INTRODUCTION

In recent years there has been a growing interest in the use of liquid supplements in cattle feeding due to their advantages over dry supplements. One advantage of liquids is the fact that they are easily absorbed by the dry ingredients in a complete ration due to their low viscosity and surface tension. Another major advantage of liquids is that they may be fed in diversified ways; (1) as a top dress on grain and silage; (2) from lick-tanks in a pasturing situation; (3) mixed as an ingredient in a complete ration. The storage and handling of liquid supplements may also be easier than dry.

Even though liquids have advantages over dry supplements there are still problems such as product uniformity, overconsumption, and product stability that present problems to the manufacture and user of liquid supplements. Many of the liquid supplements being fed today undergo a physical segregation of ingredients and nutrients. This may be visually observed but many times analytical techniques must be employed to determine the uniformity of these liquids. Overconsumption is always a major concern of livestock feeders when feed is fed on a free choice system. Chemical decomposition of nutrients presents a problem in liquids due to air oxidation and interaction of nutrients such as trace minerals and vitamins. This may be enhanced when these ingredients are fed in a liquid carrier.

In December 1975, Rumensin[1] received Food and Drug approval to be used in the feeding of confinement cattle. The active ingredient of this additive is monensin sodium insin and will be referred to as monensin throughout the remainder of this

[1]Trademark, Elanco, Greenleaf, Indiana

paper. The benefit of the addition of this ingredient was an improvement of approximately 10% in feed efficiency. However clearance has not been given for the use of monensin in liquid supplements. If liquids are proven to be suitable carriers of monensin it is felt that cattle will respond in a similiar manner to this type of feed as they do to dry feed supplemented with Monensin.

The addition of Trace Minerals and Vitamins to liquid supplements would prove to be advantageous for many of the same reasons stated earlier for the use of liquids. By adding these micro-ingredients to liquids a more complete dispersion of these nutrients may be achieved through the improved mixing capabilities of liquid over dry supplements.

The purpose of this research was to investigate the use of a mold inhibitor (Delvocid®) in a corn based liquid supplement and then determine its effect on the products uniformity and stability. Investigation of the parameters necessary to stabilize monensin and soluble vitamin A and trace minerals in a corn based liquid supplement were also conducted. Urea was used as a non-protein nitrogen (NPN) source in the formulation of the corn based liquid supplement. Determination of crude protein, dry matter, starch damage, and several in vitro techniques were used to evaluate the effects of the mold inhibitor on the uniformity and stability of the liquid supplement. The stability of the vitamin A and trace minerals was investigated by determining the concentration of each micro-nutrient at different levels in storage tanks throughout a storage trial. Product uniformity was also investigated by determining crude protein, dry matter, and starch damage on samples taken

-2-

at different levels of the storage tanks throughout the
trial.

LITERATURE REVIEW

History of Liquid Supplements and Their Ingredients

The term "liquid supplement" has been defined and used in the feed industry to describe a variety of feeds that are fed to livestock. These include any supplement that is made up of a liquid carrier to which a nitrogen source and other essential nutrients are added. The nitrogen source of these supplements may be one of the following types: protein nitrogen (ie: soybean meal or fish meal) or non-protein nitrogen (NPN ie: urea). The story of liquid supplements has parallelled the development and acceptance of urea as a NPN source for ruminant animals.

Urea was first synthesized by Wohler in 1828 and the first reports of its use in ruminant feeding was by Zuntz in 1891. Throughout the next fifty years many papers were written on the use of urea in the ruminant and in monogastric nutrition as described by Stangel in 1963. These reports however demonstrated that urea was only utilized by ruminants through the synthesis of bacterial and protazoal protein by the rumen microflora. The full scale production of urea in the United States began in 1935 and the first studies of its use in this country was reported in the Digest of Research on Urea and Ruminant Nutrition (1958).

At about the same time that urea was being investigated as an ingredient in cattle, feed molasses was accepted as an ingredient in animal rations. The first report of the use of molasses in animal feed in this county was by Gulley et al (1890). As research on the utilization of urea continued it

was discovered that a readily available energy source was needed for maximum utilization of the urea NPN. Thus due to the high solubility of urea in water and water based liquids it was a natural conclusion to dissolve the urea into molasses and thus the idea of liquid supplements was born. The use of a molasses urea mixture had the following advantages: (1) the sugars in molasses provided a readily available energy source; (2) increased palatability of the feed due to the high palatability of molasses; (3) decreased dustiness of complete feeds when the molasses urea mixture was added to ground grain.

It was reported in Feedstuffs in 1958 that the use of alcohol increased the utilization of urea by the ruminant animals by functioning as hydrogen donors during the ruminant fermintation.

The estabilshment of phosphoric acid as a highly available source of phosphorous in animal feeds proved to be a step forward in the development of liquid supplements. Richardson and coworkers (1961) along with Tillman and Brethour (1958) have shown that phosphoric acid is comparable to dicalcium phosphate and steamed bone meal in supplying the phosphorous required by livestock. Due to some of the constituents of molasses a gel may be formed when mixing molasses with phosphoric acid. This normally occurs when the pH and temperature of the mixture is elevated. Weber and Miller (1965) demonstrated that the gel formation was eliminated upon the addition of small amounts of non-phosphatic acids such as sulfuric. They showed that the addition of sulfuric acid at a rate of 12 parts per 100 parts of 75% phosphoric acid on

-5-

a weight bases prevented gel formation. Phosphoric acid has been used in liquid supplements to repel insects, facilitate dissolution of urea, stabilize the product against fermentation, and to reduce the viscosity of the supplement. Anderson (1956) also claimed that addition of phosphoric acid increased vitamin stability due to the lowering of the pH.

In the late 60's and early 70's studies conducted at Kansas State University by Helmer and others (1970) showed that the processing of a starch-urea mixture through a cooker extruder increased the utilization of urea by ruminants. The gelatinization and structural damaging of the starch in this process allowed for better utilization of the carbohydrates during the fermintation and protein systhesis process of the rumen. Thus there was a lessening in the occurance of ammonia-toxicity by increasing the utilization of the NH_4^+ and allowing little NH_3 to escape the rumenal wall. Skoch (1976) and Binder (1976) investigated the possibility of a hydrothermally processed starch based liquid supplement containing urea. They determined that this product was stable and comparable with molasses based liquids and dry supplements.

Other studies by Huber (1972), Lofgreen and Otagaki (1960) have shown equal performance of dry and liquid supplements when fed to lactating cows. Studies by Arias et al (1951), Bell et al (1953) showed no consistant advantage of dry over liquid protein supplements.
Na-Monensin

Monensin is a biologically active compound produced by a strain of <u>Stretomyces Cinnamonensis</u> which is effective in preventing coccidiosis in poultry with some activity against gram-positive organisms, Haney and Hoehn (1967). Figure 1 shows a planner representation of Monensin and of its sodium salt as described by Agtrarap and Chamberlin (1967). Monensin is a pentacylic compound with rings A and B forming a spiro-ketal moiety, rings C and D are substituted tetrehydrofuran rings and ring E is a cyclic hemiketal. Vicinal primary and tertiary hydroxal groups are found in ring E and a secondary hydroxal group is located in ring A. A single methoxyl group is found on the side chain bearing the carboxyl group. A total of eight methyl groups are present, one is a tertiary and another is part of an ethyl group.

In addition to its effectiveness against coccidiosis in poultry, Monensin has been shown to alter rumen fermentation by increasing the molar proportion of propionic acid. Work by Richardson and coworkers (1974) showed that a level of 1.0 ppm Monensin increased propionic acid production by 45% without affecting total volatile fatty acid production <u>in vitro</u>. Another study by these researchers has shown that feeding 200 mg/day <u>in vitro</u> increased proprionic acid molar percentage by 52%.

Potter <u>et al</u> (1974) has shown that steers and heifers grazing on grass-legume pasture had significantly lower rum-inal molar percentages of acetic and butyric acid when Monensin was supplied. Campbell <u>et al</u> (1973) however reported that

FIGURE I: STRUCTURAL FORMULA OF
MONENSIN AND ITS SODIUM SALT
addition of Monensin to diets of grazing steers had little
effect on the molar percentages of volatile fatty acids in
the rumen. Utely et al (1975) and Hale et al (1975) showed
that hay diets supplemented with small amounts of grain
containing Monensin increased the molar percentage of
propionic with a corresponding decrease in acetate and butyrate.
Campbell et al (1973a), Wilson et al (1975), and Utely (1976)
have all reported that Monensin supplementation of high-
concentrate diets cause a small change in the volital fatty
acid (VFA) production of the rumen. But there was a definite
increase in propionate with a decrease in acetate and butyrate.
Hale et al (1975) however observed that acetate values tended
to increase while propionate values remained the same when
Monensin was fed in combination with high-concentrated diets.

