18 Effect of pasture different recovery periods

19

20 **Abstract**

21 Pasture management that considers pasture growth dynamics remains an open  
22 question. Conceptually, such management must allow for grazing only after the  
23 recuperation of the pasture between two separate timely grazing periods when  
24 pasture reaches optimum recovery, as the first law of Voisin's Rational Grazing  
25 system (**VRG**). The optimum recovery period (**ORP**) not only implies a pasture with

26 better nutritional value and higher biomass yield, but one that also reduces the  
27 production of enteric methane (**CH<sub>4</sub>**) to improve the grazing efficiency of cattle.  
28 Therefore, this study aimed to evaluate three different recovery periods (**RP**) of  
29 mixed grasses on the grazing behaviour of heifers, as well as herbage selectivity,  
30 herbage yield and nutritional value, *in vitro* degradability, and CH<sub>4</sub> production. Based  
31 on these criteria, three pasture RP of 24 (**RP24**), 35 (**RP3**) and 46 (**RP46**) days were  
32 evaluated in six blocks using a randomized block design. At each predetermined RP,  
33 samples of the pasture were taken before the animals were allowed to graze. Right  
34 after collecting the pasture samples, heifers accessed the pasture during four  
35 consecutive hours for grazing simulation and behavioural observations. We also  
36 measured the bite rate of each animal. The pasture growing for 24 days had the  
37 highest biomass production, best nutritional value, best efficiency of *in vitro* CH<sub>4</sub>  
38 relative emission (ml) per DM degraded (g), and bite rate of the three RP. Heifers all  
39 selected their herbage, irrespective of RP, but with different nutritional value and  
40 higher *in vitro* degradability. However, this did not change the production of *in vitro*  
41 CH<sub>4</sub>. Considering the growth conditions of the area where the study was performed,  
42 we recommend the shorter RP24 as the most suitable during the summer season.  
43 The study's findings support the idea of management intervention to increase the  
44 quality of grazing systems.

47 Sustainability

48

49 **Implications**

50 The enteric methane (CH<sub>4</sub>) is the most important greenhouse gas emitted from  
51 agriculture and ruminants raised in grazing systems are accepted as the bigger  
52 emitters, mainly in Tropical countries. However, the pasture management adopted in  
53 intensive grazing systems is shown to be an efficient strategy that influences the  
54 production of the gas. Controlling the period of pasture growth as well as the access  
55 of cattle to graze enables high nutritional value and productive pasture. This,  
56 therefore, will influence the grazing behaviour of cattle towards improving their  
57 performance and efficiency which promotes the reduction of environmental impacts  
58 like CH<sub>4</sub> emissions.

59

## 60 **Introduction**

61 Livestock is widely accepted as the biggest anthropogenic source of greenhouse gas  
62 **(GHG)** emissions. Enteric methane **(CH<sub>4</sub>)** is the most important GHG and accounts  
63 for 40% of total GHG emissions from agriculture. Of this percentage 74% of CH<sub>4</sub>  
64 emissions comes from cattle (Faostat, 2016). Methane emissions are more prevalent  
65 in cattle fed pasture than in cattle fed grain, especially in tropical pastures  
66 (Archimède *et al.*, 2018).

67 Most pasture-based countries have pastures composed of tropical species increasing  
68 even more CH<sub>4</sub> enteric emissions. Therefore, these countries have been criticized  
69 worldwide, jeopardizing the reputation of their livestock production. Nevertheless,  
70 most of the information that supports high emissions from grazing cattle comes from  
71 extensive systems in which the pasture is degraded and/or poorly managed and with  
72 low nutritional value (Berndt and Tomkins, 2013). Additionally, in extensive systems,  
73 animals are free to select their own grazing paths (Badger *et al.*, 2017).

74 Consequently, they end up coming back to the same areas, which results in

75 complicating soil restoration and impairing the radicular development systems of  
76 plants (Pulido *et al.*, 2018).

