52 of  $\sim 0.4$ -1.6 kcal/mol in solid AcAc.<sup>19,65</sup>  
53  
54

55  
56

Table 3: Observed methine CH-stretching overtone wavenumbers and local mode parameters ( $\text{cm}^{-1}$ ) of acetylacetone and hexafluoroacetylacetone.

$\Delta v$	$\tilde{\nu}(\text{AcAc})$	$\tilde{\nu}(\text{HFAA})$
2	6056	6150
3	8913	9047
4	11640	11841
5		14527
$\tilde{\omega}$	$3205.7 \pm 4.7$	$3243.0 \pm 3.5$
$\tilde{\omega}x$	$59.0 \pm 1.2$	$56.4 \pm 0.7$

tions of AcAc and HFAA and the local mode parameters obtained from the observed  $\Delta v = 2$  to 5 transitions are presented in Table 3. The methine CH-stretching local mode frequency of HFAA is  $40 \text{ cm}^{-1}$  higher than that of AcAc, and its anharmonicity is slightly smaller. The small standard deviations in the local mode parameters indicate that the Morse oscillator is a good approximation for the methine CH oscillator.

## Computational Vibrational Spectroscopy and the Barrier to H-Transfer

Direct contact with the experimental spectra analyzed above can be made from IR spectra determined from atomistic simulations. This is a powerful approach which has been successfully followed in previous work.<sup>77–82</sup>

*IR spectra from Molecular Dynamics Simulations at Finite Temperature:* The computed IR spectrum for AcAc from the 5 ns MD simulation in the gas phase is reported and compared with the experimental spectrum in Figure 6a. The simulated spectrum reproduces most experimentally observed features. Certain band positions could be improved by explicitly adjusting the corresponding force constants of the force field. However, this is not the primary aim in the present work. Improved intensities could be obtained with a more accurate dipole moment surface (DMS) instead of point charges. For protonated water dimer a full (15)-dimensional DMS<sup>83</sup> has been used in previous work together with MMPT/MD simula-

1  
2  
3 tions, which leads to improved IR intensities.<sup>57</sup> No such DMS is currently available for AcAc.  
4  
5  
6

7  
8 One advantage of MD simulations is that power spectra of individual vibrational motions  
9 can be used to assign the spectra. Table 4 reports the most relevant bands and assignments.  
10  
11 The strong band at 1624 cm<sup>-1</sup> in the IR spectrum of AcAc was previously assigned to either  
12 the CO stretching mode or the OH in-plane bending mode.<sup>36,37,84,85</sup> The power spectrum  
13 of the CO stretching vibration (Figure 6b) finds a single peak at 1602 cm<sup>-1</sup> and clearly  
14 relates the experimentally observed band to the CO stretching band. It is noted that the  
15 lineshape of the CO-stretch vibration is not very well reproduced by the simulations. This  
16 is related to the fact that computing the IR spectrum from the Fourier transform of the  
17 dipole-autocorrelation function alone does not necessarily lead to realistic lineshapes. For  
18 this, additional factors such as the lifetimes of the transitions would need to be taken into  
19 account.<sup>86</sup> However, for comparing line positions the present approach is suitable.<sup>87</sup> The  
20 power spectra can also be employed to identify potentially coupled coordinates. For exam-  
21 ple, a peak at 520 cm<sup>-1</sup> (the O–O vibration) is found in both OH stretching and OH bending  
22 modes, illustrating that these modes are coupled. Also, the CH<sub>3</sub> torsion is coupled to this  
23 mode and to a number of other motions. However, the CH<sub>3</sub> torsional spectrum does not  
24 line up exactly with the O–O vibration probably because the coordinate from which this  
25 spectrum was determined is coupled to other motions of the methyl group, such as a CCH  
26 bending motion. As already stated, no explicit coupling terms between different vibrational  
27 degrees of freedom are taken into account in the CHARMM force field although this would, in  
28 principle, be possible. This has been done because the focus in the present simulations is on  
29 the proton transfer mode which is represented by the dedicated MMPT-part of the force field.

