ACKNOWLEDGEMENTS

I would like to thank my family, the faculty and personnel of the Department of Industrial Engineering at Kansas State, and my fellow students. Each of these groups helped make this segment of my education meaningful. Special thanks is given to Dr. Doris Grosh, whose faith and guidance were instrumental in my completing my course of studies and to my wife, Debora, without whose encouragement and understanding nothing would have been worthwhile.

Chapter 1

Introduction

1.0 GENESIS

This study had its origin in an earlier study for the United States Nuclear Regulatory Commission concerned with diesel engine failure data obtained from several nuclear power plants throughout the United States (3). A result of this earlier study was a number of questions concerning differences between statistical distributions with the primary question being "How does one determine statistically significant differences between statistical distributions?". A subsequent study by K. Lakshminarayan (4) applied the methodology used in this study to Beta distributions.

1.1 THE PROBLEM

Statistical significance is usually concerned with comparing different sets of sample data or with making inferences about the populations being sampled. Various parametric and non-parametric techniques therefore exist for making these decisions. However, no such techniques exist for comparing the populations themselves. The problem to be investigated is: given a family of statistical distributions, how much may a pair of distributions from this family differ before they can be detected as being significantly different, or "How different is different?".

1.2 PURPOSE AND OBJECTIVE

There are primarily two reasons for studying differences between similar distributions of the same family. The first reason deals with the theoretical insights which can result from studying the effects that perturbations of distribution parameters have on the "sameness" of family members.. With better understanding of the role of distribution parameters and their

relative importance in determining the characteristics of a particular distribution, hopefully more powerful estimating and comparative statistical techniques can be developed. The second and probably more important reason is the practical applications which could result from studying differences between statistical distributions. Applications could include new methods for establishing when sample data from similar sources could be pooled, parametric "goodness of fit" tests, and sample-free hypothesis testing.

With these two broad underlying reasons for studying differences in statistical distributions from the same family, the expressed objective of this study is: to develop a method of comparing differences in statistical distributions from the same family (normal distributions and exponential distributions are the families of statistical distributions studied), to use this technique to examine the effects of varying the parameters of the distributions on their "sameness", and to attempt to draw some conclusions pertaining to the usefulness of this technique in answering the question of "How different is different?".

1.3 METHOD

1.3.1. The Index of Non-Congruity - δ

The following discussion is an adaptation of material presented by Lakshminarayan (3).

Theoretically, two continuous distributions are the same only if their probability density functions are identical and for their probability density functions to be identical the two distributions must have exactly the same parameters. In practical situations however, two distributions whose probability density functions (and therefore parameters) are nearly the same, may produce random samples which are indistinguishable from one

another. It is this type of situation which indicates that merely examining the probability density functions (or the parameters) of two distributions to see if they are identical does not provide enough information to judge if the two distributions are similar enough to consider them practically as being the same, or if they are different enough that they must be considered as different.

One measure that determines differences between continuous distributions is the difference in the areas bounded by each probability density function in the region of interest or the amount of non-overlapping area bounded by the curves. If $f_1(x)$ and $f_2(x)$ are the probability density functions (Figure 1-1) of the two distributions being compared, then the amount of non-overlapping area or what we have termed "the index of non-congruity" is given by:

$$\delta = \int_{-\infty}^{\infty} |f_1(x) - f_2(x)| dx \quad (1)$$

The non-overlapping area is shown by the shaded portion of Figure 1-1 and the total amount of this shaded area equals δ . To qualify as probability density functions, $f_1(x)$ and $f_2(x)$ each must satisfy the criterion:

$$\int_{-\infty}^{\infty} f(x) dx = 1 \quad (2)$$

Therefore the values that can be assumed by the index of non-congruity are $0 \leq \delta \leq 2$. If two distributions are approximately the same then δ will be close to zero and if two distributions are radically different the value of δ will approach 2.

1.3.2. The Procedure

The general procedure used in this study is to choose a particular

FIGURE 1-1 Illustration of the Index of Non-Congruity

distribution from a family of distributions and then compare it to a similar distribution from the same family. The first distribution will be termed the "model distribution" (Distribution 1) and the similar distribution will be termed the "alternative distribution" (Distribution 2).

The procedure by which the alternative distribution is compared with the model distribution consists of a number of steps. The first step is to calculate the index of non-congruity between the two distributions as explained in Section 1.3.1.

Secondly, the model distribution is divided into ten equi-probability regions. A set of values $\{x(i)\}$ of the independent variable is calculated such that:

$$\int_{-\infty}^{x(i)} f_1(x) dx = i/10 \quad i = 1, \dots, 10 \quad (3)$$

The values $\{x(i)\}$ are such that the sample space of the independent variable is divided into regions which have the same area under the curve of the probability density function, as shown in Figure 1-2. After the equi-probability regions for the model distribution have been determined, a "perfect" sample is drawn from the alternative distribution by using the $\{x(i)\}$ from the model distribution as interval boundaries of the alternative distribution. A "pseudo" - χ^2 statistic is then calculated from this "perfect" sample. This pseudo- χ^2 statistic, χ^2_{PS} , is :

$$\chi^2_{PS} = \sum_{i=1}^{10} \frac{\{[F_2(i) - F_2(i-1)]M - .1(M)\}^2}{.1(M)} \quad (4)$$

where

$$F_2(i) = \int_{-\infty}^{x(i)} f_2(x) dx, \quad (5)$$

M is the sample size and $F_2(0) = 0$. We are interested in small sample sizes because small sample sizes are usually encountered in practical

FIGURE 1-2 Distribution divided into Equi-probability Regions

situations, and with very large sample sizes even small differences are discernable. Therefore a value of 50 is used for M in this study. The "pseudo" χ^2 and "perfect" sample are used to reduce the effects introduced by random fluctuations and to better ascertain the basic relationship between the index of non-congruity and differences between the model and alternative distributions.

The third step in the procedure comparing the alternative distribution to the model distribution is that a genuine random sample of size M is drawn from the alternative distribution and the sample is compared to the model distribution. The comparison is made by an ordinary χ^2 goodness of fit test. The random χ^2 statistic is calculated to provide a check on the χ^2_{PS} results and to provide additional insight into the question of differences between statistical distributions. Once the random χ^2 , denoted by χ^2_R , has been determined, the level of significance $\hat{\alpha}$ is calculated. Usually when a χ^2 statistic is calculated it is then compared to a value obtained from an appropriately chosen χ^2 distribution to determine significance at a prescribed confidence level. In this situation this technique is not totally satisfactory since we are not only interested in whether a particular χ^2_R value is significant but also in how significant it is. The level of significance $\hat{\alpha}$ is the area to the right of the computed (observed) χ^2_R of a χ^2 distribution with 9 degrees of freedom. There are 9 degrees of freedom since the model distribution is divided into 10 equiprobability regions and the random observations are sorted into these regions for ease of computation. The level of significance gives a more intuitively comprehensible measure of difference than the χ^2_{PS} and χ^2_R values.