77 The improvement of pastures in tropical grass-based systems plays an important role  
78 in mitigating CH<sub>4</sub> gas emission due to its influence on herbage utilization and animal  
79 performance (Souza Filho *et al.*, 2019). Voisin's Rational Grazing (**VRG**) is an  
80 agroecological pasture management system widely used in countries of South  
81 America (see 1<sup>st</sup>, 2<sup>nd</sup> and 3<sup>rd</sup> Pan-American Meeting on Agroecological Pasture  
82 Management in: Cadernos de Agroecologia [http://cadernos.aba-  
84 agroecologia.org.br/index.php/cadernos/issue/view/5](http://cadernos.aba-<br/>83 agroecologia.org.br/index.php/cadernos/issue/view/5)). Following VRG, total pasture  
85 area is divided into paddock, in which the presence of the animal is based on the  
86 growth of monitored plant species which is controlled by the visual evaluation of herd  
87 management, thus differing from extensive systems. VRG is based on four laws of  
88 rational grazing (Voisin, 1974). One of these laws allows for the complete restoration  
89 of pasture reserves at the root level between two separate grazing periods. During  
90 such times, plants will grow and achieve high digestibility and accumulation of  
91 nutrients, as well as high DM yield per time and per area. This is called the optimum  
92 recovery period (**ORP**), and it is also the designated time when animals should gain  
93 access to the paddock (Voisin, 1974).

94 In practice, VRG enables high nutritional value and productive pasture towards  
95 improving animal performance, including the reduction of environmental impacts like  
96 enteric CH<sub>4</sub> emissions (Stanley *et al.*, 2018). Moreover, VRG pastures are associated  
97 with high soil carbon (**C**) accumulation due to the increase biocenosis that increase  
98 and conserve the soil organic matter (Seó *et al.*, 2017) that helps reduce carbon  
dioxide (**CO<sub>2</sub>**) concentration in the atmosphere and further mitigate GHG emissions

99 (Stanley *et al.*, 2018). Moreover, this system can reduce overgrazing, which  
100 potentially protects the soil against erosion and degradation.  
101 When the recovery period (**RP**) is not managed correctly, plants might achieve  
102 maturity. Therefore, the vegetative phase ends, and the reproductive phase starts,  
103 and all the energy of the plant is directed toward flowering and seed formation. This  
104 maturation stage in pasture plants has, as a result, lower nutritional value than plants  
105 at earlier growth stages (Bhatta *et al.*, 2016). In later stages, the plant will have  
106 higher fibre and less protein concentration; and this typically promotes more  
107 production of enteric CH<sub>4</sub> (Jonker *et al.*, 2016). However, considering that the VRG  
108 pasture is composed of multi-species with different growth dynamics (Voisin, 1974;  
109 Machado Filho *et al.*, 2014), animals should be able to select desired nutritional  
110 herbage (Wallis de Vries, 1995). However, in intensive systems, the animal is  
111 restricted from freely selecting their grazing areas (Badgery *et al.*, 2017) owing to the  
112 short time (i.e., 24 to 48-h) they spend in the paddock.  
113 While improvement of pasture management is known to reduce CH<sub>4</sub> emissions, to  
114 the best of our knowledge, no study has yet reported the effects of different pasture  
115 RPs in the VRG system on animal selectivity and their CH<sub>4</sub> production. *In vitro*  
116 techniques in the laboratory reproduce the methanogenic potential of different diets,  
117 which allows the opportunity of a pre-evaluating before following up with *in vivo*  
118 techniques (Hill *et al.*, 2016). Therefore, we aimed to evaluate the effect of three  
119 different RP of mixed grasses on heifers' behaviour and herbage selectivity, herbage  
120 yield and nutritional value, as well as *in vitro* degradability and CH<sub>4</sub> production.

121

## 122 **Material and methods**

123

124 *Site description*

125 The study was undertaken during the summer between December of 2017 and  
126 February of 2018 at the VRG Unit of the Federal University of Santa Catarina  
127 Experimental Farm of Ressacada, Florianópolis, Brazil (27°40'25" S; 48°32'30" W).  
128 The land is flat, and the soil of the farm is classified as a Typical Hydromorphic  
129 Quartzic Neossolo (*Neossolo Quartzarênico Hidromórfico Típico*), consisting  
130 predominantly of dark sand, with low levels of phosphorus and potash, pH in water  
131 5,5, a high content of organic matter and the groundwater level at less than 1m from  
132 the surface. The climate in this region is characterized as Cfa, i.e., subtropical humid,  
133 according to the Köppen climate classification (Álvares *et al.*, 2013). The annual  
134 average rainfall is 1462 mm, well distributed across the year, and the average  
135 temperature is 20 °C. During the experiment, no unexpected weather change was  
136 noticed.

