Abstract: This study focuses on the variation in activity-controlling factors during CO catalytic ignition over a CuO-CeO$_2$ catalyst. The activity for CO combustion follows the decreasing order of CuO-CeO$_2$ > CuO > CeO$_2$. Except for inactive CeO$_2$, increasing temperature induces CO ignition to achieve self-sustained combustion over CuO and CuO-CeO$_2$. However, CuO provides enough copper sites to adsorb CO, and abundant active lattice oxygen, thus obtaining a higher hot zone temperature

1   (208.3 °C) than that of CuO-CeO$_2$ (197.3 °C). Catalytic ignition triggers a kinetic

2   transition from the low-rate steady-state regime to a high-rate steady-state regime.

3   During the induction process, Raman, X-ray photoelectron spectroscopy (XPS), CO

4   temperature-programmed desorption (CO-TPD) and infrared (IR) spectroscopy results

5   suggested that CO is preferentially adsorbed on oxygen vacancies (Cu$^+$-[O$_v$]-Ce^{3+}) to

6   yield Cu$^+$-[C≡O]-Ce^{3+} complexes. Because of the self-poisoning of CO, the adsorbed

7   CO and traces of adsorbed oxygen react at a relative rate, which is entirely governed

8   by the kinetics on the CO-covered surface and the heat transport until the pre-ignition

9   regime. Nonetheless, the Cu$^+$-[C≡O]-Ce^{3+} complex is a major contributor to CO

10   ignition. The step-response runs and kinetic models testified that after ignition, a

11   kinetic phase transition occurs from a CO-covered surface to an active lattice

12   oxygen-covered surface. During CO self-sustained combustion, the rapid gas

13   diffusivity and mass transfer is beneficial for handling the low coverage of CO. The

14   active lattice oxygen of CuO takes part in CO oxidation.

16   behavior; Reaction mechanism

17

18   **1. Introduction**

19   　　As a key heterogeneous process, the catalytic oxidation of CO is essential not

20   only for practical applications such as automotive exhaust purification and fuel cells

21   but also as a model reaction to study the reaction mechanism and structure-reactivity

22   correlation of catalysts [1]. Our previous studies provided evidence that a high level

1 of CO can be ignited over a catalyst under a $CO/O_2/N_2$ atmosphere. When the

2 catalytic converter warms up to its ignition temperature, the sudden self-acceleration

3 of the surface rate leads to a thermochemical runaway, followed by a rapid transition

4 to self-sustained catalytic combustion [2]. The identified scenario can be applied in

5 the recovery of chemical heat in steelmaking off-gas systems. Because the CO/O_2

6 mixture tends to cause explosions, the off-gas yielded at steelmaking intermissions is

7 discharged into the atmosphere via CH_4 combustion-supporting flare burners. To

8 recover the chemical heat, self-sustained catalytic combustion can be employed since

9 a catalyst permits the flameless combustion of CO, which avoids the possibility of an

10 explosion. Such a strategy also enables CO burning outside the flammability limits

11 where the combustion can run efficiently at relatively low temperatures, thus

12 simultaneously reducing the formation of NO_x.

13 Copper-cerium bimetal catalysts have been accepted as an alternative to noble

14 metals due to their considerable activity and durability during CO combustion.

15 However, the relevant active sites over $CuO-CeO_2$ catalysts remain an unresolved

16 problem. Via acid/base pretreatment to remove dispersed CuO_x or $Cu-[O_v]-Ce$

17 structures, highly dispersed CuO_x clusters are commonly determined as the active

18 components, whereas ceria, with prominent redox behavior, tunes the dispersion and

19 chemical state of the copper nanoparticles [3]. It has been confirmed that the

20 $CuO-CeO_2$ exhibits activity via active sites: dispersed CuO_x interacting with ceria >

21 less interacting CuO_x > bulk CuO, and has good resistance towards CO_2 and H_2O

22 [4-6]. The dispersed CuO_x and adjacent oxygen vacancies contribute to the activity,

where the Cu^+ are adsorption sites for the chemisorption/activation of CO molecules and the surface reactive oxygen participates directly in the whole CO oxidation process [7,8]. Strongly bound Cu-[O_v]-Ce, which is located at the copper-cerium interface, promotes catalytic activity by providing the sites for CO adsorption [9]. This hypothesis is based on intensive experimental studies on direct (CuO/CeO_2)-inverse (CeO_2/CuO) systems. The interfacial synergy often manifests in unique geometrical, chemical or electronic properties that are complex, even for simple reaction systems. Hence, the experimental verification of the roles played by the copper and cerium ions during CO oxidation requires a specific analysis that is sensitive enough to determine the active states under different reaction conditions.