The final step in comparing the alternative distribution with the model distribution is the calculation of parametric indicators which

attempt to quantify the differences between the model distribution and the alternative distribution. It is hoped that a relationship can be discovered between a parametric indicator and the index of non-congruity. Using this relationship combined with knowledge about the relationship between the index of non-congruity and statistical significance it may be possible to find a measure of statistical difference between distributions based solely on the parameters of the distributions. Such a parametric indicator would be of considerable practical importance because it would be easy to calculate.

In summary, the comparison procedure given a model distribution and an alternative distribution is:

- 1) Calculate δ , the index of non-congruity
- 2) Calculate χ^2_{PS} , the "pseudo" chi-square statistic from a "perfect" sample
- 3) Calculate χ^2_R from a random sample from the alternative distribution
- 4) Calculate $\hat{\alpha}$, the level of significance for χ^2_R
- 5) Calculate various parametric indicators

1.3.3 The McGill Random Number Generator

This study is primarily based on the use of a computer to perform the comparison procedure outlined in Section 1.3.2. One of the major problems in the development of a program to perform this procedure is the generation of a random sample from the alternative distribution to be used in calculating χ^2_R . The McGill Random Number Generator developed by members of the School of Computer Science of McGill University seemed particularly well suited for the requirements of this study. The McGill RNG has several features which led to its selection. First, the use of the McGill RNG

is FORTRAN compatible and the rest of the program will be written in FORTRAN. Second, the McGill RNG is called as a FORTRAN function rather than as a subroutine, which is advantageous in terms of computation time. Third, the previous value returned is maintained internally by the McGill RNG which leads to easier programming. Fourth, the McGill RNG has special procedures for generating random samples from normal and exponential distributions, thereby eliminating the need to program a transformation for converting a uniform distribution to either of these distributions. Finally, the McGill RNG is included in the subroutine library of the Kansas State University computing system, eliminating the need to include an additional subprogram for the random number generator in the index of non-congruity program.

Chapter 2
THE EXPONENTIAL CASE

2.0 INTRODUCTION

This chapter describes the specific procedure for calculating the index of non-congruity for exponential distributions, the program developed to perform the comparison procedure outlined in Section 1.3.2. for exponential distributions, and the results of using this procedure to compare several pairs of exponential distributions.

2.1 DETERMINATION OF THE POINT OF INTERSECTION

Let $f_1(x)$ be the probability density function of an exponential distribution with parameter λ_1 and let $f_2(x)$ be the probability density function of an exponential distribution with parameter λ_2 . Assume that $\lambda_2 > \lambda_1$. Consider Figure 2-1 which shows two exponential distributions fulfilling these requirements. The shaded area represents the index of non-congruity for this pair of distributions. This area difference is given by Equation (1) which is repeated again for clarity.

$$\delta = \int_{-\infty}^{\infty} |f_1(x) - f_2(x)| dx \quad (1)$$

To facilitate calculation of δ , this integral can be divided into 2 components.

$$\delta = \int_0^{\infty} |f_1(x) - f_2(x)| dx = \int_0^{X_A} [f_2(x) - f_1(x)] dx + \int_{X_A}^{\infty} [f_1(x) - f_2(x)] dx \quad (6)$$

X_A is the point of intersection of the two probability density functions. Finally note that this expression applies for the case where $\lambda_2 > \lambda_1$ and for the case where $\lambda_1 > \lambda_2$ the limits of integration for the component integrals would have to be exchanged to insure the proper sign for δ .

FIGURE 2-1 The Index of Non-Congruity for Exponential Distributions

The following calculation demonstrates the determination of the point of intersection X_A . At $X = X_A$

$$\lambda_1 e^{-\lambda_1 X_A} = \lambda_2 e^{-\lambda_2 X_A} \quad (7)$$

$$e^{(\lambda_2 - \lambda_1) X_A} = \frac{\lambda_2}{\lambda_1} \quad (8)$$

$$(\lambda_2 - \lambda_1) X_A = \ln \frac{\lambda_2}{\lambda_1} \quad (9)$$

$$X_A = \left[\frac{1}{\lambda_2 - \lambda_1} \right] \ln \frac{\lambda_2}{\lambda_1} \quad (10)$$

2.2 THE INDEX OF NON-CONGRUITY: EXPONENTIAL CASE

Having determined the point of intersection X_A the expression for the index of non-congruity can be modified. Substituting into Equation (6) we obtain:

$$\delta = \int_0^{X_A} [\lambda_2 e^{-\lambda_2 X} - \lambda_1 e^{-\lambda_1 X}] dx + \int_{X_A}^{\infty} [\lambda_1 e^{-\lambda_1 X} - \lambda_2 e^{-\lambda_2 X}] dx \quad (11)$$

$$= \int_0^{X_A} \lambda_2 e^{-\lambda_2 X} dx - \int_0^{X_A} \lambda_1 e^{-\lambda_1 X} dx \quad (12)$$

$$+ \int_{X_A}^{\infty} \lambda_1 e^{-\lambda_1 X} dx - \int_{X_A}^{\infty} \lambda_2 e^{-\lambda_2 X} dx$$

$$= -e^{-\lambda_2 X} \Big|_0^{X_A} - e^{-\lambda_1 X} \Big|_0^{X_A} \quad (13)$$

$$+ -e^{-\lambda_1 X} \Big|_{X_A}^{\infty} - -e^{-\lambda_2 X} \Big|_{X_A}^{\infty}$$

$$= [-e^{-\lambda_2 X_A} + 1] - [-e^{-\lambda_1 X_A} + 1] \quad (14)$$

$$+ [0 + e^{-\lambda_1 X_A}] - [0 + e^{-\lambda_2 X_A}]$$

$$= 2e^{-\lambda_1 X_A} - 2e^{-\lambda_2 X_A} \quad (15)$$

Therefore

$$\delta = 2[e^{-\lambda_1 X_A} - e^{-\lambda_2 X_A}] \quad (16)$$

This development is for the case where $\lambda_2 > \lambda_1$. For the case where

$\lambda_1 > \lambda_2$ the index of non-congruity is:

$$\delta = 2[e^{-\lambda_2 X_A} - e^{-\lambda_1 X_A}] \quad (15a)$$

and:

$$X_A = \frac{1}{\lambda_1 - \lambda_2} \ln \frac{\lambda_1}{\lambda_2} \quad (10a)$$

2.3 DESCRIPTION OF EXPONENTIAL PROGRAM FEATURES

2.3.1 Program Listing

A complete listing of the computer program to perform the comparison procedure for exponential distributions is given in Appendix 1.