137 The animals are routinely maintained on a 21 ha pasture platform divided into 84  
138 paddocks averaging 2500 m<sup>2</sup> under a VRG management system. The pasture is  
139 mainly composed of native tropical species classified as C4. The main species  
140 identified were *Andropogon lateralis* Nees, *Axonopus affinis* Chase, *Axonopus*  
141 *obtusifolius* Raddi, and *Ischaemum minus* J. Presl. From the Poaceae family;  
142 *Eleocharis maculosa* (Vahl) Roem. & Schult, *Rhynchospora holoschoenoides* Heiter,  
143 *Rhynchospora tenuis* Link from Cyperaceae; *Juncos tenuis* Willd. from Juncaceae;  
144 and *Desmodium adscendens* (Sw.) DC. and *Desmodium incanum* DC. from  
145 Fabaceae. Although the pasture is fairly diverse, composition among paddocks is  
146 consistent. Animals were moved on a daily basis to a new paddock with mineral salt  
147 and water *ad libitum*.

148

149 *Animals, treatments, and experimental design*

150 Six paddocks from the VRG unit were used in a randomized block design to minimize  
151 possible differences on soil and vegetation among paddocks. Every paddock (block)  
152 was then divided into three plots (834 m<sup>2</sup>) in which three different RPs were  
153 established: **RP24**: 24 days, **RP35**: 35 days, and **RP46**: 46 days. In each block  
154 (paddock), each RP was randomly assigned to a given plot. These periods were  
155 chosen to represent the average RP of 35 days  $\pm$  11 days used at the experimental  
156 farm.

157 Eighteen heifers (15 Jersey, 1 Holstein, and 2 Jersey  $\times$  Holstein) were selected and  
158 separated into three groups according to weight and to social hierarchical ranking of  
159 the herd to which they belonged, each having an average weight of 300  $\pm$  36.07 (SD)  
160 kg. Groups of heifers were scheduled to be used in accordance with a systematic  
161 distribution and the pre-determined RP. The groups went through all the blocks  
162 according to the RP in a 3x3 double Latin Square design.

163

164 *Measurements*

165 *Pasture collection and samples.* At the beginning of the experiment, the blocks were  
166 trimmed at about 2 cm from soil level on specific days in order to allow the pasture to  
167 grow to a predetermined RP (24, 35, and 46 days) and the scheduled organization of  
168 the sample collections. At each predetermined RP of the pasture, samples of the  
169 available biomass were taken of the pasture before that the animals were allowed to  
170 graze. At soil level, five random samples were cut using a 0.5 x 0.5 m<sup>2</sup> square. Each  
171 sample was weighed to measure biomass production and then composed as a final  
172 sample for bromatological analysis. By dividing the total biomass production over  
173 number of days of each RP, we determined biomass daily growth of each RP.

174 Samples were weighed, taken to a laboratory, dried at 55°C for 72-h, and then  
175 weighed to determine DM (AOAC, 1995). After drying, samples were ground to one  
176 mm in a hammer mill for further analysis.  
177 Ash concentration was estimated according to the AOAC (1995) methods. For Crude  
178 Protein (CP), Neutral Detergent Fibre (NDF) and Acid Detergent Fibre (ADF), Near  
179 Infrared Reflectance Spectroscopy (NIRS) was used. The reflectance spectra of  
180 samples were collected with an MPA FT-NIR spectrometer (BRUKER OPTIK GmbH,  
181 Rudolf Plank Str. 27, D-76275 Ettlingen) in triplicate. The spectral area of 3600 to  
182 12500 cm<sup>-1</sup>, accumulating after 64 scans, accounts for the bromatological values  
183 estimated by least square means regression calibration curve obtained by an OPUS  
184 7.5 (PLS) (Bjorsvik and Martens, 2001).

185

186 *Behavioural observations and hand-plucking.* Right after collecting the pasture  
187 samples at each scheduled RP, the groups of heifers accessed the plots during four  
188 consecutive hours for grazing simulation and behavioural observations. Grazing  
189 simulation was performed according to the hand-plucking technique (Wallis de Vries,  
190 1995), and three subsamples were collected from each animal per grazed plot in  
191 order to compose a representative sample from each group per block per RP.  
192 Samples collected by hand-plucking were used for the same bromatological analysis  
193 as previously described.

