Abstract

Microbes, which live in the human body, affect a large set of pathophysiological processes. Changes in the composition and proportion of the microbiome are associated with metabolic diseases (Fulbright et al., *PLoS Pathog* 13:e1006480, 2017; Maruvada et al., *Cell Host Microbe* 22:589–599, 2017), psychiatric disorders (Macfabe, *Glob Adv Health Med* 2:52–66, 2013; Kundu et al., *Cell* 171:1481–1493, 2017), and neoplastic diseases (Plottel and Blaser, *Cell Host Microbe* 10:324–335, 2011; Schwabe and Jobin, *Nat Rev Cancer* 13:800–812, 2013; Zitvogel et al., *Cell* 165:276–287, 2016). However, the number of directly tumorigenic bacteria is extremely low. Microbial dysbiosis is connected to cancers of the urinary tract (Yu, *Arch Med Sci* 11:385–394, 2015), cervix (Chase, *Gynecol Oncol* 138:190–200, 2015), skin (Yu et al., *J Drugs Dermatol* 14:461–465, 2015), airways (Gui et al., *Genet Mol Res* 14:5642–5651, 2015), colon (Garrett, *Science* 348:80–86, 2015), lymphomas (Yamamoto and Schiestl, *Int J Environ Res Public Health* 11:9038–9049, 2014; Yamamoto and Schiestl, *Cancer J* 20:190–194, 2014), prostate (Yu, *Arch Med Sci* 11:385–394, 2015), and breast (Flores et al., *J Transl Med* 10:253, 2012; Fuhrman et al., *J Clin Endocrinol Metab* 99:4632–4640, 2014; Xuan et al., *PLoS One* 9:e83744, 2014; Goedert et al., *J Natl Cancer Inst* 107:djv147, 2015; Chan et al., *Sci Rep* 6:28061, 2016; Hieken et al., *Sci Rep* 6:30751, 2016; Urbaniak et al., *Appl Environ Microbiol* 82:5039–5048, 2016; Goedert et al., *Br J Cancer* 118:471–479, 2018). Microbial dysbiosis can influence organs in direct contact with the microbiome and organs that are located at distant sites of the body. The altered microbiota can lead to a disruption of the mucosal barrier (Plottel and Blaser, *Cell Host Microbe* 10:324–335, 2011) or promote or inhibit tumorigenesis through the modification of immune responses (Kawai and Akira, *Int Immunol* 21:317–337, 2009; Dapito et al., *Cancer Cell* 21:504–516, 2012) and microbiome-derived metabolites, such as estrogens (Flores et al., *J Transl Med* 10:253, 2012; Fuhrman et al., *J Clin Endocrinol Metab* 99:4632–4640, 2014), secondary bile acids (Rowland, *Role of the gut flora in toxicity and cancer*, Academic Press, London, p x, 517 p., 1988; Yoshimoto et al., *Nature* 499:97–101, 2013; Xie et al., *Int J Cancer* 139:1764–1775, 2016; Shellman et al., *Clin Otolaryngol* 42:969–973, 2017; Luu et al., *Cell Oncol (Dordr)* 41:13–24, 2018; Miko et al., *Biochim Biophys Acta Bioenerg* 1859:958–974, 2018), short-chain fatty acids (Bindels et al., *Br J Cancer* 107:1337–1344, 2012), lipopolysaccharide (Dapito et al., *Cancer Cell* 21:504–516, 2012), and genotoxins (Fulbright et al., *PLoS Pathog* 13:e1006480, 2017). Thus, altered gut microbiota may change the efficacy of chemotherapy and radiation therapy (McCarron et al., *Br J Biomed Sci* 69:14–17, 2012; Viaud et al., *Science* 342:971–976, 2013; Montassier et al., *Aliment Pharmacol Ther* 42:515–528, 2015; Buchta Rosean et al., *Adv Cancer Res* 143:255–294, 2019). Taken together, microbial dysbiosis has intricate connections with neoplastic diseases; hereby, we aim to highlight the major contact routes.

10.1 The Human Microbiome

The human body harbors different kinds of symbiotic, commensal, and pathogenic bacteria that live on the surface and the cavities of the body. Microbiota is a collective term that refers to the group of microbes colonizing the human body, and the collection of genes they encode is known as our microbiome [36]. The number of colonizing microbial cells ($>10^{14}$) is 10 times more than

the total sum of human somatic and germ cells. Therefore, their collective genome—called the metagenome—contains a large number of genes that exceed the human genome by 150 times. This metagenome performs key functions relevant to human health [37].

Each anatomical niche possesses a unique mixture of microbial populations (gut, skin, vagina, mouth, nose, and conjunctiva) that have important and functionally relevant individual variability (at the levels of genus, species, and strain) [5]. The great majority of microorganisms live in the gastrointestinal (GI) lumen. These microbes compete and collaborate with other organisms in this niche, resulting in a functionally and genetically plastic metagenome [5]. The GI microbiota plays a crucial role in digestion, maturation, immune response, protection against pathogen overgrowth, maintenance of intestinal barrier function, regulation of intestinal endocrine functions, neurologic signaling, bone density, biosynthesis of vitamins, neurotransmission, metabolism of bile salts, reaction or modification of drugs, elimination of exogenous toxins, and maintenance of the energy homeostasis of the host [38].

10.2 Bidirectional Microbiome-Host Connection

There is increasing evidence for complex and dynamic microbial interactions with hosts. The microbe-human symbiotic connection is a result of millions of years of coevolution, coadaptation, and codependence. Bacterial colonization begins at birth and progresses through childhood to adulthood. The adaptation process is nonrandom [39] and depends on the body habitat, lifestyle, physiological conditions, genotype of the host, and presence of other microbes in the niche [40]. The function and composition of the microbiome are determined by the diet of the host, probiotic or antibiotic consumption, stress, and short- or long-term travel. Besides these external factors, the host can affect the dynamics of the microbiome through its genetics, immune system, and personal hygiene [38]. Given the diverse func-

140 tional repertoire of the microbiome, it is not sur- 181
 141 prising that dysbiosis is associated with a broad 182
 142 range of diseases from neurological disorders to 183
 143 metabolic diseases and cancer [12]. Numerous 184
 144 studies highlight the relationship between 185
 145 changes in the function, composition, and pro- 186
 146 portion of microbes—also called microbial dys- 187
 147 biosis—and the progression of certain diseases. 188
 148 Koch’s concept that one microbe is responsible 189
 149 for the formation of one disease (“one microbe- 190
 150 one disease hypothesis”) was shown to be an 191
 151 oversimplification. Recent advances have shown 192
 152 that the loss of balance in microbial communities 193
 153 and the global change in our microbiome are 194
 154 directly or indirectly connected to carcinogene-
 155 sis, rather than the presence of a single causative
 156 microbe [41]. Nevertheless, there are directly
 157 tumorigenic bacteria, although their number is
 158 extremely low, including about 10 species (e.g.,
 159 *Helicobacter pylori* promote the development of
 160 gastric cancer). Dysbiosis is associated with can-
 161 cers of the urinary tract, cervix, skin, airways,
 162 colon, lymphomas, prostate, and breast [42].
 163 However, it is still unclear whether cancer is the
 164 product of alterations of the microbiota or modi-
 165 fications in the “normal” microbiome are the
 166 consequences of cancer progression.