The mode of action through which Monensin alters the rumen
fermentation and production of VFA is not completely under-
stood. Work by Beede and Farlin (1975a, and 1975b) showed that
Monensin did not reduce the in vitro lactic acid levels and
therefore they postulated that the increased propionate pro-
duction due to Monensin was through the acrylate metabolic
pathway. Dinius and Simpson (1975) and (1976) found no effect
on pH, dry matter digestion, crude protein digestion, or cellose
digestion when varios levels of Monensin were fed. These work-
ers showed a characteristic decrease in the acetate to propion-
ate ratio but showed no effect on the number of protozoa, total
bacteria, or cellulolytic bacteria in the rumen fluid obtained
from animals fed up to 33 ppm of Monensin.

Monensin has been approved for use in feedlot rations for several years and recently it has been approved for use with range cattle. However it has not been approved for use in liquid supplements that are stored at pHs below 4.2. This is due to the chemical shift in the structure of Monensin under mild acid conditions to a spiroketal group of ring A, Agtarap and Chamberlin (1967).

However work by Cassler (1971) and by Choy et al (1974) have shown that Monensin and the other ionophors of this group of compounds are capable of transporting mono and divalent cations across membranes against concentration gradients. Work by Estrada-O et al (1972) showed that these compounds were also capable of moving Ca^{+2} and other ions across membranes against pH gradients.

Vitamin A:

McCollum and David (1915) were the first to postulate the existance of a "Fat Soluble A Factor". The structure of this factor was determined by Karrer and Coworkers (1931) and later synthesized by Kuhn and Morris (1937). Studies conducted by Steenback and Boulwell (1920) showed that naturally occuring carotenoids had vitamin A activity.

As discussed by Moore (1957) vitamin A and carotenoids are unlike most of the other known vitamins in that they can exist in a multitude of different forms. To complicate things even further each of these derivatives of vitamin A and carotenoids can exist in many isomeric forms and each of these isomers exhibits a different biological activity. These compounds are not soluble in water or glycols are slighty soluble

-10-

in methyl, ethyl, and propyl alcohols, and are extremely
soluble in chloroform, cyclohexane, ether, fats, and oils,
Windholz (1976). Vitamin A compounds and their solutions
are inactivated quite rapidly by ultra-violet light and by
oxygen. This decomposition is accelerated by rancid fats,
trace minerals, moisture, and elevated temperature. In
most cases oil solutions of Vitamin A are more stable than the
pure crystals and the Vitamin A esters are more stable than
vitamin A alsohols.

The difference in biological activity of vitamin A and
carotenoids is believed to be due to the variation in the
atomic arrangement of the side chains of these isomers.
Table I lists the six isolated isomers of vitamin A and their
activity and bio-potency. The all-_trans_ isomer of vitamin A
has been shown to exhibit the highest biological activity and
is therefore used as the international standard and is given
a value of 100% by definition. It can be seen from this
table that all other vitamin A isomers have a lower bio-potency
and activity. Also a mixture of any two of these isomers with
the all-_trans_ form will result in an activity lower than 100%.
Table II gives the relative Bio-potencies of some major caro-
tenoid isomers. B carotene is used as the international stan-
dard, all other isomers have a lower carotene conversion when
determined by rat bioassay. These values will all be much lower
for swine, poultry, and ruminants.

Biological availability is defined as the percent of the
nutrient consumed by an animal that is actually absorbed and
utilized by the body, compared to an appropriate standard.

-11-

TABLE I

Relative Bio-Potency of Vitamin A Acetate Isomers[1]

Isomer	Activity (USP Units/gr)	Bio- Potency
All-trans	2,904,000	100% *
13-cis (neo)	2,190,000	75%
9-cis	607,000	25%
9,13-di cis	688,000	24%
11-cis	690,000	24%
11,13-di cis	428,000	15%

TABLE II

Relative Bio-Potency of Carotenoid Isomers

Carotenoid	All-trans Isomer	Mono-cis Isomer
β -Carotene	100%	38%
α -Carotene	53%	13%
γ -Carotene	42%	19%
Cryptoxantjin	57%	27%

*By Definition

[1]Vitamin A, First Ed. Chas. Pfizer and Co., Inc.

The biological availability of vitamin A sources is controlled
by two major factors; (1) the diluent, matrix or vehicle con-
taining the vitamin A and; (2) the size of the vitamin A par-
ticle in the diluent or vehicle. It has been shown by Lewis
et al (1950) and Sobel et al (1950) that vitamin A absorption
is better from emulsified solutions of Vitamin A in water
than from vitamin A oil solution. Thus the smaller the particle
size of vitamin A and/or the easier vitamin A is removed from
solution (water vs oil) the better animal absorption. These
results were also shown in calves fed different particle sizes
of vitamin A and different solvents, Jacobson et al (1954).
The results showing the poor availability of vitamin A in oil
and fat suspension has been shown to be due to the solvent and
not due to the source of vitamin A itself.

The vitamin A requirements according to the National
Research Council (1978), (1970) are 10-20, 000 units/head/day
for fattening steers on corn and/or alfalfa, 20-30,000 units/
head/day of vitamin A for fatting steers on grain sorghum and
barley. This difference is due to the high vitamin A content
of corn and alfalfa. Dairy cattle require 30,000 units/head/
day while calves require 6-10 million units/head/day. These
values are higher than the requirement for normal growth,
this is due to one or a combination of the following; (1)
Maximum growth rates rather than normal growth is required;
(2) Greater stress conditions are generally present due to
temperature variation, crowding, disease, and management lapses;
(3) Averages are needed to compensate for potency losses due
to manufacturing and storage techniques.

TRACE MINERALS

INTRODUCTION

There are many elements that occur constantly in living tissue in such minute amounts that the early workers were unable to quantitate their concentration and for this reason these elements became known as trace minerals. Studies of trace minerals began about a century ago when scientists became interested in compounds of limited biological significance, as reported by Underwood (1962) some of the early studies were conducted on compounds such as turacin, a porphyrin compound which contains copper found in the feathers of birds; hemocyanin which is another copper containing compound found in the blood of snails. These studies however gave little information on the role or function of these compounds in the body. Bernard (1857) through his studies of respiration and other oxidative processes was instrumental in the discovery of the metallo-enzymes and the metal-enzyme catalysis.

In the 1920's investigation into the role of trace elements really got its start. Hart (1928) and coworkers showed conclusively the need for copper in the nutrition of rats. This gave a new stimulus to the study of trace elements and their deficiency as the cause of nutritional diseases in man and his domestic animals.

Trace elements have been classified into four divisions: (1) the essential; (2) the probably essential; (3) the toxic and (4) the physiological inactive elements. This paper will be limited to talking about the essential elements only. The essential trace minerals are those that meet the following

criteria: (A) reported demonstration of a significant growth response to dietary supplementation of the element and the element alone; (B) development of a deficiency on diets otherwise adequate and satisfactory; (C) correlation of the deficiency state with the occurance of subnormal levels of the element in the blood or tissue of animals exhibiting the response. The minerals that will be dealt with here are Iron, Iodine, Manganese, Copper, Cobalt, and Zinc which are the basic minerals that are required for ruminants.

IRON

The ancient Greeks regarded iron as having been imbued by Mars with the forces and strength and was capable of imparting these properties to people that suffered from weakness. Granick (1832) was the first to demonstrate iron deficiency in "chlorosis". Dawson (1902) demonstrated that inorganic iron cured anemia in "salt-sick" cattle. Dowale et al (1960) determined that the absorption of iron in rats occurs in three stages: (1) mucosal uptake; (2) mucosal transfer and; (3) mucosal storage. These same authors also showed that; (1) absorption of iron is more efficient when body stores are low; (2) the amount absorbed is only a small portion of that ingested; (3) absorption is directly into the blood; (4) most of the iron absorbed by the body takes place in the duodenal area of the small intestine. Even though most this work has been done in the rat it is believed by most workers that the same things happen in other species including ruminants.

Both ferric (Fe^{+2}) and ferrous (Fe^{+3}) forms of iron can
be absorbed into the epithelial cell when the proper low-
molecular weight chelating agents are present. Certain com-
pounds such as ascorbic acid, HCL sugars, and polyals have been
shown by Saltman (1965) and Pearson et al (1966) to increase
the absorption of iron. Pearson et al (1966), Benson et al
(1967) have shown that phytates, gastroferrin, endotoxins, al-
kalinizing agents and phosphates inhibit the absorption of iron.
These workers have also shown the EDTA chelated iron is absorbed
readily by the gastro-intestinal tract, however due to the
strength of this bond this form of iron is secreated via the
kidney without abosrption into the body. Other chelating com-
pounds however, rapidly transfer their iron to apotransferrin
as demonstrated by Benson and Rampone (1967) and by Rubin and
Princiotto (1961). Examples of these chelating agents are
ascorbic acid, amino acids, α-keto glutaric and kalp.

Work by Saltman (1965) has shown that iron does not
exist as the free metal in the physiological process but is
always hydrated or tightly bound to protein molecules. This
phenomenon is true especially in the transport of iron in blood
serum, with a compound known as transferrin being responsible
for this transport.