194 The observations were carried out during 4-h consecutively. Observers were  
195 previously trained and were located 15 m from the animals to reduce disturbance  
196 (Machado Filho *et al.*, 2014). A sample scan from each animal was taken every 10  
197 min (Altmann, 1974). The following behaviours were recorded: grazing, ruminating,  
198 idling, and any other behaviour of interest. Additionally, we measured the bite rate of

199 each animal five times each hour for 30 seconds each, and then one value per group  
200 was calculated.

201

202 *In vitro gas production technique.* Gas production and the *in vitro* degradability of  
203 pasture samples, as well as the hand-plucking samples, were analyzed at the  
204 Analytical Chemistry Plant Laboratory (LQAP) from Embrapa Cerrados, located in  
205 Planaltina-DF, using the methodology previously described by Mauricio *et al.* (1999).  
206 Briefly, a 0.5 g sample of each treatment was duplicated and weighed in F57 Ankom  
207 bags. These bags were introduced in 100 ml amber fermentation bottles. The bottles  
208 were kept sealed with a silicone cap and an aluminium seal at 39°C until inoculation.  
209 The culture media were prepared following the recommendation of Menke *et al.*  
210 (1979). After the mixture of reagents, the solution was infused with CO<sub>2</sub> for 2-h,  
211 followed by calibration of pH to 6.9. Rumen fluid was collected from two four-year-old  
212 male steers with an average weight of 400 kg. One was a Nelore and the other was a  
213 three-quarter Gir-Holstein. Both were kept under *Urochloa brizantha* (Hochst ex A.  
214 *Rich.* cultivated by Marandu) grazing systems with at least 10 kg of DM/kg liveweight  
215 per day allowance, including *ad libitum* water and mineral supplemented with at least  
216 65g/kg of phosphorus and 2 kg/d of concentrate (80% of total digestible nutrients  
217 **(TDN)**and 12% of CP). The use of two different male guarantee better  
218 representativeness of the inoculum, and there is no problem in using males instead  
219 of heifers, as the focus was evaluating the degradability of feedstuffs rather than  
220 animals' performance. In this case, whenever is possible, the inoculum should be  
221 obtained from donors fed with similar diets than the feedstuff is being tested (forage)  
222 (Mauricio *et al.*, 1999). The rumen fluid sample was taken through a vacuum system  
223 in which a hose with small holes for filtration was introduced into the bull's cannula.

224 The material was stored in a thermos bottle. At the LQPA, both samples were mixed  
225 together, filtered again, using cheesecloth, and then added to the culture media. This  
226 procedure was done using a water bath control of 39°C and a constant flow of CO<sub>2</sub>.  
227 After mixing, the ruminal fluid of the culture media filled 50 ml of solution in each  
228 bottle which consisted of 36.4 ml of culture media and 13.6 ml of ruminal fluid. We  
229 then put the bottles in an oven at 39°C for 48-h.

230 The gases produced were measured at 6, 24, and 48-h by the displacement of water  
231 measured by the apparatus of communicating vessels described by Fedorah and  
232 Hrudey (1983). During these measurements, bottles remained immersed in a 39°C  
233 water bath. The volume of gas produced was recorded, and a sample of gas was  
234 collected through a syringe and injected into vacuum Exetainer® vials (Labco  
235 Limited). To quantify *in vitro* degradability, F57 bags were drained from the bottles  
236 after 6, 24, and 48-h. They were washed with cold tap water, dried at room  
237 temperature for two days, baked at 105°C for 4-h in the oven, and then weighed.

238

239 *CH<sub>4</sub> measurements.* Vials with gas samples were sent to Embrapa Dairy Cattle – Juiz  
240 de Fora/MG for the reading of fermentable gases. Samples were read in gas  
241 chromatography equipment (03 CG-FID, Agilent Technologies 7820<sup>a</sup>) with EzChrom  
242 Elite interface software, equipped with 2 6-way valves. One was used for the sampler  
243 and the other one as selector, allowing the constituents to pass, or not, through the  
244 second column. Hydrogen (**H<sub>2</sub>**) was used as a carrier gas on a flux of 8.3ml/min. The  
245 chromatography calibration was realized with reference standard certificated by  
246 Linde Industry on concentrations of CH<sub>4</sub>: 5.05; 10.2; 14.7; 20.1 and CO<sub>2</sub>: 20.2; 39.7;  
247 58.3; 79.9.