The catalytic ignition of CO is a complex process that includes kinetics and heat generation since the heat produced is governed by the reaction rate, which in turn is determined by the reaction kinetics. Correspondingly, a transition from low-reactivity steady state to high-reactivity steady state can be observed due to heat transfer limitation, which exhibits different reaction processes. Our previous papers reported that the CO self-combustion passed 200-hour stability test and had the excellent resistance of water [10, 11]. Based on the $CuO-CeO_2$ catalysts, however, current studies of CO oxidation have focused on the reaction mechanism at a low-reactivity state, considering the potential application needs. As an interdisciplinary and promising research topic, this work focuses on the two-step transitions during CO catalytic ignition, and aims to bridge the missing gap between the catalyst and combustion researchers in understanding the fundamental reaction mechanism of CO

1   oxidation over the CuO-CeO$_2$ catalyst. Specifically, using step-response runs, in situ

2   IR and phase-transition kinetic models etc., this work deepens the understanding of

3   reaction mechanism that CO adsorbed at oxygen vacancies to form Cu$^+$-[C≡O]-Ce^{3+}

4   species is a major contributor to CO ignition in induction process. More importantly,

5   we revealed that the CuO rather than CeO$_2$ provides lattice oxygen to participate in

6   the CO self-sustaining catalytic combustion for the first time. This study contributes

7   to a deeper understanding of the reaction mechanism of CO catalytic combustion,

8   expanding from the intrinsic reaction kinetics stage to the self-sustaining catalytic

9   combustion stage, and proposes a CO self-combustion technology to treat the

10   steelmaking off-gas system.

11 **2. Experimental specifications**

12 *2.1. Synthesis of the catalysts*

13   Cu(NO$_3$)$_2$·3H$_2$O and Ce(NO$_3$)$_3$·6H$_2$O were combined in a 1:1 molar ratio and

14   were dissolved fully in 140 mL of ethanol at 80 °C. As a pore former, an oxalic acid

15   solution (0.24 mol/L) was added quickly to the aforementioned nitrate solution with

16   stirring to fully dissolve and evaporate ethanol until a gel was formed at 80 °C. After

17   aging at room temperature for 48 h, the gel was dried at 105 °C for 12 h and then

18   calcined in air at 550 °C for 2 h. The catalyst obtained was labeled CuO-CeO$_2$. To

19   compare the influence of the copper and cerium oxides on CO oxidation, the catalysts,

20   labeled CuO and CeO$_2$, respectively, were prepared using the same procedure. The

21   Brunauer-Emmett-Teller (BET) surface areas for CuO, CeO$_2$ and CuO-CeO$_2$ are 4.3,

22   66.4 and 44.6 m^2/g, respectively.

2.2. Characterization

X-ray powder diffraction (XRD) patterns were collected on an XD-3-automatic diffractometer (PERSEE) equipped with nickel-filtered Cu Kα radiation. Raman measurements were carried out using a HORIBA LabRAM HR Evolution spectrometer at an excitation laser wavelength of 488 nm. X-ray photoelectron spectroscopy (XPS) was performed using a Kratos Axis Ultra DLD spectrometer. Temperature-programmed reduction (H_2-TPR) was carried out on a TP5080B chemisorption analyzer. Each sample (100 mg) was reduced in a flow of a 5% H_2/He mixture (50 mL/min), with the temperature increasing from room temperature to 700 °C at a heating rate of 10 °C/min. The temperature-programmed desorption of O_2 and CO (O_2- and CO-TPD-MS) were performed via the same TP5080B instrument, where 5% O_2/He and 5% CO/He mixtures were employed, respectively. O_2 or CO was adsorbed at 50 °C for 30 min and then was exposed to He. After the baseline was stable, the reactor was heated at a rate of 10 °C/min until reaching 700 °C. TPD spectra were taken with a quadrupole mass spectrometer (Pfeiffer PrismaPlus). In situ IR spectra were recorded on the Bruker Tensor 27 instrument coupled with a self-designed magnetically driven transmission cell, where approximately 20 mg of catalysts was pressed into a self-supporting wafer. Because the optical path can be switched between the gas phase and catalyst by driving a quartz holder outside of the cell, the gas phase signals can be subtracted from the spectra at each tested temperature (Fig. S1 in the supporting information). Prior to recording the spectra, the self-supporting sample disk was pretreated in a N_2 flow at 500 °C.