50  
51  
52 The IR and associated power spectra for AcAc-*d*<sub>8</sub> are reported in Figures 7a and b, and  
53 those for HFAA in Figure S5 in the supplementary information. Similar to AcAc many fea-  
54 tures of the spectrum are reasonably well reproduced. However, one band observed around  
55  
56  
57  
58  
59  
60

Table 4: Comparison of selected IR frequencies, MD simulations and *ab initio* harmonic oscillator (HO) vibrational analysis at the MP2/aug-cc-pVTZ level. All frequencies are in  $\text{cm}^{-1}$ , and the assignments are based on the power spectra from MD simulations. The experimental frequency of OO vibration is taken from Ref.<sup>88</sup>

Exp.	MD	HO	Assignment
2000-3300	2000-3200	3013	OH stretching
1171	1180	1004	OH bending
510	520	374	OO vibration
1626	1602	1658	C=O stretching

1250  $\text{cm}^{-1}$  in the AcAc- $d_8$  spectrum is not present in the computed spectrum. On the other hand, the region of primary interest in the present work associated with the D-transfer band together with the C-D stretches is realistically captured.

A more direct comparison with experiment is afforded by comparing the spectral features corresponding to the PT mode, see Figure 8. The MMPT force field used so far has a barrier height of 2.35 kcal/mol, and the OH-spectrum is centered around  $\sim 2600 \text{ cm}^{-1}$ , see inset of Figure 6. This compares quite favourably with experiment and is further discussed below.

A sensitivity test for the PT barrier height and its influence on the spectrum in the OH-stretching region was carried out. For this, the same simulations were repeated with half (1.17 kcal/mol) and twice (4.70 kcal/mol) the MMPT-barrier height of 2.35 kcal/mol. The center of the band, as judged from the OH-stretching power spectrum reported in Figure 8, shifts to 2000  $\text{cm}^{-1}$  and 3750  $\text{cm}^{-1}$  for the low and high barrier, respectively. Hence from comparing the computed and experimentally observed spectral features in the region of the proton transfer region, a barrier for PT of  $\approx 2.5$  kcal/mol is inferred. This compares well with a barrier height of 3.2 kcal/mol from the present CCSD(T)/cc-pVTZ calculations. The pronounced features in the experimental spectrum (purple) around 3000  $\text{cm}^{-1}$  correspond to the C-H stretching vibrations which are not present in the O-H power spectrum. It is thus concluded that the H-transferring part of the IR spectrum is sensitive to the barrier height

1  
2  
3  
4 which can be qualitatively extracted from such an analysis.  
5  
6

7  
8 The power spectra of the OH-stretching are very broad and spread from 2000  $\text{cm}^{-1}$  to 3200  
9  $\text{cm}^{-1}$ , emphasizing the very anharmonic nature of the OH stretching PT-mode which agrees  
10 with observations in the gas phase IR spectrum.<sup>28,36</sup> This is further illustrated by the IR  
11 spectra of the deuterated isotopomers of AcAc computed from MD simulations in gas phase  
12 (see Fig. S5 in the SI). Deuterating the transferring hydrogen shifts this broad band to lower  
13 frequencies. The simulations suggest that replacing the  $\text{CH}_3$  groups by  $\text{CD}_3$  leaves the shape  
14 of the OH-stretching band largely unaffected. This is established when comparing the OH-  
15 and OD-stretching regions in Figures 6 and 7.  
16  
17  
18  
19  
20  
21  
22  
23  
24  
25

26 Previous computational work employed reduced-dimensionality quantum dynamics simula-  
27 tions and found considerably narrower and stronger OH stretching bands.<sup>28,88</sup> For example,  
28 density matrix evolution simulations at 300 K found the asymmetric OH stretching band  
29 centered at 2500  $\text{cm}^{-1}$  and to spread from 2300  $\text{cm}^{-1}$  to 2800  $\text{cm}^{-1}$ .<sup>88</sup> Low-temperature (1  
30 K) MD simulations with the MMPT force field lead to a strong OH-stretching band at 2728  
31  $\text{cm}^{-1}$  (see Figure S7 in the SI), which should be amenable to matrix isolation spectroscopy  
32 at very low temperature. The OH bending modes are at 1180  $\text{cm}^{-1}$ , which corresponds to  
33 the experimentally measured strong band at 1171  $\text{cm}^{-1}$  by de-convoluted IR spectra.<sup>38</sup>  
34