2.3.2. Definition of Program Variables

- AHAT: the level of significance, $\hat{\alpha}$
- CADTR: function subroutine to determine $\hat{\alpha}$
- DIFFL: absolute difference of λ_1 and λ_2 , $|\lambda_1 - \lambda_2|$
- DELTA: the index of non-congruity, δ
- EI: the expected frequency in the equi-probability regions, $M/10$
- FREQ(10): the array containing the frequency counts of the random sample sorted into the equi-probability regions
- F2SUM: the sum of the components of the array FREQ squared
- ISEED: one of the seeds for the McGill RNG
- JSEED: the other seed for the McGill RNG
- K: the index for the array FREQ. K can take on integer values from 1 to 10.
- LAMDA1: the parameter of the model exponential distribution
- LAMDA2: the parameter of the alternative exponential distribution
- M: the sample size
- NU: the degrees of freedom for the χ^2 distribution which χ_{PS}^2 and χ_R^2 are compared with

- P2(10): the array containing the cumulative probability of the alternative distribution at the region boundaries $\{x(i)\}$
- RATIO: the ratio of λ_1 and λ_2 , if $\lambda_2 > \lambda_1$

$$\text{RATIO} = \frac{\lambda_2}{\lambda_1} \text{ and if } \lambda_1 > \lambda_2 \text{ RATIO} = \frac{\lambda_1}{\lambda_2}$$
- REXP: subroutine to generate a random deviate from an exponential distribution with mean $\lambda = 1$
- RSTART: subroutine to initialize the McGill Random Number Generator
- SAMPL(200): the array containing the random sample from the alternative distribution
- T1: the point of intersection λ_A
- X1(10): the equi-probability region boundaries $\{x(i)\}$
- X2ACT: the random χ^2 statistic, χ_R^2
- X2PS: the pseudo χ^2 statistic, χ_{PS}^2
- X2SUM: the sum of $[P2(10) - X1(10)]^2$ used in the calculation of X2PS
- Z1: variable equal to the negative of the product of LAMDA1 and T1
- Z2: variable equal to the negative of the product of LAMDA2 and T1

2.3.3. Inputs to the Program

The variables required as input to the program are:

LAMDA1, LAMDA2, M, ISEED, JSEED

The input is given on two separate cards with the indicated format.

LAMDA1, LAMDA2, M 1 card (2E10.4, I5)

ISEED, JSEED 1 card (2I5)

Multiple runs of the program can be made by supplying additional input cards (two per replication) containing the information described above.

Program completion is indicated by a blank card.

2.3.4. Outputs of the Program

The program provides two types of output. The first type is an echo check of the input. The second type is information calculated by the program. The following information is produced as output of the second type: the array X1, the array P2, the first M components of the array SAMPL, the array FREQ, DELTA, X2PS, X2ACT, and AHAT. A sample output is shown in Appendix 1.

2.3.5. Special Programming Considerations

Using the McGill Random Number Generator The use of the McGill RNG is accomplished by the two subroutines RSTART and REXP. RSTART initializes the RNG. The arguments of RSTART are ISEED and JSEED. The transfer from the main program to the RSTART subroutine is made by the statement CALL RSTART (ISEED, JSEED). The RNG provides default values if RSTART is not used. REXP generates a random exponential deviate from an exponential population with parameter $\lambda = 1$. This random deviate is transformed into a random deviate from an exponential population with parameter λ_A by dividing by λ_A e.g. $z = x/\lambda_A$ where z is the random deviate from the desired distribution and x is the generated random deviate. The argument of REXP is a dummy integer constant which is ignored by the program. In other words use of REXP(10) or REXP(98765) produces the same effect i.e. the generation of an exponential random deviate. Use of the function subroutine REXP is accomplished by using REXP(1) in an arithmetic function e.g. $SAMPL(I) = REXP(1)/LAMDA2$.

Sorting the Random Sample Observations In designing a sorting procedure the objective is to minimize the expected number of sorting trials for a sample set while maintaining a level of simplicity in the programming. The sorting procedure used in the program consists of a loop containing a

set of test statements which compares the random deviate with the equal probability region boundaries sequentially until the deviate is less than the boundary value. The deviate is then placed in the frequency region which has the boundary value as its upper bound. This sorting procedure would minimize the expected number of trials for the case where $\lambda_2 > \lambda_1$. However for the case where $\lambda_1 \gg \lambda_2$ this procedure would result in a high expected number of trials. This was not considered a significant problem since we are primarily concerned with cases where λ_1 and λ_2 are nearly equal.

Calculating $\hat{\alpha}$ The level of significance, $\hat{\alpha}$, is calculated by the function subroutine CADTR which is a slightly modified version of the CDTR subroutine contained in IBM's Scientific Subroutine Package. The modifications include changing the subprogram from a subroutine subprogram to a function subprogram and modifying the inputs and outputs of the subprogram.

2.4. RESULTS OF THE EXPONENTIAL PROGRAM

Four different sets of values of random number generator seeds were used in investigating the exponential case. Values of distributions compared varied from $\lambda_2/\lambda_1 = 1/3$ to $\lambda_2/\lambda_1 = 3$. For $\lambda_1 > \lambda_2$ the value of λ_2 was set to equal 10 and for $\lambda_2 > \lambda_1$ the value of λ_1 was set equal to 10. Therefore in every pair of distributions compared the smallest parameter was equal to 10. This was done for computation convenience since only the ratio is pertinent (as seen from Equations (10) and (16)), rather than the absolute size of λ_1 and λ_2 . The sample size used in the comparison was set equal to 50 in all cases. The results of the various comparison runs are summarized in Table 2-1.

Various relationships between comparison indices are graphically presented in Figures 2-2 to 2-7. Examination of these figures indicates that there is good reason to believe that there is a strong relationship

TABLE 2-1

between all of the comparison indices plotted. It is only possible at present to make very tentative estimates of most of these relationships. The comparison variable pairs where a clear relationship exists are δ vs λ_2/λ_1 , x_{PS}^2 vs δ , and x_{PS}^2 vs λ_2/λ_1 . These relationships do not vary with different random samples. However, for the relationships involving variables which are affected by different random samples—namely x_R^2 and $\hat{\alpha}$ —it is only possible to make tentative estimates of the relationships. To obtain better insight into these relationships, it would be necessary to increase the number of replications (using different random number seed values each time). Increasing the number of replications would increase the knowledge of the distribution of the values assumed by x_R^2 and $\hat{\alpha}$ at fixed values of the non-affected variables (δ , λ_2/λ_1 , and x_{PS}^2) and would also increase the accuracy of the estimate of the mean value of the affected variables. With sufficient replications it would be possible to obtain very reliable figures of the type shown in Figure 2-8 which illustrates a possible model of the relationship of $\hat{\alpha}$ and δ . The knowledge of these tentative relationships is believed to be sufficient for the purposes of this study but it is recognized that further research should proceed in the effort to better quantify these relationships.

Examination of Figures 2-2 to 2-7 provides some valuable insights and also produces some interesting observations. First, as shown in Figure 2-2, δ changes at a faster rate for a given change in the lambda ratio for $\lambda_2/\lambda_1 < 1$ than for $\lambda_2/\lambda_1 > 1$. This indicates that if an alternative distribution is compared to a model distribution having a smaller parameter, of size $\lambda_2 - \epsilon$ say, it is more likely that the two distributions can be considered as equivalent (because of a smaller δ value) than if the alternative distribution was compared to a model distribution having a correspondingly larger parameter of $\lambda_2 + \epsilon$.