*2.3. CO self-sustained catalytic combustion*

2   The catalytic activity was evaluated in a flow-type apparatus designed for

3 continuous operation. A powdered catalyst (weight 200 mg, particle size 0.15 mm)

4 was packed into a quartz tube reactor with an inner diameter of 4 mm. The flow rates

5 of CO, O_2 and N_2 (0.2 L/min) were controlled by mass flow controllers with a

6 full-scale measurement accuracy of ±1%. Temperature-programmed catalytic ignition

7 of CO was performed at a heating rate of 5 °C/min, and two K-type thermocouples

8 (0.5 mm thick) were used. The first thermocouple was located in front of the catalyst

9 bed to control the oven temperature along the flow; the second thermocouple was

10 inserted into the center of the catalyst bed to continuously monitor the temperature.

11 Effluent gas was analyzed using an online multicomponent analyzer (QGS-08C for

12 CO/CO_2 and OGS-10T for O_2, Maihak).

13 **3. Results and discussion**

14 *3.1. Structural characterization*

15   Fig. 1a shows the XRD patterns of the CuO, CeO_2 and CuO-CeO_2 catalysts. For

16 CuO, the two sharp diffraction peaks at 35.6° and 38.8° are associated with (−111)

17 and (111) planes in the monoclinic crystal structure (JCPDS 45-0937). Typical

18 diffraction peaks of CeO_2 are observed at 28.6°, 33.1°, 47.5° and 56.4°, which

19 correspond to the (111), (200), (220) and (311) planes, respectively with fluorite

20 structures (JCPDS 34-0394). Similar diffraction peaks can be observed in the

21 CuO-CeO_2 catalyst, with a lower intensity than that of CeO_2. The weak diffraction

22 peaks of CuO indicate that either a $CuCeO_x$ solid solution is formed or dispersed CuO

1   clusters anchor onto the ceria surface. The Raman spectrum of CuO (Fig. 1b) also

2   reveals a monoclinic cupric oxide phase, according to the A_{1g}, B_{1g} and B_{2g} modes

3   located at 291, 326, and 629 cm^{-1}, respectively, but the peak at 214 cm^{-1} demonstrates

4   the existence of Cu_2O [12]. The spectrum of CuO-CeO_2 catalysts shows a main band

5   at approximately 443 cm^{-1}, which is related to the F_{2g} symmetry vibration mode of the

6   cubic fluorite structure of CeO_2. Notably, the position of the F_{2g} band deviates from

7   that of pure CeO_2 (460 cm^{-1}) since the incorporated copper ions induce a lattice

8   distortion of CeO_2, which influences the polarizability of the symmetrical stretching

9   mode of the [Ce-O_8] vibrational unit [13]. The formation of surface oxygen vacancies

10   is confirmed by two weak peaks at approximately 273 and 590 cm^{-1}. According to the

11   ratio of the two peak areas at 590 and 443 cm^{-1} (A_{590}/A_{443}), the concentration of

12   surface vacancies is analyzed semiquantitatively for these catalysts, following the

13   order of CuO-CeO_2 (0.36) > CeO_2 (0.02) > CuO (0.00).

15   **Fig. 1.** XRD patterns (a) and Raman spectra (b) of the catalysts.