167 10.3 The Tumor 181 168 Microenvironment 182

169 Cancers are not just masses of homogenous 183
 170 malignant cells. Tumors have been recognized as 184
 171 complex organs, whose complexity may exceed 185
 172 that of normal healthy tissues. Interactions 186
 173 between malignant and recruited non-transformed 187
 174 cells create the tumor microenvironment (TME). 188
 175 Nonmalignant cells include immune cells, cells 189
 176 of the vasculature and lymphatic system, cancer- 190
 177 associated fibroblasts, pericytes, and adipocytes 191
 178 [43]. The role of nonmalignant cells in the TME 192
 179 is to support cancer growth. Nonmalignant cells 193
 180 have a dynamic tumor-promoting function at all 194

stages of carcinogenesis. The communication 181
 between cell types is driven by an extremely 182
 complex network of cytokines, chemokines, 183
 growth factors, other inflammatory mediators, 184
 and matrix remodeling enzymes [44]. Cancer cell 185
 metabolism is strictly regulated by the tumor 186
 microenvironment. The microbiome is a new 187
 component of the tumor microenvironment that 188
 impairs tumor cell metabolism by maintaining a 189
 healthy barrier, inducing inflammation, and pro- 190
 ducing genotoxins and bacterial metabolites with 191
 different features. Below, we review the modalities 192
 of how dysbiosis interferes with carcinogen- 193
 esis (Fig. 10.1). 194

195 10.4 Bacteria-Driven 181 196 Carcinogenesis 182 197 Through Physical Interaction 183

The most relevant pathomechanism for 184
 microbiome-derived carcinogenesis is *barrier* 185
failure. In healthy humans, numerous commensal 186
 bacteria are found in the intestinal lumen, where 187
 some bacteria are in direct association with the 188
 epithelium. The microbiota is vital in preserving 189
 the functional luminal barrier, by maintaining 190
 epithelial cell turnover, facilitating mucin pro- 191
 duction, and competing for resources and, 192
 thereby, suppressing the growth of pathogens 193
 [45]. The physical and chemical barrier of gut 194
 epithelial cells prevents microbial translocation 181
 to the underlying connective tissue. Defects in 182
 protein-coding genes (e.g., laminin) that are 183
 essential for the maintenance of a normal barrier, 184
 infections, inflammation, carcinogenesis, or 185
 microbial dysbiosis may induce barrier failure. 186
 Inflammation and carcinogenesis may trigger 187
 barrier failure, but barrier failure also promotes 188
 inflammation and carcinogenesis, suggesting a 189
 forward-amplifying loop [6]. Breakdown of the 190
 intestinal barrier leads to translocation of bacteria 191
 and the development of a systemic inflammatory 192
 response [46]. 193
 221

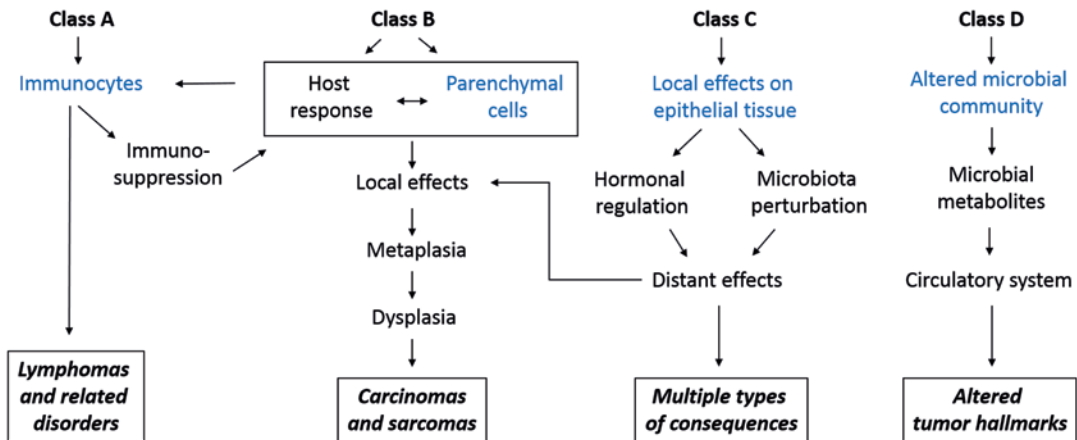

Fig. 10.1 Schematic picture of the classification of microbiota-associated human malignancies. Class A is defined by the involvement of the immune response, Class B requires direct microbial interactions with parenchymal cells, Class C covers distant effects from local interactions, and Class D shows the consequences of altered microbiome composition. (Modified figure from [5])

10.5 Microbiome-Immune System Interactions in Tumorigenesis

222
223
224

225 Microbiome-immune system interactions play
226 multifaceted roles in tumorigenesis. The microbi-
227 ome may promote tumorigenesis by inducing
228 chronic inflammation, disrupting the balance
229 between cell proliferation and cell death, and
230 triggering immune responses. The physical loss
231 of the natural gut epithelial barrier—barrier failure—
232 or the loss of the antibacterial defense system
233 enables the movement of cellular components
234 and microbes across the barrier, where they cause
235 an innate inflammatory response. The mamma-
236 lian immune system detects the presence of
237 microbial infection through *pattern recognition*
238 *receptors (PRRs)*. *Toll-like receptors (TLRs)* and
239 *NOD-like receptors (NLR)* belong to the PRR
240 family and recognize different but overlapping
241 microbial components. They are expressed in dif-
242 ferent cellular compartments (cell surface, cyto-
243 plasm, lysosome, and endosome) and activate
244 specific signaling pathways that promote inflam-
245 mation, tumor proliferation, or resistance to cell
246 death [23].

247 TLRs are one of the most powerful pro-
248 inflammatory stimuli. These structures recognize
249 microbe-associated molecular patterns, such as

lipopolysaccharides (LPS), peptidoglycan, fla- 250
gella, or microbial DNA/RNA. TLR2 recognizes 251
peptidoglycan and lipoteichoic acid (bacterial 252
cell wall components) and promotes gastric can- 253
cer, while TLR4 detects LPS (Gram-negative cell 254
wall component) and contributes to skin, pan- 255
creas, liver, and colon cancer development [6]. 256
Carcinogenesis is promoted through TLRs of 257
epithelial cells, macrophages, and fibroblasts. 258
TLR induction leads to the production of pro- 259
inflammatory cytokines, such as interleukins and 260
TNF α . Downstream effectors of TLR signaling 261
induce cell survival and suppress apoptosis 262
through NF- κ B (nuclear factor- κ B) and STAT3 263
signaling, which is in line with the role of MYD88 264
mutations that induce NF- κ B and STAT3 in many 265
human lymphomas [24]. Tumor formation is 266
reduced by pharmacologic inhibition of interleu- 267
kins (IL-17 and IL-23), antibiotic treatment, or 268
MYD88 inactivation [6]. 269

270 Although a direct link between endogenous 271
bacteria and tumor-associated angiogenesis has 272
not been shown, the microbiome is required for 273
normal development of the vasculature. LPS, 274
produced by the microbiome, may promote 275
angiogenesis through TLRs. IL-17 is produced 276
by T-helper-17 (Th17), suggesting that bacteria 277
also impact the tumor microenvironment by stim- 278
ulating Th17 lymphocytes. A connection between

279 breast cancer and immunoglobulins has been
280 established. Secretory immunoglobulin A (IgA)
281 helps to maintain the integrity of the mucosal
282 barrier, attenuates the host immune response, and
283 regulates the composition of the gut microbial
284 community.

285 Several bacterial species induce immunity in
286 tumor development. *Lactococcus* species help
287 maintain the cytotoxic activity of natural killer
288 (NK) cells, while *Sphingomonas yanoikuyae*
289 have an important role in maintaining breast tis-
290 sue health. Cytotoxic immune cells (cytotoxic T
291 lymphocytes) are essential for identifying and
292 destroying precancerous and cancerous cells;
293 *Fusobacterium nucleatum* destroy this protective
294 mechanism and enable tumor progression, while
295 others stimulate anticancer immunity.
296 *Bifidobacterium*, *Bacteroides thetaiotaomicron*,
297 and *Bacteroides fragilis* enhance dendritic cell
298 function and antitumor cytotoxic T cell immunity
299 [1]. TLRs may also promote cancer cell prolifer-
300 ation through different growth factor receptor
301 ligands (amphiregulin, epiregulin, and hepato-
302 cyte growth factors), which exert both local and
303 long-distance effects.