Second, as indicated in Figures 2-3 and 2-4, x_{PS}^2 (and therefore

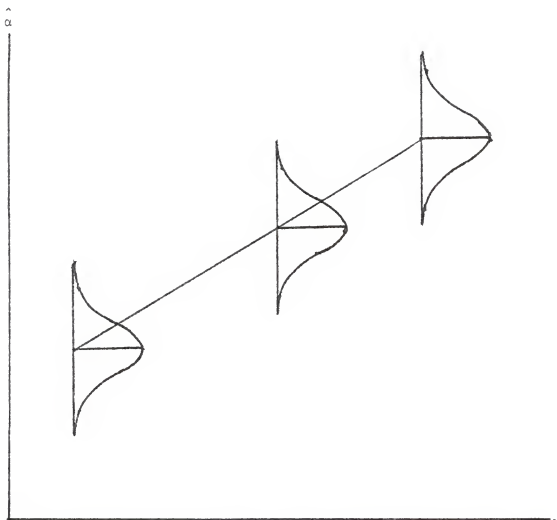

FIGURE 2-8 Possible model of the Relationship of $\hat{\alpha}$ and δ

presumably χ_R^2 and $\hat{\alpha}$) is more sensitive to differences in the distributions being compared for $\lambda_2/\lambda_1 < 1$ than for $\lambda_2/\lambda_1 > 1$. This sensitivity is in addition to the effect on δ of the relative magnitude difference of the parameters of the distributions. This indicates that in addition to the added likelihood that an alternative distribution and a model distribution can be considered equivalent for $\lambda_2/\lambda_1 > 1$ due to the magnitude effect, there is also an additional effect caused by the reduced sensitivity to difference for $\lambda_2/\lambda_1 > 1$.

Figure 2-5 indicates that χ_{PS}^2 in general tends to be smaller than χ_R^2 . It also appears that there is a linear trend between χ_{PS}^2 and χ_R^2 if the point $\chi_{PS}^2 = 76.8$, $\chi_R^2 = 120.40$ is not considered. A least-squares line was calculated for this relationship. The equation of this line is $\chi_R^2 = .95465 \chi_{PS}^2 + 9.36853$.

Figure 2-5 and Table 2-1 also produce two interesting observations. First, there is a tighter grouping of χ_R^2 from cases where $\lambda_2/\lambda_1 > 1$. Second, RNG seed A seems to produce peculiar results for cases where $\lambda_2/\lambda_1 < 1$. The underlying causes of these two phenomena are not fully understood.

From Figure 2-7 it appears that δ tends to be significant at the .05 level above values of .4. At values between $.3 \leq \delta \leq .4$ the result is ambiguous if the judgment is to be based on $\hat{\alpha}$ (χ_R^2). If χ_{PS}^2 is used to judge the two distributions for equivalence the range of uncertainty for δ can be determined from Table 2-1. Significance occurs at χ^2 values around 17 at the .05 level. Therefore χ_{PS}^2 would indicate significance at the .05 level above 8 since $.95465(8) + 9.36853 = 17$. It appears that if χ_{PS}^2 is used as the judgment criterion, then for δ to indicate significance its value must be greater than .3 for $\lambda_2/\lambda_1 < 1$ and greater than .35 for $\lambda_2/\lambda_1 > 1$. Using χ_{PS}^2 as the judgment criterion the uncertainty range for

δ appears to be

$$.2 \leq \delta \leq .3 \quad \lambda_2/\lambda_1 < 1$$

$$.25 \leq \delta \leq .35 \quad \lambda_2/\lambda_1 > 1$$

These δ values imply that if λ_2/λ_1 is to be used to test for significance as opposed to δ then the uncertainty regions are

$$\left\{ \begin{array}{l} .57 \leq \lambda_2/\lambda_1 \leq .67 \quad \lambda_2/\lambda_1 < 1 \\ 1.5 \leq \lambda_2/\lambda_1 \leq 1.75 \quad \lambda_2/\lambda_1 > 1 \end{array} \right\} \hat{\alpha} \text{ basis}$$

$$\left\{ \begin{array}{l} .65 \leq \lambda_2/\lambda_1 \leq .75 \quad \lambda_2/\lambda_1 < 1 \\ 1.45 \leq \lambda_2/\lambda_1 \leq 1.6 \quad \lambda_2/\lambda_1 > 1 \end{array} \right\} \chi_{PS}^2 \text{ basis}$$

and significance is indicated for values of

$$\lambda_2/\lambda_1 \leq .57 \quad \text{or} \quad \lambda_2/\lambda_1 \geq 1.75 \quad \hat{\alpha} \text{ basis}$$

$$\lambda_2/\lambda_1 \leq .65 \quad \text{or} \quad \lambda_2/\lambda_1 \geq 1.6 \quad \chi_{PS}^2 \text{ basis}$$

3.0 INTRODUCTION

This chapter describes the specific procedure for calculating the index of non-congruity for normal distributions, the program developed to perform the comparison procedure outlined in Section 1.3.2. for normal distributions, and the results of using the procedure to compare several pairs of normal distributions.

3.1 DETERMINATION OF THE POINT OR POINTS OF INTERSECTION

Let $f_1(x)$ be the probability density function of a normal distribution with mean u_1 and standard deviation σ_1 . Let $f_2(x)$ be the probability density function of a normal distribution with mean u_2 and standard deviation σ_2 .

At a point of intersection we have,

$$\frac{1}{\sqrt{2\pi} \sigma_1} e^{-1/2\left(\frac{x-u_1}{\sigma_1}\right)^2} - \frac{1}{\sqrt{2\pi} \sigma_2} e^{-1/2\left(\frac{x-u_2}{\sigma_2}\right)^2} = 0, \quad (17)$$

$$\text{so that } e^{-1/2\left[\left(\frac{x-u_1}{\sigma_1}\right)^2 - \left(\frac{x-u_2}{\sigma_2}\right)^2\right]} = \frac{\sigma_1}{\sigma_2} \quad (18)$$

$$\text{and } \left[\left(\frac{x-u_1}{\sigma_1}\right)^2 - \left(\frac{x-u_2}{\sigma_2}\right)^2\right] = -2 \ln \frac{\sigma_1}{\sigma_2}. \quad (19)$$

$$\begin{aligned} \text{Then } (\sigma_2^2 - \sigma_1^2)x^2 - 2(\sigma_2^2 u_1 - \sigma_1^2 u_2) + [\sigma_2^2 u_1^2 - \sigma_1^2 u_2^2 + \\ 2\sigma_1^2 \sigma_2^2 \ln \frac{\sigma_1}{\sigma_2}] = 0 \end{aligned} \quad (20)$$

Equation (20) is of the form

$$A x^2 + Bx + C = 0 \quad (21)$$

The number of roots of equations of this form can be determined from the discriminant. If $(B^2 - 4AC)$ is

negative	there are no real roots
zero	one real root $x_A = \frac{-B}{2A}$
positive	two real roots, $x_{A1} = \frac{-B + \sqrt{B^2 - 4AC}}{2A}$
	$x_{A2} = \frac{-B - \sqrt{B^2 - 4AC}}{2A}$

Denoting the discriminant by R, we find that

$$R = 4(\sigma_2^2 u_1 - \sigma_1^2 u_2)^2 - 4(\sigma_2^2 - \sigma_1^2)[\sigma_2^2 u_1^2 - \sigma_1^2 u_2^2 + 2\sigma_1^2 \sigma_2^2 u_1 \frac{\sigma_1}{\sigma_2}] \quad (22)$$

which reduce to the conditions

R negative	yields no real roots
R zero	yields one root $x_A = \frac{\sigma_2^2 u_1 - \sigma_1^2 u_2}{\sigma_2^2 - \sigma_1^2}$
R positive	yields two roots $x_{A1} = x_A + \frac{\sqrt{R}}{2(\sigma_2^2 - \sigma_1^2)}$
	$x_{A2} = x_A - \frac{\sqrt{R}}{2(\sigma_2^2 - \sigma_1^2)}$

