

## AN AUTOMATICALLY PRODUCED THESAURUS

GERHARD SCHWANHAUSSER, Thesaurus Hochschulforschung Hochschulbau, Institut für Hochschulbau, Sonderforschungsbereich 63, Stuttgart, Federal Republic of Germany

A procedure for the computer generation of a thesaurus from a set of descriptors, manually assigned to the documents in a library, is described. Recognises only a quasi-associative relationship among descriptors. The specific advantages of the thesaurus as an open-ended one, the keywords derived from actual documents being the most helpful in retrieving the documents, and as an aid in information search in the collection are pointed out. Computational procedures for generating the thesaurus include keyword statistics, matrix inversion, calculation of similarity matrix using Tanimoto coefficient, automatic cluster analysis using minimal-tree procedure, and compilation of groups and main groups of descriptors are given. An algorithm for the graphic display of the main groups of descriptors has been formulated. The main disadvantage of the procedure is that only a limited number of keywords can be processed within a reasonable computer CPU time. Points out that the procedure can be applied to a library of 10, 000 to 20, 000 documents with a keyword base of 1, 000 words using about 3 hours of computing time.

### 1 GENERAL CONSIDERATIONS

The basic prerequisite for the establishment of an automatically constructed thesaurus is the existence of an indexed corpus of documents. In the case of the library of the Zentralarchiv für Hochschulbau, Stuttgart, there has been available a corpus of 5, 900 manually indexed documents (1). We suppose that, even if the indexing has been done carefully it is still a rather subjective work and we should use the minimum of further assumptions to produce a thesaurus, which we call, on account of its inter-indexer inconsistency, a pragmatic thesaurus (3). Defining thesaurus as an inter-related list of key words of the area of knowledge which is under consideration, the question can be raised how to limit the area of knowledge and how to decide which key words do belong to this area, since new branches of science develop their vocabularies fairly rapidly and even changes of meaning occur as time goes on. A pragmatic thesaurus such as ours implies some basic assumptions. Firstly, we assumed every document entered into the library is relevant for this area of knowledge. Secondly, the manually assigned key words for every document are taken to be the most relevant ones. Thirdly, there is only one type of interrelation between the key words, namely a quasi-associative relation of every key word of a document to all other key words of that document. Having adopted these assumptions to a special library you need but to do some machine calculations

and a thesaurus is almost ready. A procedure such as this facilitates the up-dating of a thesaurus, whenever sufficient additional documents have been entered into the library. A detailed specification of the area of interest is not necessary, since the indexed document collection can be understood as a description of it. In addition to that the list of key words need not - should not - be fixed in advance. It should rather be an open ended list, adding new key words whenever it is felt necessary. As to the meaning of the key words, it can be taken that every key word is defined by the content of the document or documents to which it has been assigned in the indexing process.

The main advantage of a pragmatic thesaurus derived from actual documents is that it will be a principal retrieval aid for those documents, and it will also aid the user to find appropriate combination of key words which would give satisfactory retrieval results which he expects from the system.

Further, a pragmatic thesaurus can be a very good discussion basis for any conference interested in establishing a thesaurus on a similar area of research. There will be no need to argue by means of arbitrary examples made off-hand by the participants of the conference, because a pragmatic thesaurus will contain an adequate number of different examples along with the frequency counts from which one may draw conclusions more easily than from ficti-

tious examples. The main restriction of the approach described here, is the limited number of key words which can be processed within reasonable computer CPU time. We guess that the procedures can be applied to a library of some 10,000 - 20,000 documents with a key word repertoire of 1000 words using not more than 3 hours of calculation time.