304 In carcinogenesis, the microbiota induce acti-
305 vation of NOD-like receptors (NLRs) as well.
306 Many studies focus on NOD2, because loss of
307 NOD2 activity is connected with Crohn's dis-
308 ease. NOD2 has a key role in the activation of
309 NF- κ B signaling and the formation of a bacterial
310 community. Thus, NOD2 loss-of-function muta-
311 tions may lead to intestinal dysbiosis and an
312 enhanced risk of developing colorectal carci-
313 noma (CRC). Genetically induced CRC is also
314 evoked by NOD1 deficiency, which plays an
315 important role in intestinal defense against bacte-
316 ria. NLRP6, another NLR, is important in
317 microbiota-tumorigenesis interactions. NRRP6
318 is a component and key activator of inflamma-
319 somes (multiprotein oligomers responsible for
320 the activation of inflammatory responses), which
321 are downregulated in dysbiosis-driven carcino-
322 genesis, together with decreased IL-18 produc-
323 tion [6].

324 Immunotherapy is used to eliminate residual
325 cancer cells after chemotherapy or radiation ther-
326 apy. In therapy, monoclonal antibodies target

327 molecules, such as anti-T-lymphocyte-associated
328 antigen 4 (CTLA-4) and anti-programmed death
329 1 (PD-1) or its ligand anti-PD-L1. The advantage
330 of immunotherapy is that it stimulates and sup-
331 ports the immune system of the host to fight can-
332 cer cells. The gut microbiome can stimulate the T
333 cell response and improve inflammatory signal-
334 ing through PRRs that potentiate the immune
335 system to directly eliminate cancer cells.
336 Antibodies against immune checkpoints improve
337 T cell function and proliferation and, thereby,
338 improve the anticancer immune response, pro-
339 viding an effective therapeutic approach in
340 patients with various types of cancers, such as in
341 advanced melanoma [47], renal cell carcinoma
342 [48], or non-small cell lung cancer [49].
343 Alterations in commensal gut bacteria influence
344 therapeutic responses to inhibition of CTLA-4
345 and PD-1. Following CTLA-4 therapy, the micro-
346 bial composition shifts; *Bacteroidales* and
347 *Burkholderiales* abundance decreases and
348 *Bacteroides* and *Clostridiales* are enriched [50].
349 *Bacteroides fragilis* is capable of promoting
350 T-helper 1 (Th1) responses and activating
351 antigen-presenting cells (dendritic cells) through
352 the induction of IL-12. Thus, an improvement in
353 anti-CTLA-4 effectiveness may be partially due
354 to the enrichment of *Bacteroides fragilis*.
355 Improved effectiveness of anti-CTLA-4 therapy
356 was observed in melanoma patients with
357 increased abundance of *Bacteroides*, *Bacteroides*
358 *thetaitaomicron*, and *Bacteroides fragilis* [50].
359 The main bacterial component driving these pro-
360 cesses was found to be the LPS of *Bacteroides*
361 species. Thus, inhibition of CTLA-4 can alter the
362 composition of the gut microbiome that in turn
363 influences responsiveness to immunotherapy.
364 Studies on anti-PD-1 or anti-PD-L1 therapy
365 showed similar bacteria-driven differences in
366 tumor outgrowth. In a mouse model of mela-
367 noma, increased effectiveness of anti-PD-L1
368 therapy was associated with enhanced
369 *Bifidobacterium* (*Bifidobacterium longum* and *B.*
370 *breve*) abundance in the gut and a consequent
371 activation of dendritic cells [51]. In metastatic
372 melanoma patients receiving anti-PD-1 and anti-
373 PD-L1 treatment, patients with greater alpha
374 diversity with an enrichment of *Clostridiales*,
375

375 *Faecalibacterium*, and *Ruminococcaceae* species
 376 and decrement in *Bacteroidales* had longer sur-
 377 vival. These beneficial effects were partly due to
 378 an enhanced T cell response (connected mainly
 379 to CD8⁺ T lymphocytes) and the upregulation of
 380 antigen-presenting pathways [52]. Increased
 381 CD8⁺ T cell activation was shown in another
 382 study in advanced melanoma patients. Patients
 383 that responded to anti-PD-L1 therapy had
 384 elevated levels of *Bifidobacterium longum*,
 385 *Collinsella aerofaciens*, and *Enterococcus fae-*
 386 *cium*. Moreover, all patients that responded to
 387 treatment carried *Akkermansia muciniphila* [53].
 388 Better survival was shown in urothelial carci-
 389 noma, renal cell carcinoma, or non-small cell
 390 lung carcinoma patients undergoing anti-PD-1
 391 treatment who did not receive antibiotics during
 392 or after treatment and carried elevated levels of
 393 *Akkermansia* and *Alistipes* species. These find-
 394 ings were mainly connected to CD4⁺ T cell acti-
 395 vation [54] and demonstrated that
 396 antibiotic-induced dysbiosis could negatively
 397 influence responses to immunotherapy.

398 However, the mechanisms that contribute to
 399 dysbiosis and changes in the microbial commu-
 400 nity are not well understood. Host-driven immune
 401 and inflammatory responses are important driv-
 402 ing factors that shape the bacterial community
 403 composition. The composition of the microbi-
 404 ome, innate immunity, and inflammation deter-
 405 mine the outgrowth of different types of specific
 406 bacteria by changing the production of metabo-
 407 lites, such as nitrate. Nitrate may provide a unique
 408 energy source for facultative anaerobic bacteria
 409 (e.g., *Enterobacteriaceae*). Inflammation may
 410 promote bacterial fitness and adaptation by
 411 inducing the expression of stress-response genes
 412 in bacteria (e.g., *Escherichia coli*) [6].

413 10.6 Genotoxins and Microbiota- 414 Driven Genomic Instability

415 *Inflammation* enhances tumorigenesis by induc-
 416 ing DNA damage and altering the mechanism of
 417 DNA repair. Macrophage release of reactive oxy-
 418 gen species (ROS) in response to inflammatory
 419 cytokines directly induces DNA breakage and

420 mutations, and their downstream pathways stim-
 421 ulate transcription factors (NRF2, NF- κ B) that
 422 impair cellular growth to produce cancer [36].
 423 *Enterococcus faecalis* can generate large amounts
 424 of superoxide, while *Fusobacteria* species and
 425 *Deltaproteobacteria* produce hydrogen sulfide;
 426 both *Fusobacteria* species and
 427 *Deltaproteobacteria* are associated with CRC.

428 *Hydrogen sulfide* is a product of sulfate reduc-
 429 tion from dietary taurine and sulfur-containing
 430 amino acids and has a wide effect on the host.
 431 Hydrogen sulfide is highly inflammatory and
 432 toxic to colonocytes. Furthermore, hydrogen sul-
 433 fide can enhance colonocyte proliferation through
 434 the ERK1/2 pathway [55], inhibit mucus synthe-
 435 sis and butyrate oxidation while impairing the
 436 activity of cytochrome oxidase, and generate free
 437 radicals that lead to genotoxicity.