Iron requirements for ruminants has been the subject of
many research papers, however most of the work has been in the
area of anemia. Blarter et al (1957), Matrone et al (1957),
and Thomas et al (1954) have shown the iron requirements of
dairy calves to be 30 to 50 mg/day when given intravenously
and 60 to 75 mg/day if fed orally. From a practical standpoint,
iron deficiency does not pose a problem in older ruminants that

are fed diets containing ingredients other than milk. Iron content of ingredients normally used in cattle rations as follows: (1) leguminous plants 200 to 300 ppm; (2) grasses 100 to 250 ppm on a dry basis; (3) oilseed meals 100 to 200 ppm; (4) cereal grains 30 to 60 ppm, as reported by Underwood (1962) Studies by Ammerman et al (1967) showed that Fe-dextron injected into the body proved to be most effecient form of iron. Other forms investigated in order of decreasing availability are ferrous sulfate, ferrous carbonate, ferric chloride, and ferric oxide.

IODINE

Iodine is a unique trace element since it is only found in a functional role in thyroid hormones, thyroxin and triiodothyroxin. This mineral also has a long and fascinating history. The early Greeks used burnt sponges as a treatment of goiter. In 1811 iodine was discovered in sponges and seaweed ash as reported by Underwood (1962). Physicians were using salts or iodine to treat goiter.

Work by Alexander et al (1968), Barva et al (1968) have shown that 10% of the inorganic iodine is absorbed in the gastrointestinal tract of man and cattle. The site of iodine absorption is not limited to one specific location of the G.I. tract but iodine is absorbed all along this tract. Once the inorganic iodine is absorbed it is conjugated by the liver and secreted into the bile, most of this organic iodine is reabsorbed. There is however some lost in the feces and urine. Once this organic iodine has been absorbed it enters the "iodine pool"

of the body which is composed of extracellular space, red blood
cells, and the thyroid, salivary, and gastric glands, as reported
by Berson (1970).

The iodine requirement for ruminant animals is dependent
upon the type of production given by the animal. The require-
ments for lactating cows as reported by the NRC (1978) is .50
ppm of the complete ration, and the requirement for cattle is .25
ppm of the complete ration NRC (1978). The normal source of
dietary iodine is drinking water which contains from .1 ppb to
2 ppb in goiterous areas and from 2 ppb to 15 ppb in nongoiter-
ous areas. The use of plants for iodine supplementation is tre-
mendously variable due to different plant species, soil types,
and fertilization as reported by Hercus and Roberts (1915) and
Orr et al (1914). Iodine may be supplemented by iodized sodium
chloride or by potassium iodate.

MANGANESE

Underwood (1962) reports that manganese was first demon-
strated to be present in plant and animal in 1913. This trace
element is known to be required as a cofactor for many enzymes
that function in oxidative phosphorylation, fatty acid synthesis,
and cholesteral synthesis. Not much is known about the absor-
ption of manganese from the gastrointestinal tract, however
transportation of this mineral is in the trivalent state which
is bound to one or more subunits of a protein called trans-
maganium.

The requirement of ruminants for manganese differs con-
siderable for those that are growing and those that are re-

producing. Research by Rajas et al (1965) and by Bentley and
Phillips (1951) have shown that the manganese requirement for
lactating cow is 20 ppm. Whereas work by Anke (1966) and Embry
et al (1958) has shown that young calves require 15-36 ppm of
manganese for normal growth. Beef cattle require a manganese
level of 10 ppm in their diet as reported by Bentley and
Phillips (1951).

COPPER

It has been known for many years that copper is found
in significantly high levels in plant and animal tissues.
This occurance was believed to be accidental until it was
shown that copper was an important cofactor in hemoglobin
formation as reported by Hart et al (1928). Also copper has
been shown to be a component part of enzymes related to ox-
idative functions of the body, examples are tyrosinase, as-
corbic acid oxidase, cytochrome oxidase. Copper is also
found complexed with protein in a compound known as hemocy-
prein in red blood cells in ceruloplasmin which is located
in the blood plasma, Church and Pond (1974).

Dick (1954) has shown that copper absorption is related
to the acidity of the surrounding and for this reason it is
believed that it is absorbed in the upper portion of the
intestine and in the stomach mucosa. Comar and his coworkers
(1948), have shown that the liver contains 33% of the copper
that has been administered by either oral or intravenous
injections, whereas the blood contains 9.4% and the remain-

ing tissues of the body only 1%. The metabolism of copper is affected by the presence of other trace elements in the diet as described by Dick (1956). High levels of Molybdenum will cause a decrease in the uptake and metabolism of copper. An increase in the concentrations of sulfates and sulfites also will lead to poor metabolism.

Due to the detrimental effects of other trace minerals the dietary requirements of copper will change. Matrone et al (1957) and Dick (1956) have shown that diets containing low molybdenum and sulfate concentration the requirement is only 3.6 mg. of copper per day. The same researchers have also shown that in diets containing high levels of molybdenum and or sulfates the animals requirement is between 7.2 and 8.0 mg per day.

COLBALT

This trace element is also an unusual mineral as is Iodine since it also serves one function in the body. That is as a component part of vitamin B_{12}. Cobalt was first discovered in plant tissues as early as 1841 as reported by Church and Pond (1974). Underwood (1962) states that in 1935 work done in Austria proved conclusively that cobalt was an essential trace element.

A symbiotic relationship between the rumen flora and the host animal exist in the metabolism of cobalt. The microorganism use the cobalt to synthesize vitamin B_{12} which is required

by the animal for the transfer of methyl groups during catabolisum of certain amino acids. Besides vitamin B_{12} the microorganisms found in the rumen use cobalt to synthesize other compounds which apparently are not used by the animal. This fact may explain the high dietary requirement of this mineral as compared to other animals.

Church and Pond (1974) reported that young growing sheep have the highest daily requirement for cobalt that of 6.2 mg per day, followed by mature sheep and young calves at 0.08 mg per day. Mature cattle require 0.05 mg per day. It has been demonstrated by Davis and coworkers (1956) that diets that contain molybdenum at levels between 200-400 ppm require larger concentrations of cobalt due to the inhibiting effect of molybdenum on cobalt utilization. On the other hand work by Chapman (1957) has shown that cobalt increases the utilization of copper and iron in diets that contain either high or low concentrations of molybdenum.

ZINC

This trace element is believed to function in many ways in the body: (1) activator for enzymes; (2) association with insulin and; (3) required for the synthesis of ribonucleic acids. Only one of these functions has been proven and that is the role of zinc in the activation of enzymes.

Investigation by Miller and Cragle (1967) into the absorption and secretion of zinc in the gastrointestinal tract has shown that this trace element is absorbed in the aboma

sum and the lower portion of the small intestine. These same workers have shown that the ability to absorb zinc decreases with maturity. The absorption of zinc from the diet may be affected by: (1) concentration of calcium, Grashuis (1964) reported that for every .1% above .3% calcium increased in the diet zinc requirement of the diet increase by 16 ppm; (2) high levels of magnesium may cause reproductive disorders due to zinc deficiency; (3) high molybdenum concentration in the body causes a decrease in the zinc concentration of the bodies organs but an increase in the concentration in the blood and kidneys, Underwood (1962).

The dietary requirements of zinc are 10-14 ppm for young calves when no plant protein is supplied and 8.7 ppm when plant protein is supplied, Mills et al (1961). Work by the same researchers have shown that mature ruminants require 20-30 ppm on a dry matter basis. Studies on the concentration of zinc in different ingredients by Gladstone and Loneregan (1967) have shown that availability decreases with maturity in forage crops. The same studies showed that legumes and herbs contain higher concentrations of zinc than cereals and grasses. Miller et al (1967) have shown the availability of zinc in oxides and sulfate salt from to be high but more research is needed in this area.

EFFECT OF DELVOCID[R] ON THE STORAGE

OF A

CORN BASED LIQUID SUPPLEMENT

Introduction

Due to the high moisture content of liquid supplements
mold growth presents a large problem in the storage of pro-
ducts. The major requirement for mold-inhibiting compounds
is that they be non-toxic to the animal being fed. Wiggen
(1958) and Rao (1972) have shown various inorganic and or-
ganic acids capable of preventing mold growth on high mois-
ture grains. Skoch (1976) and Binder (1976) showed that .5%
propionic acid was effective in preventing mold growth in
starch based liquid supplements.

Delvocid[R] developed by Gist-Brocades of Delft; Holland
is a colorless, crystal of high shelf life stability pre-
sently being used in Europe in the cheese industry. The maj-
or ingredient of Delvocid[R] is pimaricin a tetraene compound
that is effective against nearly all molds and yeast, however
it has no effect on viruses, bacteria, and other microorgan-
isms as reported by Mol (1966). For this reason this product
should be acceptable for use in liquid supplements fed to
ruminants, because it is capable of inhibiting mold growth
but will not interfere with the microflora found in the rumen.

This research was designed to determine the level of
Delvocid[C] needed to prevent chemical changes during an 8 week

*[R]Gist-Brocades Industrial Products Division p.o. box 1, Delft,
Holland.

storage trial of a corn based liquid supplement, containing urea.