16   The chemical states and surface compositions of the catalysts are investigated by

17   XPS, detecting under the vacuum pressure (1×10^{-7} Torr) rather than ambient pressure

18   is employed to obtain valence states during heating process at the H_2 atmosphere [14].

1 Before the test, the samples were vacuumized to remove the moisture until the

2 vacuum reached 5.0×10^{-9} mbar in the analyzer chamber. For the binding energy of Cu

3 2p (Fig. 2a), the presence of the shake-up peak at 938-947 eV and the lower Cu $2p_{3/2}$

4 binding energy appearing at 932.9 eV are two major XPS characteristics of Cu^{2+} and

5 Cu^+, clearly suggesting the Cu^{2+}/Cu^+ redox pair exists in both CuO and CuO-CeO$_2$

6 catalysts. Fig. 2b shows the deconvoluted spectra of Ce 3d, which is decomposed into

7 four pairs of spin-orbital doublets labeled as v and u, corresponding to $3d_{3/2}$ and $3d_{5/2}$,

8 respectively. The peaks labeled as v, v_2 and v_3 correspond to the $3d_{3/2}$ level of Ce^{4+},

9 while the peaks tagged as u, u_2 and u_3 are assigned to the $3d_{5/2}$ of the Ce^{4+}. The couple

10 v_1-u_1 is considered the fingerprint of Ce^{3+} species that favors the formation of oxygen

11 vacancies on the catalyst surface. The surface Cu and Ce components, determined by

12 integrating the areas of Cu 2p and Ce 3d peaks, as shown in Table 1. The Cu^+/Cu^{2+}

13 was calculated by the ratio of relative area of Cu^+ peak to the Cu^{2+} peak. The

14 Ce^{3+}/Ce^{4+} was obtained by the ratio of the total area of the Ce^{3+} peaks to the Ce^{4+}

15 region. According to the surface compositions of the copper and cerium species listed

16 in Table 1, the Cu^+/Cu^{2+} and Ce^{3+}/Ce^{4+} ratios of CuO-CeO$_2$ are higher than those of

17 bulk CuO and CeO$_2$, respectively, indicating that these Cu^+ species are produced on

18 the Cu^+-[O$_v$]-Ce^{3+} interface ([O$_v$]= surface oxygen vacancy) via Ce^{4+} reduction to

19 form Ce^{3+}.
Fig. 2. XPS narrow spectra of Cu 2p (a) and Ce 3d (b) (Ce^{3+}: v_1 and u_1, Ce^{4+}: v, v_2, v_3, u, u_2 and u_3) over the catalysts.

Table 1 Surface compositions and H$_2$ consumption of the catalysts

| Catalyst	Surface atomic ratio		H$_2$ consumption
	Cu$^+$/Cu^{2+}	Ce^{3+}/Ce^{4+}	(mmol/g)
CuO	0.46	/	7.28
CeO$_2$	/	0.21	2.81
CuO-CeO$_2$	1.25	0.35	0.46

3.2. Temperature-programmed analysis of the catalysts

The redox behavior of the catalysts was investigated by H$_2$-TPR. A faint reduction of pure CeO$_2$ is observed at temperatures > 280 °C (Fig. 3a), arising from the poor redox properties of the ceria species. The reduction of the CuO catalyst initiates at surficially dispersed CuO$_x$ clusters centered at 230 °C (β peak), but a broad peak at 319 °C (γ peak) dominates, which corresponds to the reduction of bulk CuO. The H$_2$-TPR profile of the CuO-CeO$_2$ catalyst is characterized by three partially overlapping peaks at 163 (α peak), 196 (β peak) and 235 °C (γ peak), which are attributed to the reduction of copper species in the CuCeO$_x$ solid solution, dispersed CuO$_x$ clusters and crystallized CuO, respectively. It is evident that the synergistic effect of the interaction between CuO and CeO$_2$ results in lower reduction

11

1   temperatures compared to those of the pure materials. Although the H_2 consumption

2   of CuO-CeO_2 (2.81 mmol·g^{-1}, Table 1) is lower than that of CuO (7.28 mmol·g^{-1}), the

3   catalytic activity test, which will be discussed in the subsequent section, confirms that