438 Although the ability of microorganisms to
 439 produce ROS [56] contributes to tumorigenesis,
 440 bacteria can also release specific *toxins* that
 441 induce DNA damage responses, which also con-
 442 tribute to tumorigenesis (Fig. 10.2). Damaged
 443 barrier function may also allow the bacteria to
 444 transfer or deliver toxins, including cytolethal
 445 distending toxin (CDT), colibactin, cytotoxic
 446 necrotizing factor 1 (CNF1), and *Bacteroides fra-*
 447 *gilis* toxin. CDT and colibactin are true genotox-
 448 ins, which directly damage the DNA and activate
 449 the ataxia signaling pathway and histone phos-
 450 phorylation, which lead to G2/M cell cycle arrest
 451 [6]. CDT is created by Gram-negative bacteria
 452 (*E. coli*, *Helicobacter species*, and *Salmonella*
 453 *typhi*) and is relevant to colorectal, gastric, and
 454 gallbladder cancer. Colibactin is produced by *E.*
 455 *coli*, *Enterobacteriaceae*, *Proteus mirabilis*, and
 456 *Klebsiella pneumoniae* and is important in the
 457 development of CRC. Colibactin produced by *E.*
 458 *coli* induces DNA double-strand breaks, cell
 459 cycle arrest, and improper cell division [1].
 460 *Bacteroides fragilis* toxin activates the Wnt/ β -
 461 catenin signaling pathway, which promotes epi-
 462 thelial proliferation, by promoting the cleavage
 463 of the adhesion molecule, E-cadherin. The cleav-
 464 age of E-cadherin leads to β -catenin translocation
 465 to the nucleus and enables the transcription of
 466 proto-oncogene c-myc, leading to colonic epithe-
 467 lial hyperplasia [1].

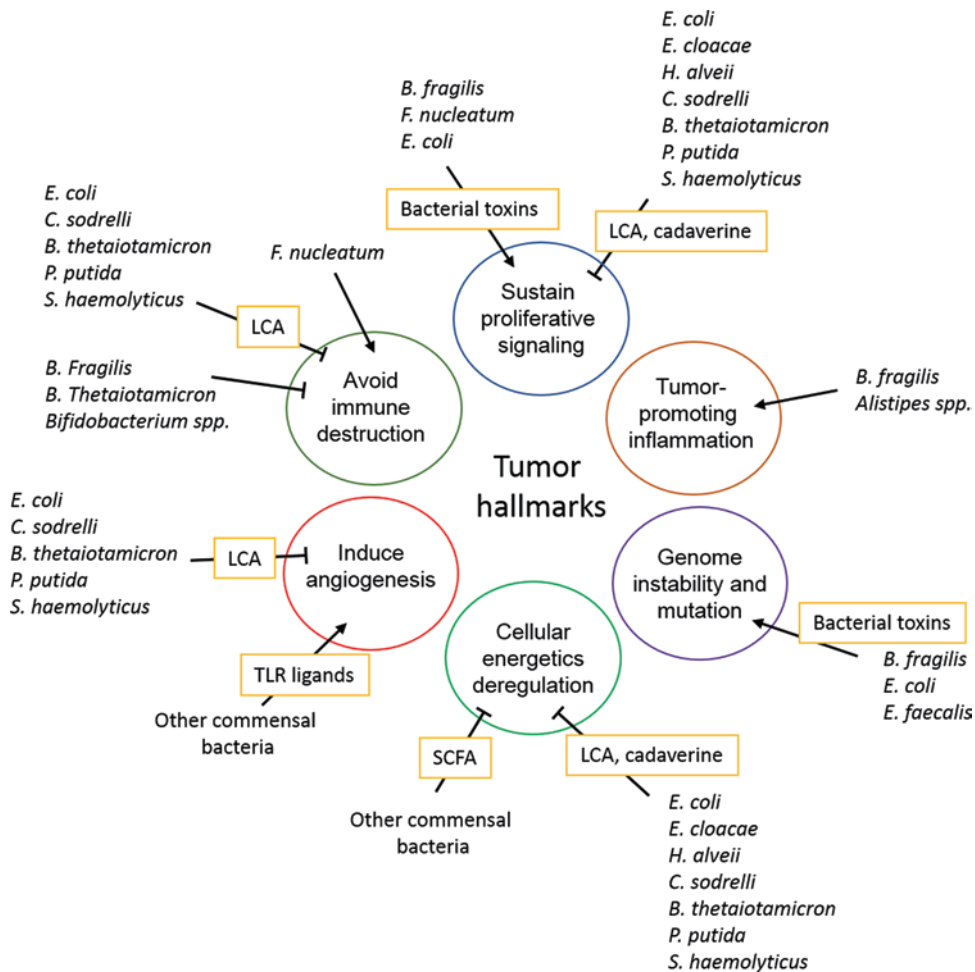

Fig. 10.2 The intestinal microbiota can modulate several hallmarks of cancer through different mechanisms

10.7 Bacterial Metabolites in Carcinogenesis

468
469

470 A major pathway in microbiome-host signaling
471 is the production of bacterial metabolites. These
472 metabolites, which are synthesized by the
473 microbiome, enter the circulation at the site of
474 production and travel to distant organs, where
475 they exert their biological effects [57]. Bacterial
476 metabolites behave like human hormones in the
477 sense that they are synthesized by an “organ” (the
478 microbiome) and are then transferred to the site
479 of action by the circulation [57].

480 Microbiota have the potential to metabolize
481 hormones, such as *estrogen*. The gut microbiome
482 is a key determinant of estrogen levels in the

body. β -Glucuronidases are the enzymes respon- 483
sible for estrogen deconjugation. Deconjugation 484
of excreted estrogen is important in estrogen 485
reuptake and, thus, modulation of systemic estrogen 486
availability and the regulation of estrogen- 487
associated pathways. Numerous bacterial species 488
can express β -glucuronidases, including 489
Firmicutes and *Bacteroidetes*: *Alistipes*, 490
Bacteroides, *Bifidobacterium*, *Citrobacter*, 491
Clostridium, *Collinsella*, *Dermabacter*, 492
Edwardsiella, *Escherichia*, *Faecalibacterium*, 493
Lactobacillus, *Marvinbryantia*, 494
Propionibacterium, *Roseburia*, and *Tannerella*. 495
Thus, these bacterial species affect circulating 496
and excreted estrogen levels. Reactivated estrogen 497
increases the serum estrogen levels and act 498

498

499 through estrogen receptors (ER α and ER β) to
500 modulate the expression of several genes, includ-
501 ing mitochondrial genes. Elevated oxidative
502 phosphorylation was shown to support metastasis
503 [58], contribute to therapy failure [59], and,
504 thereby, render the tumors more aggressive.
505 Taken together, bacterial estrogen deconjugation
506 promotes breast cancer progression and changes
507 the risk for development and progression of
508 estrogen-dependent cancers [6, 57].

509 The fermentation of nondigestible carbohy-
510 drates is beneficial for the host due to the genera-
511 tion of *short-chain fatty acids (SCFAs)*, such as
512 acetate, butyrate, formate, lactate, and propio-
513 nate. SCFAs are novel potential targets for the
514 management of obesity, metabolic disorders, and
515 lipomas, due to their ability to influence adipo-
516 cyte differentiation [60]. SCFAs have known
517 anti-inflammatory, antiproliferative, and antineo-
518 plastic effects. In addition, SCFAs can regulate
519 autophagy. Thus, SCFAs have a protective effect
520 on the colonic mucosa and play a significant role
521 in the protection against colon and liver cancer
522 [6]. In the gut, acetate, butyrate, and propionate
523 production are associated with a large group of
524 bacteria. Acetate production is widespread, while
525 the production of butyrate is connected to
526 *Faecalibacterium prausnitzii*, *Eubacterium hal-*
527 *lii*, *Eubacterium rectale*, *Roseburia faecalis*,
528 *Odoribacter*, and *Anaerotruncus* species. The
529 majority of propionate production is associated
530 with *Bacteroidetes*, *Lachnospiraceae*, and
531 *Negativicutes* species, as well as to *Roseburia*
532 *inulinivorans* and *Ruminococcus obeum*. In line
533 with this, the abundance of *Akkermansia*
534 *mucoiphila*, a propionate-producing bacterium,
535 is associated with the richness of the gut microbi-
536 ome [61]. SCFAs have both positive and negative
537 effects on breast cancer. Stroma and cancer cells
538 have free fatty acid receptors, through which
539 SCFAs modulate several hallmarks of cancer:
540 cell proliferation, invasion, apoptosis, metabo-
541 lism, and the expression level of certain genes.
542 Lactate can be used as a direct energy substrate;
543 thus, the inhibition of lactate metabolism reduces
544 cancer cell viability. Butyrate enhances mito-
545 chondrial ROS level, induces apoptosis, and