248

## 249 *Statistical analysis*

250 Statistical analyses were performed in R (R Core Team, 2018) using R packages  
251 lme4 (Bates *et al.*, 2015). Mixed-effects linear models were fitted to assess the effect  
252 of the three RP (24, 35 or 46 days) and method of grass sampling (hand-plucking  
253 and square) on each measured variable (CP, NDF, ADF, Ash, Biomass daily growth,  
254 DM, CH<sub>4</sub> production, and pasture degradability). The plots were the experimental unit  
255 and the blocks were considered as a random effect. We investigated the associations  
256 between the heifer's grazing frequency and the pasture RPs (24, 35 or 46 days)  
257 through mixed-effects binary logistic regression (Bernoulli) (Korner-Nievergelt *et al.*,  
258 2015); the effect of the pasture RPs on bite rate was evaluated by mixed-effects  
259 linear regression. Date and heifers nested within each date were used as random  
260 effects to account for pseudo replication. The group was considered the experimental  
261 unit. The results are presented as estimated marginal means  $\pm$  SEM. Model  
262 assumptions were adjusted graphically for normal distribution and homoscedasticity  
263 of the residuals. P values were obtained by Wald X<sup>2</sup> test type II ( $P < 0.05$  or  $P <$   
264  $0.01$ ).

265

## 266 **Results**

267 Table 1 shows the estimated means for bromatological composition evaluated for the  
268 different pasture RPs and the ability of heifers to select their herbage. Ash and CP  
269 decreased from RP24 to RP46 ( $P < 0.05$ ), while NDF was lower for RP24 compared  
270 to the other RPs ( $P < 0.01$ ). We noticed no difference for ADF among the RPs ( $P =$   
271  $0.86$ ). Biomass available at the moment heifers accessed the paddocks was higher  
272 ( $P = 0.003$ ) for RP3 (1582.4 kg DM/ha) comparing to RP1 (1029.6 kg DM/ha) and  
273 RP2 (1102.5 kg DM/ha), but daily growth was higher when cutting interval was 24

274 days ( $P = 0.01$ ). We found no interaction for the different RPs and the method of  
275 collecting pasture samples ( $P > 0.05$ ). However, the pasture selected by heifers had  
276 higher CP and less ADF and NDF proportion than the pasture offered on paddocks  
277 ( $P < 0.05$ ).

278 The *in vitro* degradability of the pasture was similar among the RPs evaluated ( $P =$   
279  $0.07$ ); nonetheless, the herbage selected by heifers was more degradable than the  
280 pasture offered in the paddocks in all three RPs ( $P < 0.001$ , Figure 1). The  $\text{CH}_4$   
281 production per DM degraded each hour of incubation is shown in Table 2. During the  
282 shorter RP (24 days), the pasture had better efficiency of *in vitro*  $\text{CH}_4$  relative  
283 emission (ml) per DM degraded (g) ( $P < 0.01$ ). However, we did not observe a  
284 difference between the pasture offered and the pasture selected for  $\text{CH}_4$  production  
285 in any RP tested ( $P = 0.52$ ).

286 Behavioural observations are shown in Table 3. Heifers grazed most of the time  
287 during the four hours of observation in the paddocks. The higher frequency of grazing  
288 occurred on pasture with 46 days of RP ( $P < 0.001$ ), and the bite rate was higher  
289 when heifers grazed the shorter RP24 ( $P < 0.001$ ).

290

## 291 **Discussion**

292 Generally, when compared to the other RPs, RP24 had higher biomass production,  
293 better nutritional value, better efficiency of *in vitro*  $\text{CH}_4$  relative emission (ml) per Kg  
294 of degraded DM, and heifers grazing on RP24 had higher bite rate, suggesting higher  
295 ingestion. RP35 was intermediate between RP24 and RP46 only for CP and ashes,  
296 without differences between them. Nevertheless, the higher NDF in RP35 and RP46  
297 compared to RP24 stimulated the increase of *in vitro*  $\text{CH}_4$  production per gram of  
298 degraded DM for both, RP35 and RP46. Thus, it is expected that the high nutritional

299 value of feed leads to a better fermentative parameter in the rumen and generates  
300 more end products, as volatile fatty acids (**VFA**), which are the main energy source  
301 for ruminants (Johnson and Johnson, 1995). However, the proportion of VFA  
302 produced depends on the chemical profile of the digested feed, which, in turn, affects  
303 the amount of CH<sub>4</sub> that will be produced, although we could not evaluate VFA  
304 proportions in this study.