MATERIALS AND METHODS

Hydrothermal Processing:

The experimental liquid supplements were processed using a modified Penick and Ford laboratory[1] continuous jet cooker. The cooker is equipped with a Moyno pump calabrated to deliver 1.7 liters of slurry to the hydrothermal heater per minute. Live steam is injected into the slurry through the hydrothermal heater allowing a maximum temperature of 163° and a pressure of 65 psig to be achieved. The cooker is equipped with temperature and pressure gauges to allow regulation of these processing variables. This type of processing causes extensive shearing and cooking of the starch.

Processing of Liquid Supplement Samples:

Table 1 gives the formula of a 1:1 (corn to urea on an dry basis) liquid supplement formulated to contain 60% protein equivelent. The corn, urea, and water (added before cooking) were blended together, to give 20 kg of final product. This slurry was then processed through the hydrothermal cooker described above, at 150° and 55 psig at a rate of 2 27 kg per minute. Water was absorbed due to the condenation of steam during the cooking process After cooking ɑ-amylase was added at a rate of .12% of the starch content at a temperature of 70° and allowed to react for 14 min.

[1]Penick and Ford, Ltd. Cedar Rapids, Iowa.

At the end of this reaction time the enzyme activity was terminated by the addition of 1% phosphoric acid. The product was then cooled to 45°C and the pH adjusted to 3.7 with additional phosphoric Acid (75% feed grade). The product was then divided into 3kg samples and placed in 3.8 liter plastic containers. Delvocid and propionic acid treatments were added at the levels shown in Table 2. Samples JD 5 A&B and JD 6 A&B were subdivided into four samples of 250 g each and placed in wide mouth mason jars and pressure cooked at 5 psig for 5 min. These samples were used as positive and negative controls respectively throughout the storage trials. The plastic containers and mason jars were then stored at room temperature.

Samples of each treatment were taken at 0,2,4, &8 weeks during the trial and analysis run to detect variation within and among treatments. Factors used to evaluate the effect of Delvocid levels on the storage of this supplement were: (1) pH; (2) crude protein; (3) dry matter; (4) starch damage C mg maltose/g of supplement; (5) free ammonia (NH_3-N); (6) viscosity and: (7) protein synthesis.

pH

A Beckman pH meter was used to determine the pH of the liquid supplement to the nearest hundreth of a pH unit. Results are given in Table I of Appendix A.

Crude Protein

The A.O.A.C. (1975) boric acid modification of Macro-Kjeldahl was used to determine the nitrogen content of the samples. Duplicate samples were run with the nitrogen content

-25-

of the samples. Duplicate samples were run with the nitrogen
content being multiplied by 6.25 to give the protein equivelant.
Weekly determination are reported in Table II of Appendix A.

Dry Matter

The official A.O.A.C. (1975) method for moisture was used.
This involves the drying of a 2g sample for 1 hr at 130° C
and from this the percent dry matter was calculated. Samp-
les were run in duplicate and the weekly results are report-
ed in Table III of Appendix A.

Starch Damage

Sung's (1968) method for starch damage which is based
on Sandsted and Mattern (1960) method of hydrolysis with B-
amylase with subsequent determination of reducing sugars by
ferriccyinide was modified for this analysis. The modification
was in reducing the B-amylase to 60 mg per 1g of sample digested,
this allowed for an indication of the amount of readily degrad-
able carbohydrates present in the liquid supplement. Results
are reported as mg of maltose per gram of dry matter in Table
IV of Appendix A. Variation due to daily determination was
eliminated by comparison of determination to a maltose stan-
dard.

Free Ammonia

A micro-diffusion technique as described by Conway (1962)
was used to determine the amount of free ammonia present in
the liquid supplement samples. This method involves the

liberation of ammonia by potassium carbonate which is then
trapped by a standard boric acid solution. The ammonia is
then titrated with standard HCl. Table V, of Appendix A, con-
tains the weekly determination reported as mg of free amonia
(NH_3-N) per gram of dry matter.

Viscosity

Viscosity of the samples was determined at room temp-
erature (25 to 27°C) using a LVT Brookfield Viscometer[1].
Comparison can only be made on viscosities taken with the
same spindel and rpm. For this research spindel number 2
and a rpm setting of 12 was used and the results of these
determinations are given in Table VI of Appendix A in cent-
ipose (ops).

Protein Sythesis

Barr's (1974) in-vitro rumen fermentation technique was
used to determine the amount of protein synthesized from the
liquid supplement. Rumen fluid samples were collected from
fistulated Angus steer that was adapted to a urea contain-
ing diet. Fluid was collected from all portions of the ru-
men by way of a fistula, strained through two layers of cheese
cloth into a thermos and mixed. This sample was then taken to
the lab where it was strained immediately through four layers
of cheese cloth. Ten milliliters of this strained fluid was
then introduced by way of a 20 ml syringe into a 50 ml centrifuge
tube that contained .26g of liquid supplement and .9g of corn
though a 4/64 in hammer mill screen. The use of this mixture

[1]Brookfield Engineering Laboratories, Inc., Stoughton, Mass.

of liquid supplement and ground corn was to simulate a 16% crude protein complete feed.

To the rumen fluid and sample was added 20 ml of a 6.8 pH buffer that contained electrolytes similiar to saliva. The oxygen in the tubes was then evacuated with carbon dioxide and immediately closed with rubber stoppers equipped with a busen valve. Feed blanks were also prepared by taking 0.26 g of liquid and 0.9 g 4/64 ground corn and adding 30 ml of buffer. These tubes were also evacuated with CO_2 and stoppered. The feed samples and feed blank tubes were then incubated in a 39°C water bath for four hours. At the end of this incubation period the tubes were centrifuged at 25,400 x G for 15 minutes. The supernatant was discarded and the residue was rinsed twice with 25 ml of methanal used for each wash. The remaining precipitate was then transferred to a Kjeldahl flask and the nitrogen content was determined. Rumen fluid blanks were prepared by taking 10 ml of rumen fluid and adding 20 ml of the buffer in a centrifuge tube. These tubes were not incubated prior to centrifugation and washing.

The milligrams of protein per feed sample, feed blank, and fluid blank was calculated as follows: mg protein = ml acid x 14 x 6.25. Milligrams of protein synthesized by the liquid supplement samples were calculated by the following formula;

mg protein = mg protein in feed sample - (mg protein in feed blank + mg protein in fluid blank).

Table VII and VIII of Appendix A gives the weekly determination
of protein synthesis reported as a percent of the negative
and positive controls on a dry matter protein bases.

Statistical Analysis:

SAS 76 developed by Barr et al (1976) is a canned statis-
tical analysis program that was used to analyze the re-
sults of the analysis mentioned in a split-plot design. Dif-
ferences between Treatment Means, Week Means, and Treatment
by Week interaction Means was determined. The analysis of
Variance (AOV) tables for each dependent variable is found in
Appendix D.

Results and Discussion

This study was designed to determine the optimum level
of Delvocid^R that would prevent chemical change in a starch
based liquid supplement during storage. Controls for this
experiment were .5% propionic acid (samples 5 A&B) as a
positive control and no preservatives added (samples 6 A&B)
as a negative control. The .5% propionic level was used due
to the results of Binder (1976) and Skoch (1976) who used this
preservative with starch based supplements. Samples 4 A&B were
used in this study to compare the Delvocid$^®$ treated samples to
a propionic sample that had been stored under the same condit-
ions.

The statistical analysis was conducted on a split-plot
design with the treatments being the whole plot and weeks
as subplots.

<u>Effect of Storage of pH</u>:

Table 1 of Appendix D gives the analysis of variance (AOV) table for the dependent variable pH during the storage study. It can be seen that treatments, weeks of storage, and the interaction between these two independent variables were significant. An examination of the data showed that most of the interaction was due to treatment 6 (the negative control). Removing this treatment from the analysis gave the AOV table given in Table 2 in Appendix D. This showed that at the $p < .05$ level the significant interaction was due to treatment 6, this allows one to compare the remaining treatments over time. Table 3 gives the average of each treatment per week, the trial treatment means, the weekly means of all treatments, and the weekly means with treatment 6 removed.

There was a significant difference between week 0 and 2 for all treatments with no significant change during the remainder of the trial for all treatments. Treatments 5 (positive propionic acid, pressure cooked control) and treatment 3 (250 ppm Delvocid®). The other treatments had a larger increase in pH during the first two weeks of storage and then leveled off with no further significant change. Comparison of the averages of each treatment over the entire trial shows that 5 again had the lowest pH value and that treatments 5 and 3 were close behind even though treatment 3 was found to be different ($p < .05$) from 5 mathmatically it can be seen that physiologically there is no difference between these treatments. Treatment 1 and 2 on the other hand showed an increase of greater

than .1 pH units which could be physiologically and significant-
ly different since the reason for reducing the pH down to 3.7
was to control consumption of the corn based liquid supplement.