546 inhibits histone deacetylases, which lead to ele- 546
547 vated anticancer activity [57]. 547

548 The intestinal microbiota regulate *bile acid* 548
549 metabolism and are involved in producing the 549
550 secondary bile acids, deoxycholic acid (DCA) 550
551 and lithocholic acid (LCA), through the deconju- 551
552 gation, oxidation, and dehydroxylation of pri- 552
553 mary bile acids. The enzyme responsible for the 553
554 conversion of primary bile acids to secondary 554
555 bile acids is 7 α / β hydroxysteroid dehydrogenase 555
556 (HSDH). Conversion to secondary bile acids 556
557 increases the hydrophobicity of bile salts allow- 557
558 ing recovery through the colonic epithelium. 558
559 Secondary bile acids have both pro- and anticancer 559
560 activity. The consumption of a high-fat diet 560
561 changes the gut microbiome and enhances the 561
562 level of DCA via 7 α -dehydroxylase, which is 562
563 produced by bacteria, mainly clostridia. DCA is a 563
564 promoter of carcinogenesis in certain cancers. 564
565 DCA-elicited cell signaling is connected to pro- 565
566 tein kinase C and ERK1/2 signaling through epi- 566
567 dermal growth receptors, resulting in enhanced 567
568 cell proliferation. DCA is known to increase 568
569 CRC development and promote colon and esoph- 569
570 ageal cancers [6]. Moreover, bile acids disrupt 570
571 cell membranes through their amphipathic prop- 571
572 erties and the generation of ROS and reactive 572
573 nitrogen species. Bile acids also exert antimicro- 573
574 bial activity that changes the composition of the 574
575 intestinal community. LCA is synthesized 575
576 through 7 α -dehydroxylation of chenodeoxycho- 576
577 lic acid (CDCA) or 7 β -dehydroxylation of urso- 577
578 deoxycholic acid (UDCA). The enzyme 578
579 responsible for LCA synthesis is encoded by the 579
580 bile acid-inducible (baiH) operon and expressed 580
581 by aerobic and anaerobic bacteria, including 581
582 *Bacteroides fragilis*, *Bacteroides intestinalis*, 582
583 *Clostridium scindens*, *Clostridium sordellii*, 583
584 *Clostridium hylemonae*, and *E. coli*. These bacte- 584
585 ria belong to the phyla *Bacteroides*, *Firmicutes*, 585
586 and *Proteobacteria*. LCA inhibits the epithelial- 586
587 to-mesenchymal transition, vascular endothelial 587
588 growth factor (VEGF) production, and metastasis 588
589 formation of breast cancer cells, changes the met- 589
590 abolic features of the cells, and enhances antitu- 590
591 mor immunity of the host [30]. In line with these 591
592 observations, human serum levels of LCA and 592
593 the ability of the microbiome to produce LCA are 593

largely reduced in breast cancer; this is most pronounced in in situ and early stage carcinoma (stages 0 and 1) [30]. LCA can potentially exert its effects through the farnesoid X receptor (FXR), liver X receptor (LXR), pregnane X receptor (PXR), constitutive androstane receptor (CAR), vitamin D receptor (VDR), and G-protein-coupled bile acid receptor 1 (TGR5). In breast cancer, the main receptor is TGR5. Activation of TGR5 signaling was shown to induce OXPHOS, mitochondrial biogenesis through NRF1, AMPK, and PGC-1 β signaling. The expression of mitochondrial proteins (cytochrome c, atp5g1, and ndufb5) consequently increases mitochondrial activity and exerts anti-Warburg effects in breast cancer models [30]. In supraphysiological concentrations (>1 μ M), LCA was shown to inhibit fatty acid production and induce cell death and the expression of multidrug-resistant proteins [62].

When undigested dietary compounds reach the large intestine, they are fermented through anaerobic respiration. High protein consumption is associated with elevated colonic fermentation. *Bioactive products*, similar to bile salts, can produce or inhibit carcinogenesis. Cadaverine, a *biogenic amine*, is synthesized from L-lysine by bacterial lysine decarboxylase enzymes (LdcC and CadA). Cadaverine also has a human origin, but it seems that bacterial production is more important as it highly exceeds human biosynthesis. The main cadaverine-producing bacteria include *Aeromonas veronii*, *Clostridium perfringens*, *E. coli*, *Enterobacteriaceae* bacteria, *Edwardsiella tarda*, *Hafnia alvei*, *Raoultella ornithinolytica*, *Staphylococcus*, and *Streptomyces* species. These species belong to the *Acinetobacteria*, *Bacteroides*, *Firmicutes*, *Fusobacteria*, and *Proteobacteria* phyla. Trace amine-associated receptors (TAARs) were shown to be responsible for mediating cadaverine-elicited effects. Through TAARs, cadaverine inhibits epithelial-to-mesenchymal transition, proliferation, movement, and invasion of breast cancer cells. Moreover, cadaverine treatment inhibits primary tumor infiltration to the surrounding tissue and reduces the proportion of cancer stem cells [42].

Many bacteria in the GI tract have alcohol dehydrogenase activity, which enables the bacteria to metabolize ethanol and produce reactive and toxic *acetaldehyde*. The most important gastric pathogen, *H. pylori*, and some skin bacteria have high alcohol dehydrogenase activity. The colonic mucosa has a low aldehyde dehydrogenase activity, resulting in acetaldehyde accumulation in the colon. High acetaldehyde levels contribute to the pathogenesis of alcohol-induced diarrhea and the increased risk of colon polyps and colon cancer [63] (Fig. 10.3).

10.8 The Interference of the Microbiome with Chemotherapy

Bacteria of the intestinal microbiome can interfere with therapeutic agents during cancer treatment and management. The microbiome can modulate the efficacy of both chemotherapy and radiotherapy. Bacteria can inactivate or activate chemotherapeutic drugs, alter immune responses, or interfere with the side effects of the therapy. The relationship is reciprocal, as tumor therapy can influence the composition and function of the microbiome [57].

Chemotherapeutic compounds, such as cisplatin or oxaliplatin, exert their cytotoxic effects through DNA damage, the upregulation of apoptotic pathways, or the promotion of antitumor immune responses (through a TLR4-dependent mechanism). The antitumor effects of *platinum compounds* significantly decrease upon broad-spectrum antibiotic treatment or in microbiota-deficient mice. In addition, tumor-infiltrating cells show reduced production of ROS after antibiotic treatment [35]. In this scenario, commensal microbes prime tumor-infiltrating cells for ROS production through the connection to PRRs, with the involvement of MYD88 signaling (described previously) [6, 56]. *Lactobacillus acidophilus* supplementation can restore the antitumor effects of cisplatin in mice [11]. *Cyclophosphamides* have been used for anticancer therapy for almost 60 years. In high doses, cyclophosphamides are immunosuppressive,