Now in the special case where $\sigma_2 = \sigma_1 = \sigma$, then Equation (17) reduces to

$$\frac{1}{\sqrt{2\pi} \sigma} e^{-1/2(\frac{x-u_1}{\sigma})^2} - \frac{1}{\sqrt{2\pi} \sigma} e^{-1/2(\frac{x-u_2}{\sigma})^2} = 0 \quad (17a)$$

$$\text{which yields } (x-u_1)^2 = (x-u_2)^2 \quad (24)$$

$$x^2 - 2xu_1 + u_1^2 = x^2 - 2xu_2 + u_2^2 \quad (25)$$

$$2xu_2 - 2xu_1 = u_2^2 - u_1^2 \quad (26)$$

$$x = \frac{u_2^2 - u_1^2}{2(u_2 - u_1)} \quad (27)$$

$$x_A = \frac{u_2 + u_1}{2} \quad (28)$$

3.2 THE INDEX OF NON-CONGRUITY: NORMAL CASE

The two most common situations with normal distributions, where there are two points of intersection and $\sigma_1 = \sigma_2$, are shown in Figures 3-1 and 3-2. The shaded area in these figures equals the index of non-congruity.

The index of non-congruity is given by Equation (6).

$$\delta = \int_{-\infty}^{\infty} |f_1(x) - f_2(x)| dx \quad (6)$$

This expression can be modified according to the number of intersection points. If there is no point of intersection then obviously $\delta = 2$. If there is one point of intersection, X_A , the integral can be decomposed into two terms. Assume that $f_1(x) > f_2(x)$ for $x < X_A$ then

$$\delta = \int_{-\infty}^{X_A} (f_1(x) - f_2(x)) dx + \int_{X_A}^{\infty} (f_2(x) - f_1(x)) dx \quad (29)$$

$$\delta = \int_{-\infty}^{X_A} f_1(x) dx - \int_{-\infty}^{X_A} f_2(x) dx + \int_{X_A}^{\infty} f_2(x) dx - \int_{X_A}^{\infty} f_1(x) dx \quad (30)$$

$$\delta = F_1(X_A) - F_2(X_A) + [1 - F_2(X_A)] - [1 - F_1(X_A)] \quad (31)$$

$$\delta = 2[F_1(X_A) - F_2(X_A)] \quad (32)$$

where $F_i(x)$ is the cumulative probability function of $f_i(x)$. In general, for the case where there is one point of intersection

$$\delta = 2|F_1(X_A) - F_2(X_A)| \quad (33)$$

If there are two points of intersection (see Figure 3-2) then the index of non-congruity integral can be separated into three parts. Let C_1 and C_2 ($C_1 < C_2$) be the points of intersection.

Assume that $f_1(x) > f_2(x)$ for $x < C_1$ then

$$\delta = \int_{-\infty}^{C_1} (f_1(x) - f_2(x)) dx + \int_{C_1}^{C_2} (f_2(x) - f_1(x)) dx + \int_{C_2}^{\infty} (f_1(x) - f_2(x)) dx \quad (34)$$

FIGURE 3-1 The Normal Case with Two Points of Intersection

FIGURE 3-2 The Normal Case for Equal Standard Deviations

$$\delta = F_1(C_1) - F_2(C_1) + [F_2(C_2) - F_2(C_1) - F_1(C_2) + F_1(C_1)] + [1 - F_1(C_2) - 1 + F_2(C_2)] \quad (35)$$

$$\delta = 2[(F_2(C_2) - F_2(C_1)) - (F_1(C_2) - F_1(C_1))] \quad (36)$$

In general for the case where there are two points of intersection

$$\delta = |2[(F_2(C_2) - F_2(C_1)) - (F_1(C_2) - F_1(C_1))]| \quad (37)$$

3.3 DESCRIPTION OF NORMAL PROGRAM FEATURES

3.3.1. Program Listing

This section describes the essential features of the program for comparing normal distributions. A complete listing of the program is given in Appendix 2.

3.3.2. Definition of Program Variables

AHAT: the level of significance, $\hat{\alpha}$

C1: the lower point of intersection, C_1

C2: the upper point of intersection, C_2

CADTR: function subroutine to determine $\hat{\alpha}$

D: an output parameter of subroutine NDTR which is not used in the main program

DELTA: the index of non-congruity, δ

EI: the expected frequency in the equi-probability regions, $M/10$

F1: the cumulative probability $F_1(X)$ at X_A

F1C1: the cumulative probability $F_1(X)$ at C_1

F1C2: the cumulative probability $F_1(X)$ at C_2

F1DIF: F1C2 - F1C1

F2: the cumulative probability $F_2(X)$ at X_A

F2C1: the cumulative probability $F_2(X)$ at C_1

F2C2: the cumulative probability $F_2(X)$ at C_2

- F2DIF: F2C2 - F2C1
- F2SUM: the sum of the components of the array FREQ squared
- FREQ(10): The array containing the frequency counts of the random sample sorted into the equi-probability regions
- FRSFAC: $4(\sigma_2^2 u_1 - \sigma_2^2 u_2)^2$
- IER: error indicator used in subroutine NDTRI
- IND: indicator showing the number of intersection points
- ISEED: one of the seeds for the McGill RNG
- JSEED: the other seed for the McGill RNG
- K: the index for the array FREQ
- MU1: population mean μ_1
- MU2: population mean μ_2
- M: the sample size
- NDTR: subroutine to calculate $F_i(z)$
- NDTRI: subroutine to calculate the standard normal deviate z , given $F_i(z)$
- P: input parameter to subroutine NDTRI containing $F_i(z)$
- P2(10): the array containing the cumulative probability of the alternative distribution at the region boundaries $\{x(i)\}$
- RAD: R of Equation (22)
- RADPRT: $\sqrt{R}/2(\sigma_2^2 - \sigma_1^2)$
- RATIO: the ratio of population standard deviations, σ_1/σ_2
- RNOR: McGill RNG function to generate standard normal deviate
- RSTART: subroutine to initialize the McGill RNG
- SAMPL(200): the array containing the random sample from the alternative distribution
- SIGMA1: population standard deviation, σ_1
- SIGMA2: population standard deviation, σ_2