305 The fibre benefits cellulolytic bacteria in the rumen; such bacteria specialize in  
306 degrading components of the cell wall. As a result, a higher acetate is produced,  
307 rather than propionate, which leads to a higher amount of H<sub>2</sub> free in the rumen,  
308 becoming, in turn, the substrate for methanogenic bacteria to produce CH<sub>4</sub>  
309 (McGeough *et al.*, 2019). In this study, the pasture was mainly composed of C4 plant  
310 species. Although we didn't classify the pasture consumed by the animals, it was  
311 possible to observe that most of the animals' consumption were C4 plants, which  
312 naturally have thick cell walls with high fibre, high degree of lignification, and minor  
313 concentrated nutrients that will be digested, which consequently promote large  
314 amounts of CH<sub>4</sub> gas (Archimède *et al.*, 2018).

315 C4 species have a high rate of photosynthetic ability that yields high DM potential  
316 (Silva *et al.*, 2015). When these plants grow in adequate conditions, their growth is  
317 favoured, and these characteristics are aggravated. Therefore, as plant growth  
318 advances, their chemical profile changes (Bhatta *et al.*, 2016). The length of the  
319 recovery period is negatively correlated with the digestibility of fibre, and more  
320 acetate is produced (Jonker *et al.*, 2016), creating more CH<sub>4</sub>. On the other hand, the  
321 low NDF proportion shifts fermentation towards propionate production (McGeough *et*  
322 *al.*, 2019; Johnson and Johnson, 1995) reducing substrate availability for  
323 methanogenic bacterial activity.

324 Similarly, it was expected that RP46 would have higher *in vitro* CH<sub>4</sub> production than  
325 RP35, considering its advanced pasture maturity and corresponding reduction in  
326 protein and ash proportion. However, their fibre concentration was similar, as well as  
327 their CH<sub>4</sub> production. The *in vitro* gas production technique indicates the readily  
328 available fermentable substrate that rumen microorganisms will use as energy  
329 source to produce VFA, and the rate that the feedstuff will be degraded (Mauricio *et al.*  
330 *al.*, 1999). Pasture with low nutritional value are slowly fermented and yield more  
331 acetate than propionate. We did not evaluate more than 48-h of incubation, so we  
332 cannot make inferences about the kinetics of fermentation. High nutritional value feed  
333 might also result in greater CH<sub>4</sub> production, depending of its digestibility,  
334 carbohydrate profile and the proportion of VFA produced (McGeough *et al.*, 2019).  
335 However, feed intake would most likely increase, which would reduce CH<sub>4</sub> per kg of  
336 DM intake more than feed of low nutritional value (Johnson and Johnson, 1995).  
337 Warner *et al.* (2016), evaluating three stages of maturity of grassland, observed a  
338 decrease in daily gross production of CH<sub>4</sub> from cows on longer cutting intervals.  
339 Nevertheless, when considering the emissions per kg of organic matter intake, the  
340 authors observed that increased CH<sub>4</sub> production correlated with plant maturation. To  
341 explain, for shorter pasture cut times, animal intake is increased, and CH<sub>4</sub> emissions  
342 are diluted, while on longer pasture cut times, the low daily gross production of CH<sub>4</sub> is  
343 not compensated by the reduction in animal intake. The main species from the  
344 grassland studied in Warner *et al.* (2016) was ryegrass, a C3 species, the maturation  
345 rate of which is slower than C4 species. Nonetheless, by the reduction in nutritional  
346 value from RP24 to RP46, we can speculate that the animals would consequently  
347 also reduce their intake, as the stage of maturity advances, and we would notice an  
348 increase in the intensity of CH<sub>4</sub> emissions (kg of CH<sub>4</sub>/kg of DM intake), according to

349 this advance. While RP46 and RP35 had similar CH<sub>4</sub> emission, RP46 had poorer  
350 nutritional value; therefore, RP46 is expected to have a higher intensity of CH<sub>4</sub>  
351 emissions. Meanwhile, the higher feed intake would compensate for the intensity of  
352 RP35 CH<sub>4</sub> (McGeough *et al.*, 2019 (Johnson and Johnson, 1995) and the low CH<sub>4</sub>  
353 production in RP24 would be diluted even more.