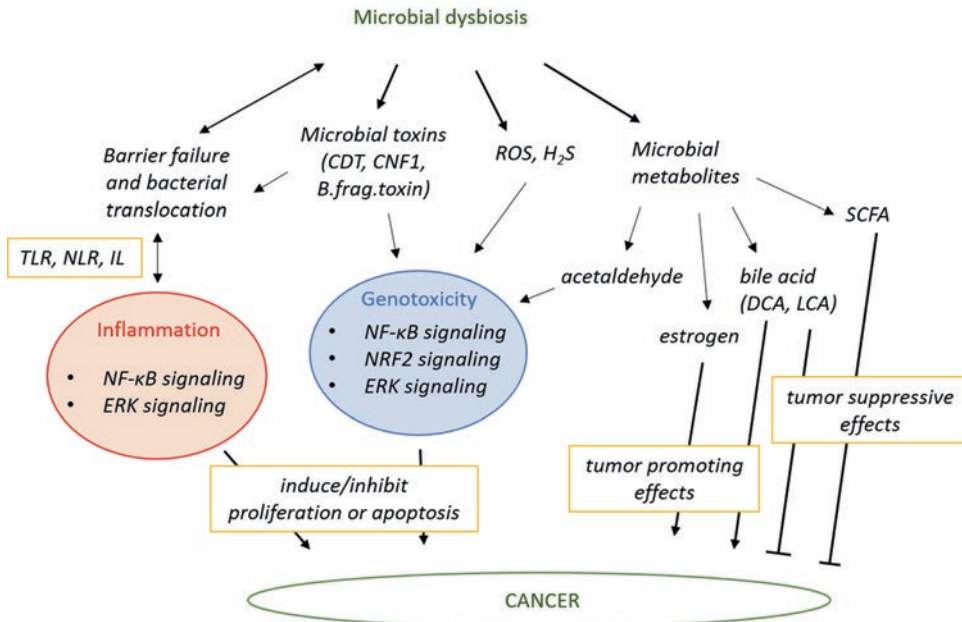

Fig. 10.3 Mechanisms by which microbial dysbiosis modulates carcinogenesis

687 while in low doses, cyclophosphamides promote
 688 the antitumor immune response through activa-
 689 tion of cytotoxic T cells and induction of immu-
 690 nogenic cell death [33]. Cyclophosphamides are
 691 used in the therapy of breast cancer; however,
 692 cyclophosphamides cause damage to the gut
 693 mucosa, making the gut leaky and allowing gut
 694 bacteria to enter the circulation. A rich microbi-
 695 ome and elevated levels of *Lactobacillus planta-*
 696 *rum* are protective against
 697 cyclophosphamide-induced mucosal injury [57].
 698 Cyclophosphamide treatment causes the overrep-
 699 resentation of Gram-negative species, such as
 700 *Barnesiella intestinihominis* that enhance effec-
 701 tor T cells (cytotoxic CD8⁺ T cell), and
 702 *Enterococcus hirae*, Gram-positive bacteria that
 703 enhance MYD88-dependent CD8⁺ T cell activa-
 704 tion in a tumor-specific manner. Both bacteria are
 705 regulated by intestinal NOD2 receptors that pro-
 706 mote a pro-inflammatory tumor environment and
 707 drive antitumor immune responses [35]. T cell-
 708 mediated immune responses against *B. intestini-*
 709 *hominis* and *E. hirae* have clinical relevance in
 710 chemotherapy-treated patients with lung and
 711 ovarian cancers.

In addition to cyclophosphamides, anthracy- 712
 713 clines, selective estrogen receptor modulators
 714 (SERMs), taxanes, and antimetabolites have key
 715 roles in breast cancer therapy. *Anthracyclines* are
 716 produced by *Streptomyces* species. Anthracyclines
 717 act mainly by intercalating into DNA and inter-
 718 fering with DNA metabolism and RNA produc-
 719 tion, or by generating excessive
 720 ROS. Anthracyclines can be bacteriostatic; they
 721 decrease the abundance of *Acinetobacter* species
 722 [32]. No bacterial drug metabolism was associ-
 723 ated with SERMs (tamoxifen, raloxifene).
 724 Tamoxifen can modulate the composition of the
 725 microbiome, while tamoxifen resistance can also
 726 be modulated by the microbiome. SERMs are
 727 toxic to different species in the GI tract, including
 728 *Acinetobacter baumannii*, *Bacillus stearother-*
 729 *mophilus*, *Enterococcus faecium*, *Klebsiella*
 730 *pneumoniae*, *Porphyromonas gingivalis*,
 731 *Pseudomonas aeruginosa*, and *Streptococcus*
 732 *mutans* [57]. *Taxanes* (paclitaxel, docetaxel) are
 733 widely used as chemotherapy agents. Taxanes
 734 disrupt microtubule formation and, hence, block
 735 cell division and proliferation. Taxanes may
 736 change the composition of the microbial commu-
 737 nity or interfere with bacterial LPS, while activat-

ing the immune system. PARP inhibitors are drugs used in the treatment of ovarian cancer with a potential to be used for other neoplasias (e.g., breast cancer, prostate cancer). PARP inhibitors were shown to induce the diversity of the gut microbiome [64].

Drugs are often used in combinations to enhance treatment efficacy. *Irinotecan* is used to treat colon cancer and small cell lung carcinoma. For treating colon cancer, irinotecan is generally used in combination with 5-fluorouracil (5FU), whereas for the treatment of small cell lung cancer, irinotecan is combined with cisplatin. Bacterial reactivation of irinotecan by bacterial β -glucuronidase leads to severe side effects, such as diarrhea, vomiting, bone marrow suppression, hair loss, shortness of breath, and fever. Antibiotic treatment or β -glucuronidase inhibition prevents most of these side effects [6]. When 5FU is used in combination with irinotecan, dysbiosis-induced mucositis leads to bacterial translocation from the GI tract. Both 5FU and *gemcitabine* undergo bacterial activation and bacterial deactivation. In human pancreatic ductal adenocarcinoma, *Gammaproteobacteria* was found to be the most important player in deactivating gemcitabine. In tumors, levels of *Gammaproteobacteria* were elevated in tumor patients as compared to healthy individuals, underlining its role in the regulation of gemcitabine availability. Both 5FU and gemcitabine have bactericidal properties; therefore, they can alter the composition of the GI microbial community [57].

Chemotherapy is often not specific for one or two bacterial species, but change the proportion and diversity of the microbiome. After chemotherapy, both the alpha diversity, which represents species richness (the number of different species in a sample), and beta diversity, which refers to the diversity in the microbial community between different environments, are altered as compared to samples without chemotherapy. These changes are independent of covariates (age, sex, previous antibiotic consumption, and previous chemotherapeutic treatment) and show increases in *Citrobacter*, *Enterococcus*, *Klebsiella*, *Megasphaera*, and *Parabacteroides*

species, while showing decrements in the abundance of *Adlercreutzia*, *Anaerostipes*, *Bifidobacterium*, *Blautia*, *Clostridium*, *Collinsella*, *Coprococcus*, *Dorea*, *Lachnospira*, *Roseburia*, and *Ruminococcus* species. Some bacteria showed resistance to chemotherapy; thus their abundance did not change upon treatment, including *Actinomyces*, *Erysipelotrichaceae*, *Mobiluncus*, *Mitsuokella*, *Oxalobacter*, *Prevotella*, *Scardovia*, and *Slackia* [34].

Besides inducing taxonomic dysbiosis, chemotherapy can disrupt microbial function. Several metabolic pathways can be suppressed by chemotherapy, including amino acid, carbohydrate, and nucleotide metabolism, as well as the metabolism of vitamins and cofactors. Other pathways are enhanced by chemotherapy, including signal transduction, xenobiotic degradation, and glycan metabolism. Glycan metabolism, together with disrupted carbohydrate and amino acid metabolism, contributes to enhanced intestinal inflammation [65] and upregulation of nitrogen, sulfate, and riboflavin pathways, which is associated with inflammatory diseases, increased ROS production, and bacterial translocation [66]. Moreover, chemotherapy increases bacterial motility proteins and flagella assembly (essential for bacterial pathogenesis, motility, adhesion, and invasion).