Crude Protein:

The results of the statistical analysis of the depen-
dent variable crude protein (as is) is given in Table 3 of
Appendix D. The average of crude protein data is given in Table
4 along with the treatment means and weekly means. It can be
seen from the AOV table that there was no difference ($p < .05$)
between the treatments but there was a difference between weeks
of the trial. This difference is found in week eight of the
trial where there was a 1% increase in crude protein content
of the liquid supplement. To determine if this difference was
due to a chemical (microbial growth) change in the pro-
duct or an artifact of a change in dry matter composition,
the crude protein values were corrected to a dry matter basis.
The results of the statistical analysis are given in Table 4
of Appendix D. Table 5 gives the treatment means by week -
the weekly means and the treatment trial means. When the
protein is expressed on a dry matter basis it is seen that the
weeks are again different ($p < .05$). An examination of the means
of each treatment by week combination weekly averages, and
treatments when averaged over the entire trial. An examination
of the means of individual weeks however does show differences
($p < .05$). This is due to the weekly variation in the determination

-31-

of crude protein. The results of this study can then be interpreted to indicate that there was no loss of nitrogen during this study.

DRY MATTER

The average of duplicate dry matter determination is given in Table 6 with the statistical analysis of this dependent variable given in Table 5 of Appendix D. This data shows the effect of Delvocid® on dry matter content of a corn based liquid supplement. The AOV table shows there was no difference ($p < .05$) between treatment means, weekly means, or treatments. Table 6 of these means, it is seen that none of the treatments had a significant effect ($p < .05$) on the dry matter content of the supplement when stored in containers that eliminate rapid evaporation of water. Thus the dry matter of this supplement will remain constant for eight weeks when stored in a licktank designed of the tank as such that rapid evaporation is controlled. This, along with the protein data indicates that there is little or no microbial activity in the supplement since no change occured in the content of these dependent variables. If there was microbial activity one would expect a decrease in dry matter and in protein due to the use of the dry matter as energy and the protein as nitrogen (for protein synthesis). Dry matter would have been lost through gaseous end products (CO_2, CH_4 ect.) of metabolism and crude protein could have decreased due to the use of the urea (NH_4^+) as a nitrogen source to build larger molecules causing a dilution of the crude protein.

<u>Starch Damage</u>:

Starch damage was used to determine the amount of readily
available carbohydrates in the corn based liquid supplement,
and is expressed in mg of maltose 1g of supplement or per g of
dry matter. This analysis is performed by using B-amylase digest-
ion with a ferricyanide titration of reducing power. Thus the re-
sults of this analytical technique gives not only the amount of
starch susceptible to B-amylase but also includes any reducing
sugars also present in the liquid supplement. The results
of the effect of Delvocid^R on this dependent variable are giv-
en in Tables 7 and 8 with the corresponding AOV tables being
in Appendix D (Table 6&7). Table 7 gives the results of mal-
tose reported on an as is basis (mg maltose 1g of supplement)
where as Table 8 gives the results when the maltose is corrected
to a dry matter basis (mg maltose 1g of dry matter). In both
cases there was no difference ($p < .05$) between the treatments
or the weeks of storage. This indicates that again there was
no no effect on this dependent variable due to the Delvocid^R
treatments. This is an indication of no microbial activity since
most organisms that would infect this supplement would either
contain B-amylase enzymes or would use the reducing sugars as
energy sources and thus cause a decrease in the maltose con-
taint over time.

<u>Free Ammonia</u>

Tables 9 and 10 of Appendix D gives statistical analysis
of this dependent variable and Table 9 and 10 gives the agerages
of replication by treatment and weekly means of free ammonia
expressed on a "as is" basis (Table 9) and on a dry matter

-33-

basis (Table 10). This analytical technique gives the amount of ammonia nitrogen (NH_3-N) released per gram of liquid supplement when mixed with saturated potassium carbonate (Conway 1962). Results are reported as averages of duplicate determinations of samples taken from replications A and B as mg of NH_3N/g of supplement or as mg NH_3-N/g of dry matter. Upon examination of these results on a weekly basis it is seen that treatment 1 (150 ppm of Delvocid[R]), treatment 2 (200 ppm of Delvocid), and treatment 5 (5000 ppm propionic acid) had no change ($p < .05$) in the amount of free ammonia present in the supplement. Treatment 3 (250 ppm of Delvocid[R]) on the other hand had a slight increase in free ammonia during week 2 but then had decreased ($p < .05$) from the 2nd to the 8th week of the trial with no difference ($p < .05$) between the 4th and the 8th week samples. Treatment 4 (500 ppm propionic acid not pressure cooked) showed a increase ($p < .05$) in free ammonia in the first two weeks of storage with a decrease ($p < .05$) during the 4th week to the original amount found at the beginning of the trial. Treatment 6 (negative control) however showed a increase ($p < .05$) for all samples taken during the trial.

These results lead one to the conclusion that propionic acid and Delvocid[R] tend to devrease the amount of free ammonia nitrogen during storage. The mode of action of these preservatives are not known but it is believed that the NH_4^+ ion may be tied up as a component part of a salt of propionic acid and that it may be complexed with the Delvocid[R]. This complexation holds the ion in solution and thus keeps it from

being released to the atmosphere. These results also indicate
that all three levels of Delvocid$^{®}$ are capable of stabilizing
the release of NH_3-N during storage of this liquid supplement.

Further information into the amount of free ammonia
present in this liquid supplement was determined by expres-
sing the free ammonia on a dry matter basis. Table 9, Appendix
D, gives the statistical analysis for free ammonia on a dry
matter basis expressed as mg NH_3-N/g of dry matter. The
analysis of variance shows that there was a difference $(p < .05)$
between treatments during the storage study however there
was also a difference $(p < .05)$ in weekly determination and
in the treatment by week interaction. To remove the significant
interaction another analysis of variance was run with treatment
6 removed. This analysis showed that the interaction was due
to this treatment alone. Thus differences between treatments
and the weekly difference could be compared.

Investigation of treatment means on a weekly basis shows
no difference $(p < .05)$ in weekly determination for treatments
1, 2, and 5. While there was a decrease $(p < .05)$ in free
ammonia in treatment 3 during the 4th and the 8th week of the
trial Treatment 4 again showed a increase $(p < .05)$ in free
ammonia during the 2nd week but then decreased back to the ori-
ginal level during weeks 4 and 8. Treatment 5 showed a increase
$(p < .05)$ during all weeks of the trial. Again it may be concluded
that all levels of Delvocid$^{®}$ retarded the release of NH_3-N during
storage of the liquid supplement.

Viscosity:

Viscosity is a measurement of the flowability of a
liquid. Table 10 of Appendix D gives the analysis of variance
for this dependent variable and Table 11 of this section gives
the treatment and weekly means during the storage trials.
The analysis of variance shows that there were no difference
($p < .05$) between the treatments or in the treatment by week
interactions. However there was a significant difference in
the weekly averages of this trial all treatments increased in
viscosity from week 0 to week 2 of the trial and decreased some
what until week 4 and then increased again. This pattern may
be due to equipment error in the determination of this depend-
ent variable however it may be concluded that the preservative
had no negative effect on the gelling capacity of this liquid.
Moreover this liquid did remain stable to gelling and separation
during this 8 week storage study.

Protein Synthesis:

This *in vitro* technique is designed to determine the
ability of rumen microorganism to change a plant or non-protein
nitrogen (NPN) source and a carbohydrate source into microbial
protein. As described earlier this procedure was
run at weeks 0,2,4, & 8 of the trial with duplicate runs made
using rumen fluid from each of two animals. In analyzing this
variable two things had to be considered: (1) the variation
between animals and (2) week to week variation in the rumen

fluid. These questions were adjusted for by running analysis on a weekly basis and determining if the estimation of variance of each weekly analysis was estimating the same error. If indeed this was the case one may pool the individual determinations and determine significant differences over the whole trial. The hypothesis that all estimates σ^2 are equal is determined by the Hartleys's F Max Test (Snedecor & Cochran, 1974). This test showed that the individual weekly estimates of variance were estimating the same error thus the data could be pooled. Table 11 of Appendix D gives the analysis of variance for this dependent variable. The protein synthesis is expressed on a dry matter protein basis to remove variation in dry matter and protein from this dependent variable. To put the dry matter protein synthesis on a common value treatment 5 (pressure cooked, 5000 ppm propionic acid) and 6 (pressure cooked, no preservative added) were each used as a control. This was done in order to express each treatment as a percent of these controls for comparison between treatments.

Table 12 gives the weekly protein synthesized as a percentage of treatment 5 and Table 13 gives the weekly protein synthesized as a percent of treatment 6. There were no differences ($p < .05$) between any of the treatments throughout the trial. Therefore it can be said that there was no detremental effect of Delvocid[R] at any level of study on protein synthesis.

Summary

Delvocid®, a product of Gist-Brocades, presently being
used in Europe as a mold inhibitor in cheese processing, was
investigated as a possible preservative for a corn based
liquid supplement. The supplement was formulated to contain
60% protein equivalent with a 1:1 ratio of corn to urea on
a dry matter basis. Delvocid® was used at 0,150,200, & 250 ppm
and compared to propionic acid at 5000 ppm. These supplements
were compared during on eight week storage study. Variables
looked at were pH, crude protein, dry matter, starch damage,
free ammonia, viscosity, and protein synthesis. There was
a significant increase in pH of all treatments during the first
2 weeks of storage. This increase amounted to approximately
0.1 pH units in all treatments except the negative control.
No further change in this variable except in the negative control
(pressure cooked no preservative added). Thus Delvocid[R] was
capable of maintaining the acid pH of the supplement as well
as propionic acid.