38  
39  
40  
41  
42  
43

44 To further help explain the observed low intensity of the OH-stretching overtone transitions,  
45 the wavenumber and intensity of the OH-stretching vibration in AcAc has been calculated  
46 assuming a 1D local mode anharmonic oscillator. The CCSD(T)/cc-pVTZ calculated local  
47 mode parameters as well as the wavenumber and oscillator strength of the OH-stretching  
48 transitions are given in Table S7. The local mode parameters are consistent with a strong  
49 hydrogen bond, although the double well nature of the potential likely adds uncertainty to  
50 these values. The CCSD(T) AO calculation the  $2\nu_{\text{OH}}$  region is predicted around 5200  $\text{cm}^{-1}$

1  
2  
3 with an intensity about 2 orders of magnitude weaker than the fundamental transition. This  
4  
5 combined with the very broad nature of the OH-stretching transition as seen in the fun-  
6  
7 damental spectrum and in the MD simulation makes it unlikely that we can make clear  
8  
9 observations of this transition.  
10

## 11 12 13 14 15 16 17 18 19 20 21 22 23 24 25 26 27 28 29 30 31 32 33 34 35 36 37 38 39 40 41 42 43 44 45 46 47 48 49 50 51 52 53 54 55 56 57 58 59 60

The IR and NIR spectra of acetylacetone, acetylacetone- $d_8$ , and hexafluoroacetylacetone were investigated from 600 to 14000  $\text{cm}^{-1}$ . Geometry optimizations of the ground state and the transition state structures of AcAc at the CCSD(T)/cc-pVTZ level yield an electronic energy difference of approximately 3 kcal/mol favoring the  $C_s$  structure.

The fundamental OH-stretching band is observed as a very broad band redshifted relative to usual OH-stretching transitions. Higher overtone OH-stretching transitions were not found in either AcAc or HFAA, likely due to a combination of the expected weak and very broad overtone transitions. A progression of methine CH-stretching transitions were observed in all molecules, with the  $\text{CF}_3$  groups of HFAA found to slightly blueshift relative to  $\nu_{\text{CH}}$ .

IR and power spectra from atomistic simulations reproduce most experimentally recorded features and clearly assign the  $\nu_{\text{OH}}$  proton transfer (PT) mode to the weak and broad band experimentally observed in the 2000-3300  $\text{cm}^{-1}$  region. Furthermore, location of this band was found to sensitively depend on the barrier for PT from which a barrier for proton transfer of  $\approx 2.5$  kcal/mol is inferred. Therefore, combining experiment and atomistic simulations allowed us to estimate the barrier for proton transfer through comparison of the power spectrum and spectroscopic signature in the OH-stretching region in AcAc.

Figure 3: a) Experimental IR spectra of vapor phase AcAc (top) and AcAc-d<sub>8</sub>. Both spectra were recorded at a pressure of 7 Torr and with a 10 cm path length. The AcAc and AcAc-d<sub>8</sub> spectra were recorded at 291 K and 294 K, respectively. b) IR spectrum of vapor phase hexafluoroacetylacetone recorded at a pressure of 10 Torr and 10 cm path length at 295 K. The ordinates of the high wavenumber region of each spectrum are expanded to reveal more detail.

Figure 4: a) Vapor phase NIR spectra of AcAc (top) and AcAc-d<sub>8</sub>. Both spectra were recorded at a pressure of 6 Torr, 294 K and with a 4.8 m path length. The left ordinate corresponds to the AcAc-d<sub>8</sub> spectrum. b) Vapor phase hexafluoroacetylacetone recorded at a pressure of 20 Torr, 293 K and with a 4.8 m path length. The high frequency region is expanded for more detail.