Dysregulated microbiota plays a significant role in the development of GI mucositis. Mucositis is a painful inflammation of the mucous membranes of the digestive system, usually as an unpleasant side effect of chemotherapy and radiotherapy for cancer. In the first step of this process, the microbiome enhances the activation of NF- κ B and TNF α signaling, leading to long-lasting inflammation. Several bacteria are reduced after chemotherapy, including *Bifidobacterium*, *Coprococcus*, *Clostridium*, *Dorea*, *Faecalibacterium*, *Lachnospira*, *Roseburia*, and *Ruminococcus*, which inhibit inflammation through blocking NF- κ B and produce mucosa-protecting metabolites (SCFAs), whereas *Citrobacter* and other species, which participate in LPS biosynthesis and enhance intestinal inflammation, are increased during chemotherapy [34]. Subsequently, GI mucositis

834 barrier dysfunction develops, leading to increased
 835 intestinal permeability, which coincides with a
 836 decrease in the amount of the previously men-
 837 tioned protective bacteria. The microbiome may
 838 modulate the composition of the mucus layer, as
 839 the terminal step of mucositis induction.
 840 *Citrobacter*, which increases after chemotherapy,
 841 may participate in the degradation of the mucosal
 842 barrier through the expression of mucus-
 843 degrading enzymes (mucinase, glycosidase), and
 844 *Enterobacteriaceae* can disrupt the mucus layer.
 845 Butyrate-producing bacteria protect the mucin
 846 layer, as butyrate increase mucin synthesis. A
 847 decrement in cysteine, proline, and methionine
 848 metabolism, which occurs during chemotherapy,
 849 can also be responsible for altered mucin compo-
 850 sition and the development of GI mucositis after
 851 chemotherapy [34].

852 Radiation therapy is used as a primary treat-
 853 ment in cancers that are localized to one area of
 854 the body to prevent tumor recurrence after sur-
 855 gery or applied together with chemotherapeutic
 856 agents. Radiation itself is genotoxic, resulting in
 857 cancer cell death. However, radiation can also
 858 abolish nontarget cells due to the activation of the
 859 immune system by radiation-induced inflammation.
 860 The microbiota is known to be involved in
 861 these off-target effects due to intestinal mucosa
 862 damage and toxicity. Radiotherapy decreases
 863 both the diversity and the total amount of gut bac-
 864 teria, particularly *Bacteroidetes*,
 865 *Enterobacteriaceae*, *Firmicutes*, and
 866 *Lactobacillus* species, while enriching
 867 *Fusobacterium* and *Proteobacteria*, which are
 868 connected with increased production of pro-
 869 inflammatory cytokines [35].

870 10.9 Modulation 871 of the Microbiome 872 to Enhance the Efficacy 873 of Chemotherapy

874 Probiotics and prebiotics are widely used to shift
 875 the composition of the microbiome, and these
 876 interventions are potentially useful in restoring
 877 the microbiome after chemotherapy. Probiotics
 878 contain live bacteria that can be administered

879 orally, while prebiotics (dietary prebiotics) are 879
 880 compounds in food, which provide substrates 880
 881 that stimulate the growth or activity of advanta- 881
 882 geous bacteria colonizing the gut. Prebiotics and 882
 883 probiotics prevent infection and moderate the 883
 884 side effects of cancer treatment. Administration 884
 885 of various strains of *Lactobacillus*, such as 885
 886 *Lactobacillus acidophilus*, is associated with 886
 887 enhanced cisplatin sensitivity and longer survival 887
 888 in lung cancer [35]. *Bifidobacterium bifidum*, 888
 889 *Lactobacillus acidophilus*, *Lactobacillus casei*, 889
 890 and *Lactobacillus rhamnosus* decrease the toxic- 890
 891 ity associated with 5FU chemotherapy and, con- 891
 892 sequently, reduce abdominal discomfort and 892
 893 diarrhea. In addition, *Bifidobacterium* and 893
 894 *Lactobacillus* species in combination were able 894
 895 to moderate the side effects after radiation treat- 895
 896 ment. Current clinical trials are focused on the 896
 897 efficacy of probiotic treatment for colorectal, kid- 897
 898 ney, breast, gynecologic, and lung cancer [35]. 898

899 Fecal microbiota transplantation (FMT), also 899
 900 known as stool transplantation, is the process of 900
 901 transplanting fecal bacteria from a healthy indi- 901
 902 vidual into a diseased subject. FMT is an effec- 902
 903 tive therapy to shift the composition of the 903
 904 microbiome. FMT is effective in the treatment of 904
 905 *Clostridium difficile*, where FMT is curative 905
 906 through enhancement of the diversity of the 906
 907 microbiome [67]. FMT could be potentially 907
 908 effective after chemotherapy or radiotherapy in 908
 909 cancer patients by avoiding gut toxicity or pre- 909
 910 venting infections. However, FMT has numerous 910
 911 side effects (fever, diarrhea, vomiting), including 911
 912 serious side effects, such as GI bleeding or perfo- 912
 913 ration, that limit its applicability in cancer 913
 914 patients [35]. 914

915 As a developing future therapy, bacterial engi- 915
 916 neering offers the opportunity to treat cancer 916
 917 without reconfiguring the gut microbiome. 917
 918 Biologically engineered bacteria could be applied 918
 919 effectively to target cancer cells or to deliver ther- 919
 920 apeutic agents, thereby avoiding serious side 920
 921 effect-eliciting anticancer therapies. Bacterial 921
 922 cells can be easily and rapidly transfected with 922
 923 vectors encoding interfering RNAs, cytokines, 923
 924 toxins, antiangiogenic factors, or antibodies. 924
 925 *Listeria* and *Shigella* species could invade 925
 926 hypoxic tumor tissues, and, given their quick rep- 926

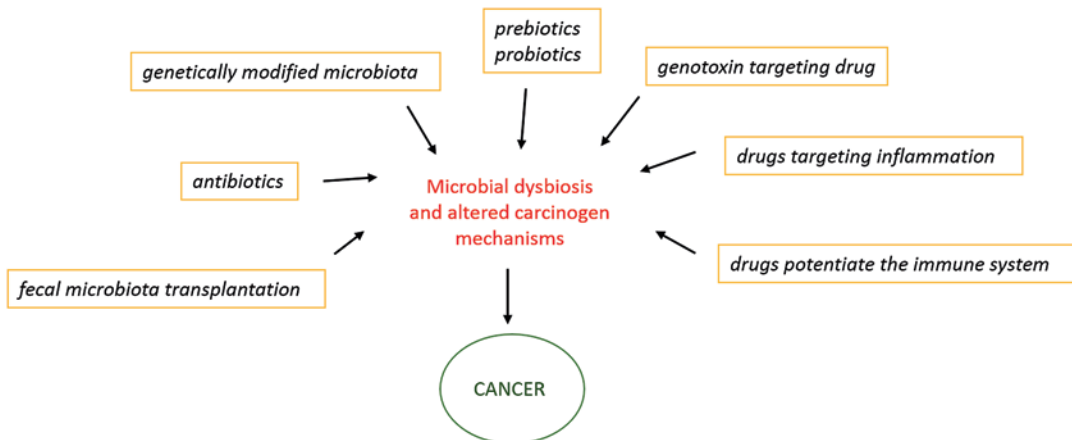

Fig. 10.4 Targeting the microbiome for modulation of carcinogenesis

927 lication rate, these bacteria could amplify their
 928 transgene(s) within the tumor microenvironment.
 929 Upon the application of bacteria, finding a good
 930 balance is necessary; one must seed a sufficient
 931 number of bacteria to elicit therapeutic effect but
 932 should avoid suppressing the immune system at
 933 the same time [35] (Fig. 10.4).