There was no significant difference ($p < .05$) in dry matter,
crude protein, or in starch damage during storage which indi-
cated no microbial growth since microbes would have decreased
the amount of dry matter and maltose present by utilization
of this constituents for growth. There was however a difference
($p < .05$) during storage in free ammonia however except for treat-
ment 6 (no preservative). There was only a .223 mg NH_3-N/g
of sample difference in any of the treatments thus there were
no practical differences in these values. There was a differ-

ence (p<.05) in the viscosity of these supplements during the first 2 weeks of the study, however there was no difference (p<.05) between the treatments.

In Vitro protein synthesis results indicate no difference (p<.05) between any of the Delvocid® treatments and the propionic acid control or the control with no preservative added. Therefore these results indicate that Delvocid® had no detrimental effect on nitrogen utilization from these supplements.

THE EFFECT OF STORAGE ON THE ACTIVITY OF MONENSIN, VITAMIN A AND TRACE MINERAL CONCENTRATION IN A CORN BASES LIQUID SUPPLEMENT

Introduction

An increasing interest in the use of liquid supplements to supply protein to grazing cattle has prompted this research. Na-Monensin a biologically active compound produced by a strain of Streptomyces cinnamonensis has been shown to alter the production of propionate during ruminant dermentation, Richardson et al (1974), Potter et al (1974), and Utely (1976). This compound has been approved for use in feedlofts and in grazing situations but not for use in liquid supplements due to instability at pHs below 4.2. Also problems with the suspendability of this material throughout the liquid supplement has been questioned. In the preparation of Monensin sodium, monensin is exposed to sodium ions during a pH adjustment and the result is monensin sodium. With this in mind and work done by Choy et al (1974), Estrada-O et al (1972), & Cassler (1971) on the ability of monensin to actively work against pH gradients in transportation of monvalent ions across membranes. It was felt by this author that an increase in sodium ion concentration along with the buffering capacity of the rumen (between pH 5.6 & 6.7) could stabilize Monensin and thus lead to better recovery from a liquid supplement stored at a pH below 4.2. A pH of 3.6 was adopted for this study. In this way other problems arising from feeding liquid supplements can be approached (i.e. over consumption, and ammonia toxicity,

Wiggin and Augustine (1958)).

Vitamin A a water soluble vitamin required by the rumin-
ant also poses a problem when supplied in a liquid supplement
due to its low stability when subject to ultraviolet light
and oxygen, and due to its suspendability in a liquid media.
For this reason a vitamin A palmitate incapsulation in gela-
tin, described in literature from the Pfizer Co., was used in
this study. Also the effect of two different types of trace min-
eral supplements were evaluated for two criteria: (1) the
suspendability in the liquid supplement and (2) their effects
upon vitamin A and Monensin activity.

MATERIALS AND METHODS

Hydrothermal Processing:

The liquid supplement used in these studies was proces-
sed through a modified Penick and Ford[1] laboratory continuous
jet cooker. This cooker was equipped with a Moyno pump that
was capable of delivering 1.7 liters of slurry to the hydro-
heater per minute. Live steam was injected into the slurry
through the Hydroheater[R] allowing for a temperature of 160°C
and pressure of 55 psig to be achieved. This temperature and
pressure is regulated by the use of a steam inlet valve.
The temperature and pressure along with the retention time
in the cooker causes extensive shearing and cooking of the
contents of the liquid supplement.

[1]Penick and Ford, Ltd. Cedar Rapids, Iowa.

Processing of Liquid Supplement Samples:

Table I shows the formulas of the 1:1 (corn to urea on a dry matter basis) 60% protein equivalent liquid supplement. Enough corn, urea, and water (before processing) to make 150 pounds of final product were mixed in stainless tubs. Treatment numbers 2 and 4 had the monensin, trace mineral sources, and vitamin A added after cooking where as 1 and 3 had only the vitamin A added after processing, the remaining ingredients were added to the slurry before processing.

Once the slurries were prepared they were introduced into the reservoir of the jet cooker apperature (Figure I). From this reservoir the slurry was conveyed to the hydroheater by way of a mono pump that delivered 1.7 liters of slurry per minute. At the Hydroheater[R] live steam is injected into the slurry under pressure. This pressure and heat causes shearing and rupturing of the starch granules of the corn. The temperature and pressure during processing was held constant at 150° and 55 psig. The water absorbed, given in Table 1, was due to the condensation of steam during the cooking process. The processed slurry was collected in an insulated 208 liter steel drum that was equipped with a stirring mechanism. After the entire sample was processed α-amylase was added at a rate of 0.12% of the starch content of the supplement. This enzyme was allowed to react for 14 minutes at a constant temperature of 70° at which time the enzyme activity was stopped through the addition of 1% phosphoric acid.

The product was then cooled to 45°C and the pH adjusted to a pH of 3.7 by the addition of phosphoric acid. At this time the remaining ingredients were added to each treatment.

Each treatment was produced in duplicate and introduced into storage vessels chosen at random to eliminate differences in storage containers. These storage containers were made from 6 inch PVC plastic pipe that was cut into 5 foot sections and sealed at one end. Sampling holes were introduced into the pipe at one foot increments and in the middle of the bottom. This allowed for sampling of the supplements at five locations. Approximately 50 g samples of each supplement treatment were taken at 0,2,4,6, & 8 weeks during the trial. These samples were used to determine the chemical and suspendable stability of monensin, vitamin A, and the trace minerals zinc, magnesium, and iron. A composit sample of each replication was used to determine the stability of this supplement.

Monensin Chemical Stability:

The stability of this antibiotic was determined through the modification of the vanillin colorimetric method developed by Golab et al (1973), in which 10 grams of supplement was mixed with 20 ml of buffer which contained electrolytes at a concentration similiar to saliva. This mixture was shaken for one hour at medium speed on a Eberbach[1] rotating shaker. At the end of one hour 100 ml of acetone; etheyl ether

[1] Eberbach Corporation, Ann Arbor, Mich.

(50:50) was added to the flask and shaken for one hour on the
Everbach rotating shaker and then allowed to stand overnight.
A mixture of acetone and ether was used to eliminate dehydration
of the sample. Dehydration was found to decrease extraction
of the monensin into the acetone phase. After setting overnight
6 ml of the top phase (acetone:ether) was transferred to a 50
ml beaker and carefully evaporated. Preliminary studies show-
ed no monensin to be present in the lower phase of this two
phase system. This agreed with the data monensin is not soluble
to any significant degree in water systems, Galab et al (1973).

The contents of the 50 ml beaker was transferred to a
10 ml volumetric flask and diluted to volume with methonol.
Five milliliters of this dilution was transferred to a sec-
ond ten milliliter volumetric flask that had been spiked with
30 ug of monensin[1] standard. To each of these flasks 1.0 ml
of vanillin reagent was added and the flask diluted to 10 ml
with methanol. The absorbance of each solution was read
at 518nm against a methanol blank and poured back into the
flask. The flask was then heated at 60°C for 25 minutes and
cooled and absorbance was then determined   The calcultion of
monensin concentration in the original sample was determined
by the following formula:

$$(\text{Absorbace heated sample} - \text{Absorbance unheated}) \times \frac{20ml}{10\ g} \times$$

$$\frac{100ml}{20ml} \times \frac{10ml}{6ml} \times \frac{10ml}{5ml} \times \frac{30ug}{10ml} \times \frac{1g}{10^6ug} \times \frac{2000lb}{ton} \times \frac{454g}{lb} =$$

$$\text{Monensin, g/ton.}$$

[1]Elli Lyle Inc. Greenleaf, Ind.

Duplicates of each sample were determined and results are given in Table 1 of Appendix B.

Vitamin A Chemical Stability Determination:

The chemical activity of Vitamin A was determined by using the direct solvent extraction technique of Bayfield (1971). In this procedure one gram of the supplement was added to 50 ml of a 1:1 mixture of acetone and light petroleum ether. This mixture was then shaken for 30 minutes on the Eberbach rotating shaker and allowed to stand for 30 minutes in order that the particulate matter could settle from the extracting liquid. A 5 ml alequot of the extraction fluid was evaporated to dryness and dissolved in 5 ml of chloroform. One milliliter of the chloroform mixture and 2.0 ml of saturated trichloroacetic acid was added to a spectra grade cavet. The absorbance of this mixture was recorded at 620 nm and concentration on vitamin A determined by extrapolation from a standard curve. Duplicate determination of each sample was made and results are given in Table 2 of Appendix B.

Trace Minerals: The concentration of zinc, iron, and magnesium were determined by Atomic Absorption analysis as follows: A 5 - 10 gram sample of the corn base supplement was accurately weighed and dried at 50°C overnight. The residue remaining after this drying step was ashed at 550° overnight. Enough 6 N HCl was added to the ashed sample to dissolve it.