- SNDFAC: $4(\sigma_2^2 - \sigma_1^2)[\sigma_2^2 u_1^2 - \sigma_1^2 u_2^2 + 2\sigma_1^2 \sigma_2^2 \ln \frac{\sigma_1}{\sigma_2}]$
 SQMU1: u_1^2
 SQMU2: u_2^2
 VAR1: σ_1^2
 VAR2: σ_2^2
 VARDIF: VAR2 - VAR1
 VXM12: $\sigma_1^2 u_2$
 VXM21: $\sigma_2^2 u_1$
 VXMD2: $(\sigma_2^2 u_1 - \sigma_1^2 u_2)^2$
 VXMDIF: $(\sigma_2^2 u_1 - \sigma_1^2 u_2)$
 VXS12: $\sigma_1^2 u_2^2$
 VXS21: $\sigma_2^2 u_1^2$
 X1(10): the equi-probability region boundaries {X(i)}
 X2ACT: the random χ^2 statistic, χ_R^2
 X2PS: the pseudo χ^2 statistic, χ_{PS}^2
 X2SUM: the sum of [P2(10) - X1(10)] used in the calculation of X2P
 XLNFAC: $2 \sigma_2^2 \sigma_1^2 \ln \frac{\sigma_1}{\sigma_2}$
 XX: the single point of intersection, X_A
 XX1: one of two points of intersection, X_{A1}
 XX2: the other of two points of intersection, X_{A2}
 Z: a standard normal deviate used in calculating X1(10)
 Z1: standard normal equivalent of X_A for distribution 1
 Z1C1: standard normal equivalent of C_1 for distribution 1
 Z1C2: standard normal equivalent of C_2 for distribution 1
 Z2: standard normal equivalent of X_A for distribution 2
 Z2C1: standard normal equivalent of C_1 for distribution 2
 Z2C2: standard normal equivalent of C_2 for distribution 2
 Z2PS(10): array containing standard normal equivalent of X1(10)
 for distribution 2

3.3.3. Inputs to the Program

The inputs to the program are the distribution parameters - μ_1 , σ_1 , μ_2 , σ_2 ; the sample size M ; and the RNG seed values - ISEED, JSEED. The input is given on two separate cards with the indicated format.

MU1, SIGMA1, MU2, SIGMA2, M	1 Card	(4E10.4, I5)
ISEED, JSEED	1 Card	(2I5)

Multiple runs are possible by supplying additional input cards (two per replication). Program completion is indicated by a blank card.

3.3.4. Outputs of the Program

The output of the normal program is almost identical with the output of the exponential program. There are two types of output of the normal program. The first type is an echo check of the inputs to the program and the second type is the set of values calculated by the program. As in the exponential program, the second type of output for the normal program consists of the values of δ , χ_{PS}^2 , χ_R^2 , $\hat{\alpha}$, $X1(10)$, $P2(10)$, the first M elements of $SAMPL(200)$, and $FREQ(10)$. In addition to these second type outputs, the normal program also prints the number of intersection points and their values. A sample output is contained in Appendix 2.

3.3.5. Special Programming Considerations

Definition of Non-Overlapping Distributions In actuality any two normal distributions will intersect in at least one point, since both span the interval from $-\infty$ to $+\infty$ and both have unit area. However, for widely separated distributions the amount of overlapping area is small and at some point could be considered zero. In the program, if $u_S + 5\sigma_S$ is less than $u_L - 5\sigma_L$ (where u_S refers to the smaller mean, u_L refers to the larger mean, and σ_S and σ_L refer to the corresponding standard deviations) then the distributions are defined as non-overlapping and δ is set equal

to 2.

Using the McGill RNG Use of the McGill RNG is accomplished in this program through the use of two subprograms - RSTART and RNOR. The use of RSTART is described in section 2.3.4. RNOR is used to generate a sample from a standard normal distribution. Its use is similar to the use of REXP described in Section 2.3.4. The sample from a standard normal distribution is transformed to a sample from a normal distribution with mean u and standard deviation σ by the equation

$$X = u + \sigma z \quad (38)$$

where z is the sample from a standard normal distribution and X is the observation from the desired distribution.

Sorting the Random Sample Observations The normal index of non-congruity program uses a different sorting scheme than the exponential program did because of the different shapes of the two distributions. The sorting scheme is shown in the tree diagram shown in Figure 3-3. This scheme is designed to search the middle equi-probability regions first. The efficiency of this sorting scheme is dependent on the nature of the alternative distribution and, therefore, the scheme does not minimize the expected number of tests in all situations. However, the scheme does reduce the maximum number of tests to 5, as compared with 9 in the scheme used in the exponential program.

Calculating the Normal Cumulative Probability of X The cumulative probability for an argument X is calculated by first converting the number to standard form by the transformation,

$$z = (x - u)/\sigma . \quad (39)$$

The cumulative probability is then calculated by the IBM Scientific Subroutine Package subroutine NDTR which uses the following approximation taken from Hastings

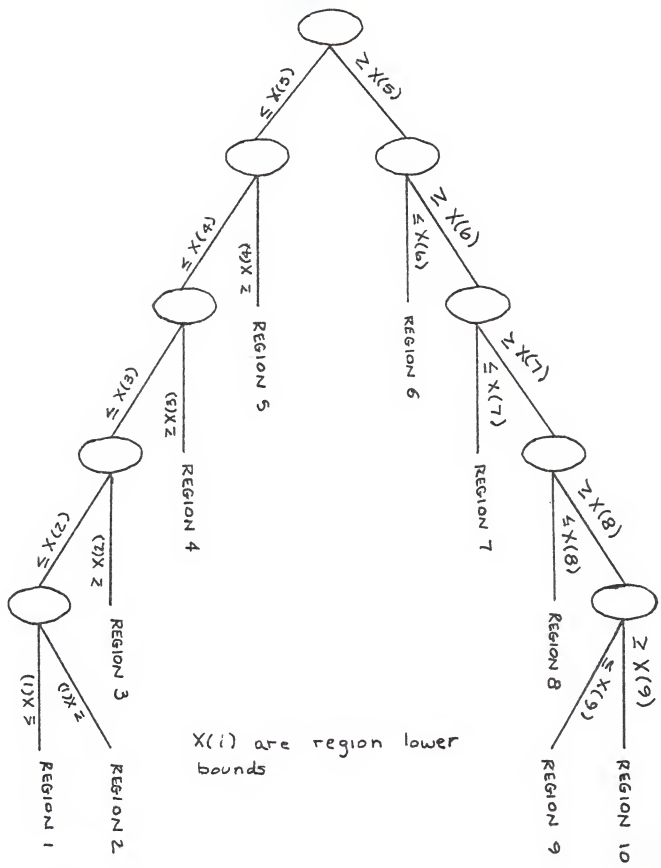

FIGURE 3-3 Tree Diagram for Sorting Procedure

$$F(z) = 1 - f(z)(b_1 t + b_2 t^2 + b_3 t^3 + b_4 t^4 + b_5 t^5) \quad (40)$$

where

$$f(z) = \frac{1}{\sqrt{2\pi}} e^{-z^2/2}, \quad t = \frac{1}{1 + rz}, \quad r = .2316419,$$

$$b_1 = .31938153, \quad b_2 = -.356563782, \quad b_3 = 1.7181477937,$$

$$b_4 = -1.821255978, \quad \text{and} \quad b_5 = 1.33027449$$

This approximation has a maximum error of 7.5×10^{-8} and is valid only for $z \geq 0$. For $z < 0$ the complement of $F(-z)$ gives the desired value.