## COMPUTATIONAL PROCEDURES

### 21 Key Word Statistics and Matrix Inversion

The library of the Zentralarchiv für Hochschulbau keeps all its documents with a numerus currens for identification (5, 7). For every key word, there is a peek-a-boo card carrying the numbers of the documents to which this key word has been assigned during the manual indexing process. The information on the peek-a-boo cards have been key punched coding the key words with a number. The statistical evaluation came up with two tables concerning the key word frequency and the indexing depth. The graphic display shows that most key words have been used between 20 and 400 times. The indexing depth shows that on the average a document has been indexed with 4 to 12 descriptors. Because the representation of all document numbers per key word is a matrix it was necessary to make a matrix inversion to get all key words per document.

### 22 Associate Relationship

It is assumed that there is an associative relation between every two descriptors (= Key words), whenever they have been assigned to one or more documents. The reduction of all possible types of relations to a single one, not distinguishing between them at all, is the reason why we call our thesaurus a pragmatic one. In spite of the fact that true semantic analysis would be a very useful thing, there are up to now no computerized systems known, which would do this for a real library. Even intellectual thesaurus construction is a very hard and time consuming task, so that many authors have not specified the type of relation between key words for manually compiled thesauri (8). We checked our procedure against the recommendations for the establishment of monolingual thesauri (3) and found it to be within the rules. The associative relation between two descriptors is understood to be independent of the sequence and of the context of possible other descriptors. All pairs of descriptors have been checked even if the combination of some descriptors do not make sense.

### 23 Calculation of Similarity Matrix

The similarity matrix has been calculated on the basis of the Tanimoto coefficient for which is a function of the frequency of the descriptor A and the frequency of descriptor B and of the frequency of the two descriptors taken together C.

## TANIMOTO COEFFICIENT

$$f = \frac{C}{A + B - C}$$

A = FREQUENCY OF THE DESCRIPTOR A  
 B = FREQUENCY OF THE DESCRIPTOR B  
 C = FREQUENCY OF THE DESCRIPTORS  
 A AND B TOGETHER

The calculation of the similarity matrix was the most time consuming one, because 450,000 combinations had to be checked whether there is a common frequency C different from zero and some 45,000 Tanimoto coefficients had to be calculated. Since the necessary computer time of one and a half hour was not available for a single job, the symmetry of the similarity matrix has not been used, to make a restart of the programme easier without passing all the results calculated up to the breaking point. The input data, namely the inverted file could be kept within the core memory putting always three integer numbers into one word using a MASK/SHIFT subroutine. The complete similarity matrix has been printed out, the coded key words written in plain text along with their absolute and relative frequency counts. According to suggestions of Ivanova (4) only those descriptors should be assumed to be related whose Tanimoto coefficients sum up to half of all coefficients of the same line. We did use an approximation to the proposal of Ivanova putting all those descriptors into one group, which have a Tanimoto coefficient greater than the mean value of that line. The result of this procedure was a list of as many overlapping groups as there were descriptors. A manipulation was made concerning the very rare and the very frequent descriptors. All thirtyeight descriptors appearing once and six descriptors appearing more than 500 times have been deleted from the analysis, such that there were left 710 descriptors. A similar recommendation has been made by Salton for the SMART system. The list of the resulting 710 descriptor groups corresponds to the alphabetical lists in traditional thesauri, except that this list does not distinguish different types of relations.

## 24 Automatic Cluster Analysis

In general, there is a systematic part and an alphabetical part in every thesaurus. The systematic part describes the area under consideration by means of some subsets of the keywords. The automatic procedure for cluster analysis can be divided into those which produce separated clusters and those which produce overlapping clusters. Since in our case the alphabetical list of descriptor groups is already overlapping we decided to use the minimal-tree procedure which divides all keywords into exactly separated groups. The name of the minimal-tree procedure derives from the fact that a matrix of distances has been used in the original work (6), choosing the minimal distance between the words. In our case we had the similarity matrix as a basis, so it is obviously the maximum of the similarity which corresponds to the same procedure. We have kept the name in spite of using the opposite measure.