10.10 Type of Cancers Related to Microbial Dysbiosis

936 Besides the GI tract, other organs are colonized
 937 by a unique microbial community, such as the
 938 skin, oral cavity, and germinal tracts. Growing
 939 evidence confirms a significant relevance of bac-
 940 terial microbiota in the carcinogenesis of the
 941 colon, liver, breast, lung, oral cavity, and
 942 pancreas.

943 The liver receives 70% of its blood supply
 944 from the intestinal vein. This close functional
 945 relationship between the liver and GI tract results
 946 in constant exposure to nutrients, toxins, micro-
 947 bial metabolites, and microbes. Various types of
 948 immune cells (NK cells, macrophages, lympho-
 949 cytes) defend this organ against harmful agents
 950 derived from the intestine. An altered microbio-
 951 me may contribute to the development of *hepa-*
 952 *tocellular carcinoma* (HCC), which is preceded
 953 by chronic liver disease, fibrosis, and cirrhosis
 954 [68]. The disrupted microbiome may drive this
 955 process through the loss of intestinal barrier func-

tion, the activation of the NF- κ B pathway, the
 production of pro-inflammatory cytokines, and
 increased anti-apoptotic signals.

Pancreatic cancer is an aggressive cancer type
 with low therapeutic success and survival rate.
 Periodontal disease, low oral hygiene, obesity,
 smoking, and alcohol consumption are well-
 known risk factors for pancreatic cancer, because
 they facilitate the translocation of bacteria
 through disrupted barrier layers. Bacteria can
 reach the pancreas through the circulation.
 Furthermore, although the pancreas does not
 have a microbiome, carcinogenesis of this organ
 is enhanced by distant dysbiotic microbiota [6],
 through the involvement of inflammatory
 responses, LPS expression, and TLR4 activation
 [69].

973 About 90% of all lung cancer cases are attrib-
 974 uted to smoking, while only 15% of smokers
 975 develop *lung cancer*, suggesting other mecha-
 976 nisms and influences. The interface of the lung
 977 is continuously connected to the outside environ-
 978 ment, and the microbiota of the lung reflect the
 979 microaspiration of oral microbiota. The lung has
 980 a unique microbiome with different species of
 981 *Proteobacteria*. The connection between lung
 982 cancer and chronic pulmonary disease is assigned
 983 to toxic pro-inflammatory and neoplasia-causing
 984 compounds. Different bacteria species, such as
 985 *Moraxella catarrhalis*, *Haemophilus influenza*,
 986 and *Streptococcus pneumoniae*, are associated
 987 with 50% of chronic pulmonary disease, and

988 their presence can elicit chronic inflammatory
989 responses [70].

990 The oral cavity harbors diverse individual
991 microbiota. Moreover, the composition of the
992 microbiota differs between microenvironments
993 within the oral cavity; the lateral and dorsal
994 tongue and tooth surface all have unique micro-
995 bial communities. The normal oral microbiome
996 includes *Actinobacteria*, *Bacteroidetes*,
997 *Firmicutes*, *Fusobacteria*, *Haemophilus*,
998 *Neisseria*, *Prevotella*, *Proteobacteria*,
999 *Streptococcus*, and *Veillonella* species.
1000 *Capnocytophaga gingivalis*, *Prevotella melanin-*
1001 *ogenica*, and *Streptococcus mitis* are found in
1002 oral squamous cell carcinoma (OSCC) and are
1003 considered biomarkers of this disease. Risk factors
1004 for OSCC, which are connected to anaerobic,
1005 Gram-negative bacteria that liberate
1006 inflammatory markers, include smoking, heavy
1007 alcohol consumption, poor oral hygiene, and
1008 periodontal disease [71].

1009 Genetic factors, infection, inflammation, and
1010 diet are well-known risk factors for colorectal
1011 carcinoma (CRC). CRC is associated with other
1012 diseases, such as inflammatory bowel disease,
1013 autoimmune, allergic reactions, obesity, and dia-
1014 betes. Despite the great diversity of bacterial spe-
1015 cies of the GI tract, CRC is closely related to
1016 changes in the diversity and activity of microbes.
1017 Microbes produce metabolically active mole-
1018 cules that alter homeostasis or carcinogenesis
1019 [72]. The microbiota may contribute to CRC
1020 through different mechanisms that result in an
1021 imbalance between cellular proliferation and
1022 apoptosis pathways, such as PRR signaling and
1023 inflammation, metabolites that induce DNA dam-
1024 age and chromosome instability, or the loss of
1025 protective metabolites (due to microbial dysbio-
1026 sis), such as SCFAs, secondary bile acids, or bio-
1027 active amines [73].

1028 Recent research showed a strong correlation
1029 between gut microbiome dysbiosis and breast
1030 cancer. In addition to the gut microbiome, the
1031 breast has a unique microbiome that shows dras-
1032 tic changes in breast cancer. The microenviron-
1033 ment of breast cancer cells is modulated by
1034 bacterial metabolites (SCFAs, secondary bile

1035 acids, amino acid degradation products, and
1036 estrogen derivatives) that are produced in the
1037 intestine and reach cancer cells of the breast via
1038 the circulatory system. In breast cancer, various
1039 pathways are disrupted or altered in addition to
1040 the general changes in glycolysis and mitochon-
1041 drial function, including glutamine, fatty acid,
1042 cholesterol metabolism, protein translation, and
1043 glutamine-serine pathways in cancer cells. These
1044 changes are the consequence of the rearrange-
1045 ment of a complex homeostatic system and
1046 energy sensors and lead to changes in cell prolifer-
1047 ation and angiogenesis. Microbial dysbiosis
1048 occurs in both the fecal flora and the breast
1049 microbiome in breast cancer [20]. Fecal samples
1050 of breast cancer patients contain increased levels
1051 of *Clostridiaceae*, *Faecalibacterium*, and
1052 *Ruminococcaceae* and decreased levels of *Dorea*
1053 and *Lachnospiraceae* species [18]. Moreover, the
1054 microbiota composition differs not only between
1055 cancerous persons and healthy volunteers but
1056 also between breast cancer stages and grades and
1057 according to different tumor subtypes (triple-
1058 negative breast cancer associated with unique
1059 microbiome) [74]. For example, patients with
1060 grade III cancer have an increased number of
1061 *Blautia* species, compared with grade I patients,
1062 and samples from stage II/III showed elevated
1063 absolute numbers of *Bacteroidetes*, *Clostridium*,
1064 and *Blautia* species [75].

1065 10.11 Future Prospects

1066 The recent emergence of studies on the microbi-
1067 ome in various diseases highlights the impor-
1068 tance of bacterial dysbiosis in different cancers.
1069 Despite the increasing literature on colorectal
1070 cancer, the data and observations on those can-
1071 cers that are not in direct contact with the (gut)
1072 microbiome are limited and the available studies
1073 are often restricted to observational studies.
1074 Hence, mechanistic studies are largely missing.
1075 Minor microbiome compartments are understud-
1076 ied, in terms of the number of bacteria (e.g.,
1077 lower airways). These caveats will need to be
1078 filled in the future.

1079 The currently available data suggest that pre-
 1080 biotics and probiotics may have beneficial effects
 1081 in restoring/preventing the microbiome dysbio-
 1082 sis, but these findings will have to be assessed in
 1083 well-controlled clinical studies. Along those
 1084 same lines, the use of antibiotics in cancer
 1085 patients will need to be assessed in detail. Finally,
 1086 the microbiome-drug interactions, a key element
 1087 in cancer-related personalized medicine, will
 1088 need to be precisely mapped.

1089 **Acknowledgments** Our work is supported by grants
 1090 from NKFIH (K123975, PD124110, FK128387,