This solution was then quantitatively transferred to a 25
ml volumetric flask and diluted to the mark with dionized
distilled water. The diluted sample was then asperated into
the air-acetylene flame of a Jarrel Ash Atomic Absorption
Spectrophotometer. The concentration of the three minerals
was determined at the following wavelengths; iron 2482λ,
zinc 2138λ, and magnesium 2852λ. The concentration of Zinc and
Iron were determined directly from Beers Law standard curve,
however the magnesium concentration was determined by diluting
the original sample 1 to 100 with dionized distilled water.
Averages of duplicate determinations of each sample are re-
ported in ppm on a dry basis in Table X of Appendix A.

pH

The pH of the composite samples of each replication was de-
termined on a Beckman pH meter to the nearest hundreth of a
pH unit.

Statistical Analysis:

SAS 76 is a canned statistical analysis program that
was developed by Barr et al (1976 which was used to analize
the data collected for the above mentioned dependent variables.
Differences between treatment means, weekly means, level means,
and interactions was determined by use of a Split-Split Plot
design. The treatments were analyzed as the whole plots, with
the week storage analyzed as the split-plots and the level of
storage analyzed as the split-split plots. Least significant
difference (LSD) analysis was used to determine differences

in the means investigated. The statistical analysis of variance table (AOV) are found in Appendix D.

Results and Discussion:

The objectives of this study were to determine (1) the effect of NaCl addition on the stability of Monensin chemical activity; (2) to determine the effect of storage on this chemical stability; (3) to determine the stability of vitamin A palmatate activity during storage; (4) to determine the ability of two soluble trace mineral supplements to remain suspended during 8 weeks of storage; and (5) to determine the effect these trace minerals had on the chemical activity of monensin and the activity of vitamin A.

Effect of NaCl addition on Monensin Chemical Activity:

A 100 lb batch of hydrothermally processed liquid supplement was subdivided into 10-10 lb subunits and Rumensin 30^R (30 mg of Monensin) was added to each to give a final Na-Monensin concentration of 200 mg/lb of supplement. Table 2 lists the amount of NaCl added to each of 5 samples, the remaining 5 samples were used as replications of these treatments. The chemical activity of Na-Monensin was determined as reported earlier by the Modified Vanillin colorimetric procedure. Table 3 shows the results of this study. It can be seen that the addition of .5% NaCl gave a recovery of 90% of the initial concentration of Na-Monensin and the addition of 2,5, & 10% NaCl increased this recovery considerable. From the results of this study treatment of 5% NaCl was selected

to use in an eight week storage study to determine whether
or not the chemical activity of Na-Monensin would remain above
90% of the original.

Chemical Activity of Monensin During Storage:

Table 4 shows the treatment averages of the five sampl-
ing levels during each week of storage. The analysis of vari-
ance, Table 12 Appendix D, table for this dependent variable.
There were no difference ($p < .05$) found in treatment and level
means, how ever a difference was found in the weekly averages.
A LSD test ($p < .05$) (least significant difference), Table 5,
however showed there was no difference in treatment means,
week of storage means, or level of storage means. One needs
to look at the interaction to determine where differences exist-
ed. From the analysis of variance, Table 12 Appendix D, it is
seen that the week by treatment, treatment by level, and treat-
ment by level by week were the significant interactions. Table
6 lists the means for weekly determination for each treatment.
A LSD ($p < .05$) has shown no difference to exist in treatment
1 during storage, where was a difference ($p < .05$) found in treat-
ment 2 in the 4th week of storage. This was an increase in
activity and therefore was not a detrimental effect. This may
be due in part to a sampling error during this weeks deter-
mination since level 2 of replication 1 and levels 2 and 3 of
replication 2 for this treatment had exceptionally high act-
ivity during the 4th week of storage. This activity of Na-
Monensin in this treatment returned to the original level
during the 6th and the 8th week of storage which conforms the

idea of sampling error during week 4. In treatments 3 and 4 there was a difference (p<.05) found in the 2nd week of storage and again this was an increase in activity from the original and is believed to be due to sampling error. When these two cases are removed from the study it is seen that there was no difference (p<.05) in Na-Monensin activity for any of the treatments during storage.

This then allows one to compare the level of storage means for each treatment during storage. Table VII lists these means and their respective LSD (p<.05). There was no difference (p<.05) found between any level sampled during storage. Thus there was no effect due to trace mineral source used in this study. This may be extended a step further; there is no stable complex formed between the ionized minerals used that is stronger than the Monensin complex.

Table 7 gives the level of storage means for monensin activity and Table 8 the treatment by week combination. All levels of storage sampled for all treatments were the same at the beginning of the trial, ranging from 398 to 404 mg/lb of supplement. At week 2 of storage all treatments showed a tendency of segregation towards the top and center of the storage tank. Week 4 showed the same trend as week 2. After 6 weeks of storage however there was no difference between levels in treatments 1,3, and 4. Treatment 2 showed difference (p<.05) however there was a shift back towards equilibrium in the tank. At the end of the trial (week 8) there were no differences (p<.05) found in any of the treatments.

From these results it may be concluded that Na-Monensin remained suspended well in the corn based liquid supplement

during the entire eight weeks of storage.

As for the chemical activity of Monensin it remained the same throughout the trial even at a constant pH of 3.6 as reported in Table 9.

Further work must still be done to determine if the biological activity as well as the chemical activity is maintained when the supplement is stored and fed at a pH of 3.6 and treated with 5 to 10% added NaCl.

Vitamin A Stability:

Table 13 Appendix D, gives the analysis of variance for the vitamin A data collected during this 8 week trial. Of the main effect treatment, week of storage, and level of storage only the week of storage was different ($p < .05$). Table 10 gives the weekly averages for the trial. The initial activity of vitamin A was 130 ug/g or 107,309 IU of vitamin A per pound. There was no difference ($p < .05$) found in activity after the 2nd week of storage (130.09 as compared to 131.07 ug/g). After 4 weeks of storage however a difference ($p < .05$) was found and this difference increased after the 6th week of storage and then remained the same through 8 weeks of storage. There was a decrease of 4,820 IU of Vitamin A activity during the 4th week and a 8,353 IU & 8,114 IU decrease from the initial activity at week 6 and 8 of the trial respectively. This decrease in activity may be due to the oxidation of the vitamin by ultraviolet light and/or due to oxidation caused by the interaction between the trace minerals and vitamin A. There was no difference ($p < .05$) between treatment means and level means during storage as shown in Table 10. To determine if

-61-

there was an effect of trace mineral supplement used on the activity of vitamin A one must look at the interaction between the main effects.

In the analysis of variance Table 13 Appendix D, it is seen that the only difference (p<.05) interaction is between weeks of storage and treatment. Table 11 gives the week of storage means for each treatment. As LSD (p<.05) has shown that there was a difference (p<.05) has shown that there was a difference (p<.05) in treatments 1 (CTM soluble trace minerals before processing) and in treatment 2 (CTM soluble trace minerals added after processing). This difference (p<.05) is seen in the 4th, 6th, and 8th week of storage. During the 4th week there was no difference (p<.05) however there was a decrease in activity from 130 ug vitamin A palmitate/g of supplement to 125 ug of vitamin A palmitate in treatment 1 and a decrease from 130 to 120 in treatment 2. This decrease in activity became significant (p<.05) after 6 weeks of storage. Treatment 1 had only 117 ug of activity or 90% of the initial no further loss of vitamin A after 8 weeks of storage.

In treatments 3 and 7 (Sea-Questra Min trace mineral, added before and after processing respectively), there were no difference (p<.05) between the beginning and the end of the eight week storage study. Thus there was a difference due to the type of trace mineral used in conjunction with Vitamin A palmitate in this corn based liquid supplement. This is supported by work done by the Stauffer Chemical Company (1976) in which Sea-Questra Min was compared to other

trace mineral supplements to determine what effect it had on vitamin A activity when used in dry and molasses based premixes. However with only 10% loss in activity it is felt that either trace mineral supplement may be used with vitamin A.

Comparison of Trace Mineral Supplement Suspensibility:

To evaluate the suspensibility of the minerals present in the two supplements used in this study samples from levels 1 (top), 3 (middle), and 5 (bottom) were analyzed by the atomic absorption method previously described. Table 14 of Appendix D, gives the analysis of variance for the concentration of iron, magnesium, and zinc determined in this trial. From this analysis it is seen that the main effect due to treatment is the only significant effect ($p < .05$) for the iron concentration during storage. The main effect due to treatment, and week of storage are significant ($p < .05$) for the magnesium concentration. Also the interactions between week of storage and treatment is significant ($p < .05$) for this mineral. There was no significant ($p < .05$) effects for thw zinc concentration found in this study.