The minimal-tree procedure is started with an arbitrary descriptor. A second descriptor is picked up out of the group of descriptors of the first one, so that the second one has maximum similarity to the first. The third descriptor has to have the maximum value of similarity to one of the predecessors, and is linked correspondingly. The procedure has to be continued until all descriptors have entered the tree exactly once. The tree obtained by this procedure is independent from the starting point as to the sum of all similarities which have been entered into the tree. To cut the minimal-tree into pieces it is recommended to use an arbitrary level of similarity which should be surpassed unless a branch of the tree is not to be cut off (2). A series of trials showed that an appropriate level of similarity is hard to define, since too low a level does not break the tree into a sufficient number of fractions, some being very large, others being very small. The number of fractions increases as the level of similarity increases at which the branches stand the cutting trials, but unfortunately the size of the fractions decreases more rapidly so that a number of single descriptors were found to form clusters of their own. To finish a first version of our thesaurus we decided to cut the minimal tree manually using the mean value of all similarities as decision aid. I will return to this point at the end. The arbitrary division of the minimal tree could be made such that all fractions are almost of the same size. We have 23 so called main groups each containing some 10 descriptors, which is a quickly scannable size. The definition of our groups and main

groups is analogous to the facet and semantic classes in traditional thesaurus work.

## 3 COMPILATION OF GROUPS AND MAIN GROUPS

This part of the total procedure is mainly for output purposes. It produces lists of all groups of descriptors indicating the number of the main groups within which a descriptor can be found. This scheme of reference among the descriptors will be of great use to one who is trying to retrieve documents on the basis of key words but has not found the proper key word combination to get the relevant documents. Using the references he can change his key word combination step by step, always checking the statistical neighbourhood of any key word. The list of main groups has been printed along with two selected key words which may be some sort of intuitive representatives for the main groups. This method too has to be replaced by some better, objective method when a revision of the thesaurus is made. To make the clusters of the main groups easier to read a graphic representation has been produced by the program described in the next section.

## 4 GRAPHIC DISPLAY OF THE MAIN GROUPS

The graphic display was not a principal aim of this thesaurus project, but the practical value of such a thing is well recognised. Therefore, the program necessary to do this has been designed to be as easy as possible, not striving for the gain of computer and plotter time. The algorithm is based on an equidistant grid with limitation in the direction of the one axis. The difficulty was to find a free place for every point which has to be entered into the tree such that a line could be drawn not creating ambiguity concerning previously drawn lines. This has been solved by the selection of 32 points which could never produce confusion. Whenever there was a big cluster there has been an auxiliary routine to escape from that part of the area all filled up with points. This escape could be made checking the vertical lines at left and at right for the nearest free point. Obviously this drawing procedure could not represent the similarity by the geometric distance. But the measure of similarity stronger than the mean value has been made visible by double lines between the descriptors. The main groups have been drawn in separate pictures as well as all to-

gether, representing the whole minimal tree

## 5 CONCLUSIONS

\* The procedures described here have enabled the automatic construction of a pragmatic thesaurus for a given medium sized special library. This thesaurus will be a valuable retrieval aid for the same document collection from which it has been derived. Since the collection has been manually indexed, this thesaurus cannot be an indexing instrument except for erroneous misuse of key words.

The procedures for the construction allow for some manual steering of parameters and cut-off values. Besides they are also objective procedures which can be repeated whenever necessary, producing an exact mapping of all the meanings of all the documents within the library. The basic assumption that manual indexing can be a good starting point is assured through the fact, that it is easier for an expert to say this is a valuable book for that library and it should be assigned these descriptors, which can be read in the title or the table of contents or the headings, than to ask an expert or expert conference "Which are the key words of the area of knowledge which you are experts in" ?. The automatic indexing of documents can be expected in the future, but there is still a considerable amount of work to be done on both sides, linguistic and computer research. We, therefore, hope that automatic thesaurus construction is an aid for people looking into libraries to find the information they need.