Calculating X given a Normal Cumulative Probability A value X from a $N(\mu, \sigma^2)$ population can be calculated from a given normal cumulative probability P by first calculating the value z from a standard normal distribution with cumulative probability P and then applying the transformation given in Equation (38). The value z is calculated by the IBM Scientific Subroutine Package subroutine NDTRI which uses the following approximation taken from Hastings,

$$z = w - \frac{\sum_{i=0}^2 a_i w^i}{\sum_{i=0}^3 b_i w^i} \quad (41)$$

where $w = \sqrt{\ln(1/P^2)}$, $a_0 = 2.515517$, $a_1 = .802853$, $a_2 = .010328$,

$$b_0 = 1, \quad b_1 = 1.432788, \quad b_2 = .189269, \quad b_3 = .001308$$

This approximation has a maximum error of 4.5×10^{-4} and is valid only for $P \leq .5$. For $P > .5$, z of $1-P$ is calculated and then the sign of z is changed.

3.4 RESULTS OF THE NORMAL PROGRAM

Four different sets of values for random number generator seeds were used in investigating the normal case. The standard normal distribution was chosen as the model distribution. Three different types of alternative distributions were considered. In the first type the mean of the alternative

distribution was different from zero and the standard deviation was equal to one. This set of alternative distributions is referred to as the mean-variate set. In the second type the mean of the alternative distribution was equal to zero and the standard deviation was different from one. This set of alternative distributions is referred to as the variance-variate set. In the third type of alternative distribution considered, the mean of the alternative distribution was different from zero and the standard deviation was different from one. This set is referred to as the mean-variance-variate set. The sample size used in the comparisons was 50 in all cases.

One of the steps in the comparison procedure outlined in Section 1.3.2 is the calculation of various parametric indicators. The parametric indicator which was chosen in the normal case was,

$$\eta_1 = |u_1 - u_2| + |\sigma_1 - \sigma_2| \quad (42)$$

Various relationships between comparison indices are graphically presented in Figures 3-4 to 3-20. There appears to be a strong relationship between all of the comparison indices plotted. Examination of these figures provides some valuable information. Figure 3-4 shows the relationship between χ_{PS}^2 and δ . This figure indicates that for the cases of the mean-variate and variance-variate sets of alternative distributions χ_{PS}^2 and δ are strongly related. The figure also indicates that two distributions with a particular δ value are more easily detected as being significantly different if their means are different than if their standard deviations are different. The figure also shows a greater difference in χ_{PS}^2 for a given δ value for $\sigma_1 < \sigma_2$ than for $\sigma_1 > \sigma_2$. (Recall that in the exponential case this type of a relationship existed; χ_{PS}^2 for $\lambda_2/\lambda_1 < 1$ was greater than χ_{PS}^2 for $\lambda_2/\lambda_1 > 1$. This is a similar result since the standard deviation of an exponential distribution is $1/\lambda$ and therefore

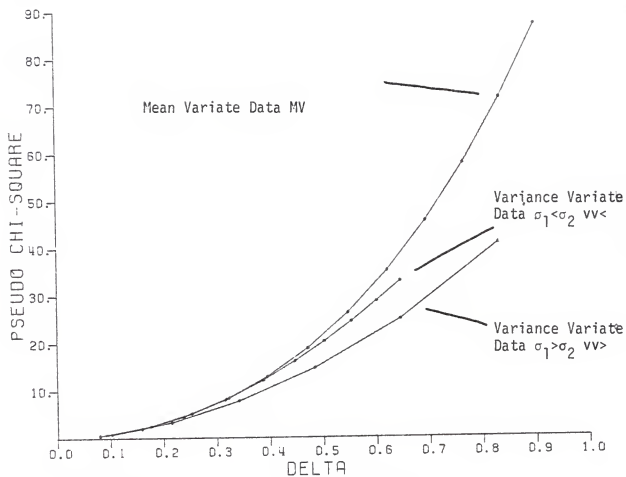

FIGURE 3-4 x_{PS}^2 vs. δ - Single Variation

FIGURE 3-14 $\hat{\alpha}$ vs. δ - Mean-Variate Data

FIGURE 3-15 $\hat{\alpha}$ vs. δ - Variance-Variate Data $\sigma_1 < \sigma_2$

FIGURE 3-16 $\hat{\alpha}$ vs. δ - Variance-Variate Data $\sigma_1 > \sigma_2$

FIGURE 3-17 $\hat{\alpha}$ vs. δ - Dual Variation

FIGURE 3-18 $\hat{\alpha}$ vs. η_1 -- Mean-Variate Data

FIGURE 3-19 $\hat{\alpha}$ vs. η_1 - Variance-Variate Data $\sigma_1 < \sigma_2$

FIGURE 3-20 $\hat{\alpha}$ vs. η_1 - Variance-Variate Data $\sigma_1 \neq \sigma_2$

the ratio of the standard deviations is $1/\lambda_2/1/\lambda_1 = \lambda_1/\lambda_2$. Hence if $\lambda_2/\lambda_1 < 1$ then $\sigma_{\text{exp1}} < \sigma_{\text{exp2}}$.)

Figure 3-6 indicates the relationship between δ and η_1 for the mean-variate and variance-variate data. The most sensitive case is for the variance-variate case with $\sigma_1 > \sigma_2$. This sensitivity is partially offset by the relationship between χ_{PS}^2 and δ for this case (which is not as sensitive as the other two cases shown) as shown in Figure 3-4. However it is not completely offset as seen in Figure 3-8 which shows that the case of variance-variate data with $\sigma_1 > \sigma_2$ produces a much higher χ_{PS}^2 value for a given η_1 than the other two cases (which produce comparable values).

As in the exponential case χ_{PS}^2 tends to be smaller than χ_{R}^2 , as seen in Figures 3-10 to 3-13. There also appears to be a linear trend between χ_{R}^2 and χ_{PS}^2 in each of these figures. A least-squares line was calculated for each of these cases. The obviously outlying points of Figures 3-11 and 3-13 were omitted from the calculations. The derived lines are

Figure 3-10 Mean-Variate Data

$$\chi_{\text{R}}^2 = .90935 \chi_{\text{PS}}^2 + 6.55919$$

Figure 3-11 Variance-Variate Data $\sigma_1 < \sigma_2$

$$\chi_{\text{R}}^2 = .92777 \chi_{\text{PS}}^2 + 4.95750$$

Figure 3-12 Variance-Variate Data $\sigma_1 > \sigma_2$

$$\chi_{\text{R}}^2 = .85908 \chi_{\text{PS}}^2 + 3.29251$$

Figure 3-13 Mean-Variance-Variate Data

$$\chi_{\text{R}}^2 = .580767 \chi_{\text{PS}}^2 + 5.83267$$

From Figures 3-14 to 3-16 it appears that (based on $\hat{\alpha}$ as the criterion) δ tends to be significant at the .05 level as indicated below:

Figure	Type	Significance Range
3-14	Mean-Variate Data	$\delta \geq .47$

Figure	Type	Significance Range
3-15	Variance-Variate Data $\sigma_1 < \sigma_2$	$\delta \geq .39$
3-16	Variance-Variate Data $\sigma_1 > \sigma_2$	$\delta \geq .6$

If χ_{PS}^2 is used as the criterion, χ_{PS}^2 would indicate significance at the following values calculated from the regression equations to correspond to a χ_R^2 value of 17 ($\hat{\alpha} = .05$).