Table 12 gives the means treatments, week of storage, and the level of storage for all three minerals investigated. From the LSD ($p < .05$) it is seen that the difference found in the effect due to treatment for iron concentration is only found in treatment 4. This can partially be explained by the low levels of iron found in the top and middle levels of storage for treatment 4 replication 2 during the 2nd, 4th, and 6th weeks of storage, as reported in Table 1 of Appendix C. This is

probably do to error in sampling these two levels when the analysis was run. Therefore comparison between iron concentrations for level of storage means can only be made between the levels in which the week of storage by treatment means are not different ($p < .05$). Table 13 lists the means for the week of storage by treatment combinations. An LSD ($p < .05$) found in treatment 1 & 4 for all weeks of storage. Treatments 2 & 3 showed a difference and therefore will not be used to examine the suspensibility of this mineral.

Table 14 shows the level means for treatment 1 (CTM soluble) and treatment 4 (Sea-Questra-Min) and compares the concentration of each weekly level to the original concentration at that level as a percentage of week 0. It is seen from this table that the iron concentration shifted towards the top of the storage vessels in both sources of minerals, with the CTM soluble iron migrating more towards the top than the Sea-Questra-Min (CTM; top level 122%, middle level 100%, and bottom level 85% as compared to Sea-Questra-Min; top 113%, middle 91%, and bottom 95%). Thus the claim made by the Stauffer Chemical Company that sequestered trace minerals stay in suspension better than chealated minerals holds true in the case of iron for this liquid supplement.

Table 10 shows that there was a difference ($p < .05$) in magnesium concentration between treatments 1 & 2 and treatments 3 & 4 this is due to the difference in percent composition of the two trace mineral sources. However a comparison may still be made between the sources. Table 15 gives the treatments means at each week of storage. The LSD ($p < .05$) shows no difference in means for the first 6 weeks of storage for

-64-

treatments 1 & 2 and no difference in means for the first 4 weeks of storage for treatments 3 & 4. Therefore comparison may be made on level magnesium concentration for the first 4 weeks of storage. Differences in the other weekly means are due to sampling error as shown in the replicate data reported in Table II of Appendix C.

Table 16 gives the lever of storage means for the first 4 weeks of storage for each treatment reported as a percent of week 0. During the first 2 weeks of storage there was a tendency for the magnesium to settle to the bottom of the tank in treatment 1 (CTM added before) and treatment 3 (Sea-Questra-Min added before). In treatment 2 (CTM added after) and treatment 4 (Sea-Questra-Min added after) there was not much change in the level of concentrations of magnesium in the first 2 weeks of storage. After 4 weeks of storage all treatments maintained essentially the same magnesium level as week zero. Therefore it can be seen that magnesium concentration after 4 weeks is dependent of source used.

The zinc concentration during storage was independent of treatment since there was no difference ($p < .05$) found in mean treatment concentration as reported in Table 10. Table 17 lists the zinc concentrations by week of storage and it can be seen that the only two treatments in which there is no difference ($p < .05$) are treatment 1 (CTM added before) and treatment 4 (CTM added after) the other two treatments have too large of differences between weekly means to allow for comparison. Therefore Table 18 lists the mean level concentration of zinc for treatments 1 & 4 expressed as a percent of week 0. Again as in the case of iron concentra-

tion the zinc contration remained constant throughout storage
when the source of trace minerals was Sea-Questra-Min.

The results of this study leads one to believe that Sea-
Questra-Min in the trace mineral supplement of choice for
this liquid supplement. However due to the large deviation
found in the weekly means of treatments it is felt that this
conclusion can not be made without reservation.

SUMMARY

Monensin chemical activity, Vitamin A palmitate activity, and trace mineral suspendibility were investigated in a corn based liquid supplement. It was found that when Na-Monensin was added to this supplement at a pH of 3.6 there was basically no chemical activity. However the addition of NaCl at a level of either 5 or 10% caused a change in this feed additive's stability. An 8 week storage study showed that at the level of 5% added NaCl the chemical activity of Monensin was maintained at 400 mg/lb of supplement. It was also found that there was no effect on activity when trace mineral supplements were added.

It was found that Vitamin A activity was affected by the type of trace mineral supplement. The activity of this vitamin remained the same ($p < 0.05$) when the sequestered trace minerals were used. The activity decreased after 4 weeks of storage when chealated trace minerals were used (130 ug to 122 ug). This decrease continued during the 6th week of storage (117ug) and then remained the same at 8 weeks of storage. However the loss in activity of Vitamin A was only 10% over the 8 weeks of storage and there was a loss of 5% of the activity due to ultraviolet light oxidation.

When looking at the suspendibility of the trace mineral sources, it was found that the sequestered source of iron and zinc remained constant throughout the trial. The chealated source however migrated to the top of the tank. Magnesium concentration however changed in both sources of trace

minerals. This change was towards the bottom of the tank.

From the results of this study it can be concluded that Monensin remains chemically active in liquids stored and fed at a pH of 3.6 when 5% added NaCl is used. Also Vitamin A activity and trace mineral concentration remained constant when a sequestered trace mineral source is used.

(Week of Storage)

[A] Zinc concentration expressed in ppm on a dry matter basis.

SUMMARY OF THESIS

Two storage trials were conducted to determine: (1) if the product Delvocid®could be used as a preservative in a corn based liquid supplement; (2) to determine what steps need to be taken to maintain Monensin's chemical activity in a corn based liquid stored at a pH of 3.6; (3) to determine the stability of Vitamin A palmitate in this liquid supplement when two different types of trace minerals were used; (4) to determine the suspensibility of trace mineral from the two sources used.

In study one concentrations of 150, 200, and 250 ppm of Delvocid were compared to a positive control (5,000 ppm propionic acid) and to a negative control (no preservative added). The parameters pH, crude protein, dry matter, ammonia release, maltose equivalence, protein synthesis, and viscosity were monitored during the study. Results indicated that either the 200 or the 250 ppm level of Delvocid was able to maintain constant values during the trial and it compared well with the propionic acid control.

Preliminary investigation on the effect of NaCl addition on Na-Monensin chemical activity indicated that a level of 5 or 10% was capable of maintaining activity for 24 hours. To investigate the effect of 5% NaCl to maintain chemical activity during storage and to determine the stability of Vitamin A palmitate and the effects of trace mineral supplements on these feed additives, a second storage trial was run. The results of this study indicated that Na-Monensin's chemical activity was maintained during 8 weeks

of storage. There was no difference (p<.05) in the chemical
activity when trace mineral sources were compared. The act-
ivity of vitamin A palmitate remained constant when a seques-
tered trace mineral source was used. A decrease of 10%
activity was found when a chealated trace mineral source
was used.

The suspensibility of iron magnesium, and zinc were
studied for the two trace mineral sources. It was found that
for iron and zinc the sequestered minerals remained constant
thoughout storage. The magnesium concentration increased
at the bottom of the storage tanks for both mineral sources
studied.

ACKNOWLEDGEMENTS

The author wishes to express his gratitude and appreciation to his major professor, Dr. Charles W. Deyoe, for prodiding guidance, assistance, financial support and use of facilities throughout the cource of this study.

Appreciation is also extended to Dr. Keith C. Behnke for his guidance and assistance. Acknowledgements are also extended to Dr. E.E. Bartley and Dr. R.A. Wilcox for serving on the advisory committee and reviewing this manuscript. Thanks are also extended to Mr. Donald Duncan for his patience during this study and to the student help of the K.S.U. feed mill for their help.

The author wishes to also extend his deepest appreciation and love to his wife, Judy, for her encouragement and inspiration during the preparation of this thesis. He also wishes to extend deepest gratitude to her and to Mrs. Janie Beaman for the patience and time during the typing of this manuscript.

DELVOCID® AND SODIUM CHLORIDE EFFECTS
ON THE STABILITY OF A CORN BASED LIQUID
SUPPLEMENT CONTAING UREA, MONENSIN,
VITAMIN A AND TRACE MINERALS

by

Joseph Charles Dietz

ABSTRACT OF THESIS

Two storage trials were conducted to determine: (1) if
the product Delvocid could be used as a preservative in a
corn based liquid supplement; (2) to determine what steps
need to be taken to maintain Na-Monensin's chemical activ-
ity in a corn based liquid stored at a pH of 3.6; (3) to de-
termine the stability of Vitamin A palmitate in this liquid
supplement when two different types of trace minerals were
used; (4) to determine the suspensibility of trace mineral
from the two sources used.

In study one levels 150, 200, and 250 ppm of Delvocid
were compared to a positive control (5,000 ppm proprionic
acid) and to negative control (no preservative added). The
parameters pH, crude protein, dry matter, ammonia release,
maltose equivalence, protein synthesis, and viscosity were
monitored during the study. Results indicated that either
the 200 or the 250 ppm level of Delvocid was able to main-
tain constant values during the trial and it compared well
with the proprionic acid control.

Preliminary investigation on the effect of NaCl add-
ition on Na-Monensin chemical activity indicated that a
level of 5 or 10% was capable of maintaining activity
for 24 hours. To investigate the ability of 5% NaCl addi-
tion on the chemical activity during storage and to determine
the stability of Vitamin palmitate and the effects of trace
mineral supplements on these feed additives a second storage
trial was run. The results of this study indicated that
Na-Monensin's chemical activity was maintained during 3 weeks