354 RP24 was more productive than RP35 and RP46 with higher biomass production per  
355 day. Shorter RP has been associated with more resilient pasture, thereby increasing  
356 efficiency and the number of grazing cycles (Silveira *et al.*, 2013). Shorter RP is  
357 found to be sufficient for the accumulation of carbohydrates and plant restoration,  
358 resulting in minor dead material proportionally and better leaf-stem relationship for  
359 grazing (Chapman *et al.*, 2014). This relationship positively affects plant growth,  
360 promoting better cell content and better nutritional value (Moura *et al.*, 2017). While  
361 fibre is expected to increase and protein is expected to decrease in long periods of  
362 pasture growth, shorter regrowth intervals (under 30 days) are associated with a  
363 greater leaf-stem ratio with minor cell wall fraction and major DM soluble fraction  
364 (Moura *et al.*, 2017). Furthermore, higher biomass production leads to higher C stock  
365 in soil. RP24 resulted in less efficiency of CH<sub>4</sub> relative emission, but it is also  
366 assumed to have had higher ability in sequestering C (Silva *et al.*, 2016; Stanley *et*  
367 *al.*, 2018).

368 It is also important to consider the composition of the sward. C4 species present a  
369 high rate of senescence, mobilizing nutrients faster for their growth (Silva *et al.*,  
370 2015). Thus, since they were in an adequate environment and climate, their growth  
371 and maturation were favoured and accelerated. On the other hand, when areas have  
372 low productivity, short RP might not be enough for plant recovery (Badgery *et al.*,  
373 2017). Since many factors influence pasture dynamics, the scenario in which the

374 pasture is established is very important to its composition and growth, as are  
375 management and species characteristics per se (Badgery *et al.*, 2017). For that  
376 reason, it is difficult to define a fixed RP, especially when the pasture is a mixture.  
377 This accounts for the variability of RP in the VRG system and explains why RP must  
378 be defined from time to time based on species with the greatest interest (Voisin,  
379 1974). Following this VRG law, determining the pasture's ideal RP in the context of  
380 the control of pasture growth and plant species growth dynamics can result in  
381 improving productivity and nutritional value. Taking the present study as an example,  
382 35 days is the average RP used at the Experimental Farm of Ressacada, the study  
383 site; nevertheless, considering the predominance of C4 species during the summer  
384 season and the results obtained in this study, 24 days of RP seem to be the best  
385 option for the season. For other seasons, like fall and winter, we may have an  
386 "optimum" RP interval even longer than the average 35 days. The region has a well-  
387 defined warm and cold season, with well distributed rainfall across the year (Álvares  
388 *et al.*, 2013). During the experiment, no unexpected weather change was noticed.  
389 The seasonal climate changes influences plants growth. This is an ultimately reason  
390 why RP should vary over the seasons. Although this study hasn't been conducted  
391 over multiple growing seasons, as would be ideal, we know from a number of other  
392 studies that RP is highly variable according to season, soil fertility, plant species  
393 composition, among other factors, as well documented (see 1<sup>st</sup>, 2<sup>nd</sup> and 3<sup>rd</sup> Pan-  
394 American Meeting on Agroecological Pasture Management in: Cadernos de  
395 Agroecologia [http://cadernos.aba-](http://cadernos.aba-agroecologia.org.br/index.php/cadernos/issue/view/5)  
396 [agroecologia.org.br/index.php/cadernos/issue/view/5](http://cadernos.aba-agroecologia.org.br/index.php/cadernos/issue/view/5)). Moreover, it is not the aim of  
397 this study to determine an ideal RP, but to better understand how different RPs can  
398 affect herbage quality, production and enteric emissions. Variable RP among

399 paddocks and seasons is a characteristic of the VRG (Voisin, 1974). Further  
400 research is required to be conducted over multiple growing season to better  
401 understand how RP for each season varies.

402 Pasture management is the gold standard for increasing the sustainability of grazing  
403 systems. While we showed the best RP to reduce the CH<sub>4</sub> emission from cattle, other  
404 studies have shown that plants from well-managed pastures also have the ability to  
405 sequester C from the atmosphere during photosynthesis (Seó *et al.*, 2017; Stanley *et*  
406 *al.*, 2018). When the amount of C emitted is lower than the amount that is being  
407 accumulated in soil by plant roots, we have a positive balance of C, and the livestock  
408 emissions are indeed offset (Silva *et al.*, 2016). The different rates of C balance  
409 between the different livestock systems illustrate that intensive grazing systems, like  
410 VRG, can mitigate GHG emissions from livestock by adopting the best management  
411 practices (Stanley *et al.*, 2018; Souza Filho *et al.*, 2019).