Type	Significance Range
Mean-Variate Data	$\chi_{PS}^2 \geq 11.5$
Variance-Variate Data $\sigma_1 < \sigma_2$	$\chi_{PS}^2 \geq 13.0$
Variance-Variate Data $\sigma_1 > \sigma_2$	$\chi_{PS}^2 \geq 16.0$

Based on these values and consulting Figure 3-4, δ would indicate significance at the .05 level as given below.

Type	Significance Range
Mean-Variate Data	$\delta \geq .36$
Variance-Variate Data $\sigma_1 < \sigma_2$	$\delta \geq .4$
Variance-Variate Data $\sigma_1 > \sigma_2$	$\delta \geq .55$

The uncertainty regions can be estimated as

Mean-Variate Data	$.38 \leq \delta \leq .47$	
Variance-Variate Data $\sigma_1 < \sigma_2$	$.34 \leq \delta \leq .39$	$\hat{\alpha}$ basis
Variance-Variate Data $\sigma_1 > \sigma_2$	$.48 \leq \delta \leq .6$	
Mean-Variate Data	$.32 \leq \delta \leq .36$	
Variance-Variate Data $\sigma_1 < \sigma_2$	$.34 \leq \delta \leq .4$	χ_{PS}^2 basis
Variance-Variate Data $\sigma_1 > \sigma_2$	$.45 \leq \delta \leq .55$	

These values for δ imply that if η_1 is to be used as a test for significance instead of δ , then the uncertainty regions can be estimated from Figure 3-6 to be

Mean-Variate Data		$.48 \leq \eta_1 \leq .6$	
Variance-Variate Data	$\sigma_1 < \sigma_2$	$.43 \leq \eta_1 \leq .5$	$\hat{\alpha}$ basis
Variance-Variate Data	$\sigma_1 > \sigma_2$	$.4 \leq \eta_1 \leq .46$	
Mean-Variate Data		$.4 \leq \eta_1 \leq .44$	
Variance-Variate Data	$\sigma_1 < \sigma_2$	$.42 \leq \eta_1 \leq .52$	x_{PS}^2 basis
Variance-Variate Data	$\sigma_1 > \sigma_2$	$.38 \leq \eta_1 \leq .42$	

These regions compare favorably with results which can be taken from Figures 3-18 to 3-20 for the $\hat{\alpha}$ basis and Figure 3-8 for the x_{PS}^2 basis.

Significance is therefore indicated for η_1 values of

Mean-Variate Data		$\eta_1 \geq .6$	
Variance-Variate Data	$\sigma_1 < \sigma_2$	$\eta_1 \geq .5$	$\hat{\alpha}$ basis
Variance-Variate Data	$\sigma_1 > \sigma_2$	$\eta_1 \geq .46$	
Mean-Variate Data		$\eta_1 \geq .44$	
Variance-Variate Data	$\sigma_1 < \sigma_2$	$\eta_1 \geq .52$	x_{PS}^2 basis
Variance-Variate Data	$\sigma_1 > \sigma_2$	$\eta_1 \geq .42$	

Figures 3-5, 3-7, 3-9, 3-13 and 3-17 show the various relationships between indices for the mean-variance-variate data. Indications of strong relationships between the various indices are shown by these figures. However, it is believed that the knowledge of these relationships is too limited to draw any satisfactory results. Further research, in which the range of the comparison indices is expanded, is needed to better quantify these relationships.

Chapter 4
CONCLUSION

In concluding this study, two questions need to be answered. The first question is "How well did this study accomplish its objective?". The second question is "What direction should future research in this area take?".

The first question can be answered by reconsidering the objective of this study which was to develop a comparison method, use this method to investigate the effects of varying distribution parameters, and to evaluate the usefulness of this technique. The first two parts of this objective have already been accomplished and the third part can be completed by a brief review of the results of the study. The technique used in this study to compare statistical distributions appears to have considerable usefulness because of the consistency of results (i.e. δ in all cases indicated significance in the range $.3 \leq \delta \leq .6$), the ability to compare distributions for statistical difference in terms of only their parameters (λ_2/λ_1 for exponential distributions, τ_1 for most normal distributions), and the relative simplicity of the method.

The reader should recognize that in the normal case, a technique already exists to answer the question of "How different is different?" based on the classical z-test. This technique is statistically sufficient and is therefore more powerful than the method presented in this study. The use of the z-test is demonstrated below for $M = 50$, $\alpha = .05$, and $\sigma_1 = \sigma_2 = \sigma$.

$$1.96 \leq (u_1 - u_2) / \sqrt{\sigma^2/50}, \quad (43)$$

$$u_1 - u_2 \geq .277 \sigma \quad (44)$$

This indicates that for our investigation ($\sigma = 1$) significance would be indicated for a η_1 value greater than or equal to .277, as compared to a η_1 value of .60 for the index of non-congruity method.

The second question concerning the direction of future research is easily answered. There are four readily apparent directions for future research. They are:

1. Extension of this research in terms of additional replications and inclusion of more mean-variance-variate comparisons for the normal case as mentioned in Sections 2.4 and 3.4.
2. Application of the methodology used in this study to other continuous distributions such as the Weibull, Log-Normal, or Gamma distribution.
3. Development of a similar methodology which can be applied to the evaluation of statistically significant differences in discrete distributions.
4. Application of the methodology used in this study to study statistical differences of similar distributions which are from different families.

NON-CONGRUENCE OF STATISTICAL DISTRIBUTIONS:

HOW DIFFERENT IS DIFFERENT?

by

TERRY LEE APPLIGATE

B.S., Kansas State University, 1977

AN ABSTRACT OF A MASTER'S THESIS

Submitted in partial fulfillment of the
requirements for the degree

Manhattan, Kansas

1978

This thesis studies differences between statistical distributions of the same family. In particular it studies members of the exponential and normal families of statistical distributions. In theory two distributions are the same only if their probability density functions are identical (which implies that their parameters are identical also). However, in practical situations, two distributions which have closely similar probability density functions may produce random samples of small size which are indistinguishable from one another. This thesis is concerned with studying this situation in an attempt to better understand the question of "How different is different?" in relation to differences in statistical distributions from the same family.

The methodology used to study the difference between a pair of statistical distributions from the same family consists of a number of steps. The first step in the comparison procedure consists of determining the amount of non-overlapping area bounded by the probability density functions of the two distributions being compared. The second step consists of drawing a "perfect" sample from one distribution and comparing it with the other distribution. The third step consists of drawing a random sample from one distribution and comparing it with the other distribution. The final step consists of calculating certain indices from the parameters of the distributions and relating these indices to the other comparison results.

Results of the comparison procedure for a sample size of 50 indicate that in both the exponential case and the normal case statistical significant differences at the .05 level would be indicated for amounts of non-overlapping area in excess of a threshold value occurring somewhere in the region of .3 to .6. In addition to this there appears to be strong relationships between the indices derived from the parameters of the distributions being compared and the various other comparison indices.

These strong relationships would allow the comparison of statistical distributions solely on the basis of their parameters without requiring the use of sampling.

Special topics covered in the study which might be of interest to other researchers are the use of the McGill Random Number Generator developed by members of the School of Computer Science of McGill University and the suggestions for further research in this area.