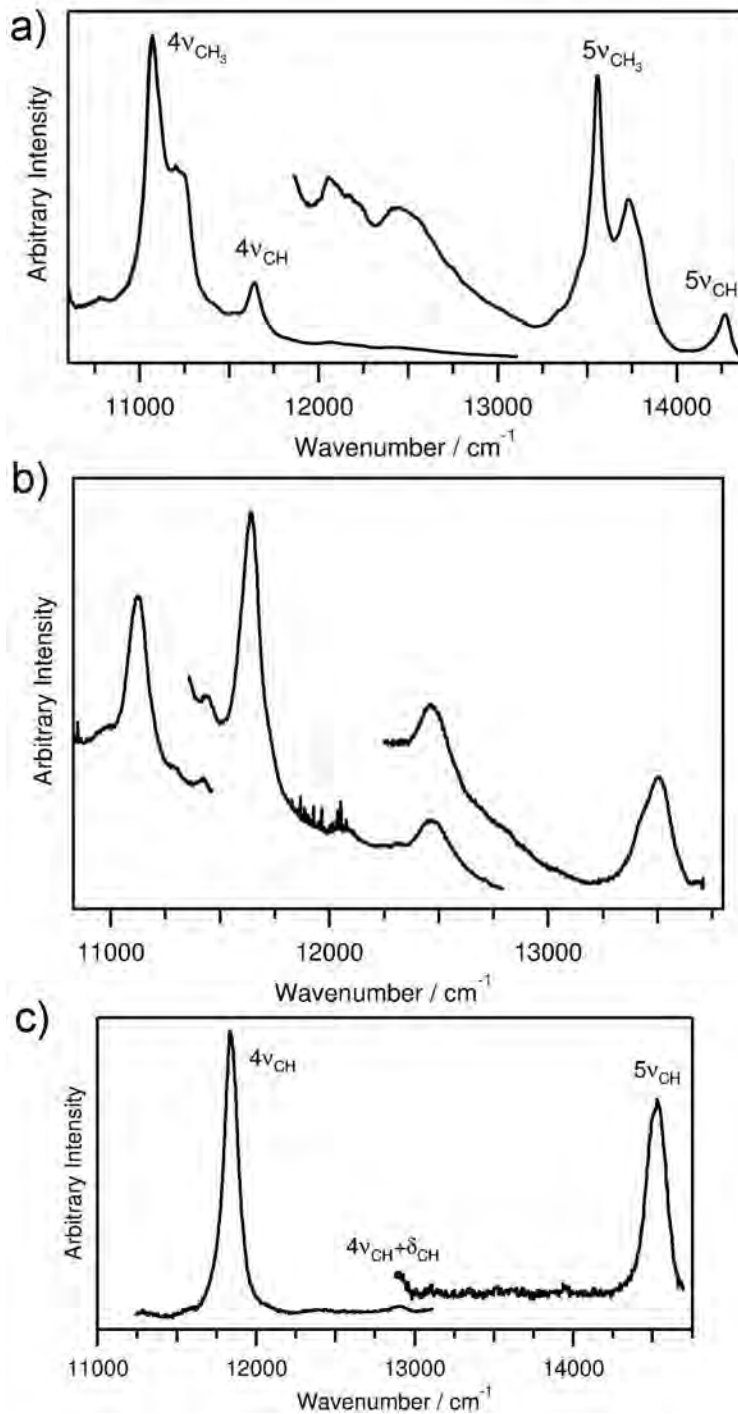

Figure 5: Room temperature photoacoustic spectra of a) 7 Torr AcAc vapor, b) 8 Torr AcAc-d<sub>8</sub> vapor, and c) 0.5 Torr hexafluoroacetylacetone vapor. The high frequency regions are expanded for more detail.

Figure 6: IR spectra computed from 5 ns *NVE* MD trajectories at 300 K: a) IR spectrum of AcAc in the gas phase, with the experimental spectrum superimposed; b) power spectra (from top to bottom) for CO stretch, OO stretch, OH stretch, OH bends, and the CH<sub>3</sub> torsion, respectively.

Figure 7: IR spectra computed from 5 ns *NVE* MD trajectories at 300 K: a) IR spectrum of AcAc-*d*<sub>8</sub> in the gas phase, with the experimental spectrum superimposed; b) power spectra (from top to bottom) for CO stretch, OO stretch, OH stretch, OH bends, and the CH<sub>3</sub> torsion, respectively.

Figure 8: Effect of scaling the barrier for PT on the IR-band for AcAc. Comparison of the experimental spectrum (purple) in the PT-band region with those from simulations with different barrier heights of the MMPT PES: simulations with the reference PES - barrier height of 2.35 kcal/mol (orange, black), with half the barrier height (dark and light green) and with twice the barrier height (magenta and red). The pronounced peaks in the experimental spectrum around 3000  $\text{cm}^{-1}$  correspond to CH stretch vibrations which do not appear in the computed power spectrum of the transferring hydrogen atom.