412 Intensive grass-based systems, like VRG, are found to reduce animal selectivity  
413 (Badgery *et al.*, 2017). Despite that, herbage selected by heifers was higher in  
414 protein, degradability rate and lower in fibre in all the three RPs. The same was  
415 observed by Machado Filho *et al.* (2014) who reported that grazing cows in a VRG  
416 system compensated for the low levels of protein from supplement that they received  
417 through the selection of plants with better protein value. Taking into account that our  
418 paddocks were composed of ample species diversity, heifers could select species to  
419 meet their nutritional requirements. Animal selectivity is also connected to the  
420 frequency of grazing behaviour and herbage mass offered. Cows are tempted to  
421 spend more time in grazing when more plant biomass is available (Motupalli *et al.*,  
422 2014). RP24 was more productive than RP35 and RP46 with higher biomass  
423 production, considering the period that the pasture was allowed to grow. However,

424 the biomass available at the moment that heifers accessed the paddocks was higher  
425 in RP46 (1582.4 kg DM/ha) compared to RP35 (1102.5 kg DM/ha) and RP24 (1029.6  
426 kg DM/ha), since RP46 had more days of pasture growth. Nevertheless, grazing  
427 involves the search for herbage, not just DM intake per se. In RP46, heifers grazed  
428 for longer time, but had a lower bite rate than they did in RP24 and RP35.

429 Considering the poorer nutritional value, we can suppose that heifers were more  
430 selective when in RP46, compared to RP24 and RP35, in order to achieve a more  
431 satisfactory pasture with better nutritional value amenable to their preference.

432 Moreover, the higher NDF concentration in RP46 required the animals to devote  
433 more effort in harvesting and chewing this pasture, which agrees with the lower bite  
434 rate in this RP. This might indicate that the intake most likely was reduced in RP46,  
435 thus reinforcing the idea that heifers have higher intensity of CH<sub>4</sub> emission when  
436 grazing on longer RP, as previously stated. In contrast, in RP24, heifers increased  
437 bite rate as a strategy to compensate for pasture structure variations and probably to  
438 increase the volume of forage intake (Mezzalana *et al.*, 2014), demonstrating an  
439 inverse relationship between bite rate and mass volume. Although we did not  
440 measure plant height, it most likely varied among the three RPs tested, considering  
441 the different time plants were given to grow. Since heifers grazed an equal amount of  
442 time when in RP24 and RP35, the higher bite rate in RP24 suggests a higher intake  
443 when heifers were in this treatment. Moreover, methane production was higher in  
444 RP35 than RP24 (Table 2). Thus, heifers grazing in the RP35 pasture probably  
445 emitted more CH<sub>4</sub>/kg of DM intake than when grazing in the RP24 pasture.

446 In summary, the shorter RP24 seems to be the most suitable RP for the C4 species  
447 in the area where the study was done during the summer. Further research is  
448 needed to understand the best RP in other seasons. Heifers apparently adjusted

449 their grazing behaviour according to the different RPs. This study supports the idea  
450 of adequate pasture management and variable RP in order to increase herd grazing  
451 efficiency and provide a better quality grazing system. Furthermore, the study  
452 indicates the cows' ability to select their own herbage when needed and their  
453 compensatory strategies in the context of variable pasture structure.

596 **Table 3** *Frequency of grazing behaviour (%) and bite rate per minute of heifers in*  
 597 *relation to different recovery periods of pasture: 24 days, 35 days, and 46 days.*

	24 days	35 days	46 days	SEM	P-value
Grazing (%)	63.5 <sup>B</sup>	64.3 <sup>B</sup>	66.5 <sup>A</sup>	0.09	***
Bite rate per minute	44.4 <sup>A</sup>	36.8 <sup>B</sup>	37.2 <sup>B</sup>	1.34	***

598 <sup>A,B</sup> Values within a row with different superscripts differ significantly at  $P < 0.01$ .

\*\*\* indicate probabilities levels at  $P < 0.001$

599 **Figure captions**

600

601 **Figure 1** Herbage selected by heifers (solid line) had higher pasture DM  
602 degradability (%) than herbage offered on paddocks (dotted line) at all three points of  
603 fermentation evaluated (6, 24, and 48-h).  $P < 0.05$ .