4   the redox properties of the catalysts decrease mainly according to their reduction

5   temperature rather than H_2 consumption, following the sequence CuO-CeO_2 > CuO >

6   CeO_2.

7   O_2-TPD is used to investigate the mobility of oxygen species in all catalysts. As

8   shown in Fig. 3b, all the catalysts display desorption peaks centered at 59 °C,

9   assigned to the desorption of physisorbed oxygen (O_{ads}). Clearly, the CuO-CeO_2

10   exhibits a stronger O_{ads} peak, followed by CuO and then CeO_2. These results suggest

11   that the abundant active oxygen connects with oxygen vacancies (Cu^+-$[O_v]$-Ce^{3+}) that

12   are easily released from the CuO-CeO_2 surface to participate in the oxidation reaction.

13   Pure CuO is a nonstoichiometric oxide, as confirmed by XPS, where the cation

14   deficiency formed tends to adsorb oxygen more easily than CeO_2. Therefore, the

15   contribution of vacancies (Ce^{4+}-$[O_v]$-Ce^{3+}) over pure CeO_2 to oxygen adsorption is

16   quite limited. The desorption peak of CuO at 909 °C corresponds to lattice oxygen

17   (O_{lat}) escaping from copper cations. Because CeO_2 is thermally stable, it has no lattice

18   oxygen desorption. The synergistic effect between copper and cerium leads to a

19   shifting of the O_{lat} peak to a higher temperature (928 °C) and the intensity weakening

20   of the CuO-CeO_2. Compared with CeO_2 and CuO-CeO_2, CuO exhibits the high

21   mobility of O_{lat}, which might accelerate the oxygen transfer from the bulk to the

22   surface, favoring a reaction at high temperatures.

1   The CO-TPD results over the catalysts are shown in Fig. 3c. In a comparison of

2 the three catalysts, the $CuO-CeO_2$ catalyst reveals that CO desorbed at the lowest

3 temperature with highest intensity, followed by CuO and lastly CeO_2. All CO

4 molecules adsorbed on the catalyst surface desorbed as CO_2 during the heating cycle

5 with no remaining CO signal detected. This finding indicates that lattice oxygen is

6 involved in CO oxidation and that the amount of desorbed CO_2 reveals the quantity of

7 the active surface lattice oxygen on the catalyst. The O_2-TPD experiments show that

8 the CuO and $CuO-CeO_2$ catalyst gives the O_{lat} desorption signal at a temperature >

9 900 °C, suggesting that the thermal depletion of O_{lat} is difficult. However, it should be

10 noted that the depletion of O_{lat} can be much easier when a strong reducing agent (i.e.,

11 CO and H_2 shown in H_2-TPR) is present, particularly at the metal-support interface

12 [15]. The involvement of O_{lat} in the reaction will be further discussed based on the

13 kinetic results in the subsequent section.

14
15   **Fig. 3.** H_2-TPR-TCD (a), O_2-TPD-MS (b) and CO-TPD-MS (c) profiles of the catalysts.

16 *3.3. Temperature-programmed catalytic ignition of CO*

17   The catalytic combustor can exhibit a steady-state multiplicity typical of highly

18 exothermic reactions, where increasing the temperature induces the transition of CO

1 combustion from the step kinetically controlled to that controlled by diffusion. As

2 shown in Fig. 4, the CeO_2 catalyst is inactive in order to achieve self-sustained

3 combustion. The experimental run is performed by first raising the furnace

4 temperature from a low conversion condition up to an ignited condition (heating

5 process). However, the temperature was subsequently decreased, leading to the

6 progressive blow out of the reaction (cooling process). For the CuO and $CuO\text{-}CeO_2$

7 catalysts, the rate increases slowly as the temperature increases and then much more

8 steeply at the light-off stage. Once ignition occurs, complete CO conversion can be

9 maintained even when the controlled temperature falls to room temperature. The

10 $CuO\text{-}CeO_2$ catalyst exhibits the higher low-temperature activity than that of CuO

11 according to the ignition temperatures of 72 and 117 °C (defined as the temperature at

12 30% CO conversion). From the temperature profiles during CO self-sustained

13 combustion (Insert in Fig. 4), however, CuO provides enough copper sites to adsorb

14 CO and thus obtains a higher hot zone temperature (208.3 °C) than does $CuO\text{-}CeO_2$

15 (197.3 °C).
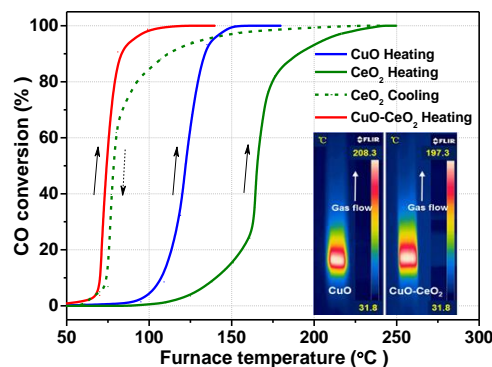

16

17 **Fig. 4.** Ignition curves of CO and the temperature fields in the reactor under a 5% CO+10% O_2/N_2

18 atmosphere.

19 Using the best catalyst, i.e., $CuO\text{-}CeO_2$, the transient behavior of CO ignition

14

1   was carried out under 1%-7%CO+5%O$_2$/N$_2$ conditions. Fig. 5 shows that CO

2   self-sustained combustion can be achieved at CO concentrations ≥2%. Notably, from

3   a partially enlarged view, the CO conversion rate decreases during the induction

4   process (CO conversion<10%) when the CO concentration increases from 1% to 5%.

5   Such a slow reaction rate with high CO partial pressure is caused by the competitive

6   coadsorption between CO and oxygen, where the kinetic transition occurs from an

7   oxygen-covered surface to a CO-poisoned surface steady state that prevents the

8   dissociation of O$_2$ [16]. This dilemma does not change significantly until it has

9   entered the light-off stage with temperature. Once the accumulation of heat promotes

10   ignition, the steady-state coverage of CO is diminished to the degree where the

11   dissociation of O$_2$ can efficiently occur. Then, the adsorbed CO molecules react

12   rapidly with oxygen to form CO$_2$. The light-off process has a high gas diffusivity D_v

13    $\propto T^{1.81}$ and high mass transfer coefficient $K_s=(D_v\cdot S)^{1/2}$ (*T* denotes the temperature and

14   *S* denotes the turnover frequency) [17], which leads to the retaliatory rise of the

15   reaction rate (high slope, Fig. 5) with a CO partial pressure.
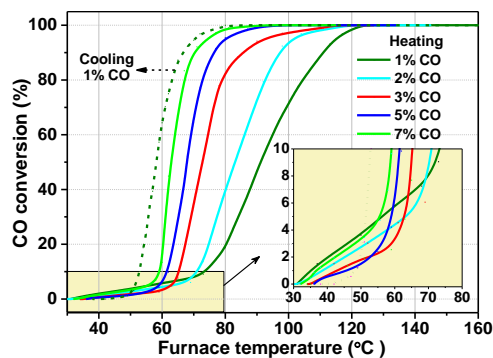

16

17   **Fig. 5.** Ignition curves of CO over the CuO-CeO$_2$ catalysts under a 1%-7%CO+5%O$_2$/N$_2$

18   atmosphere.

19   *3.4. In situ infrared spectroscopy analysis*

1   To further measure the intermediates of CO oxidation, in situ IR spectroscopy is

2   used to monitor the adsorption and oxidation behavior of CO over the catalysts (Fig.

3   6). Gaseous CO is coordinated to the copper sites to form [Cu$^+$-CO] carbonyls on the

4   CuO catalyst. Because the d-orbitals of the Cu$^+$ cations have an outer-shell electron

5   distribution of 3d10, the synergy between the σ bonds and π-back-bonding is

6   responsible for the catalyst stability [18]. Under a 1%CO+1%O$_2$/N$_2$ atmosphere, an

7   increasing temperature leads to a decrease in the [Cu$^+$-CO] band, followed by the

8   formation of CO$_2$. Here, the physically adsorbed CO$_2$ is observed in the ground

9   vibrational state (2382 and 2347 cm^{-1}, P and R branches, respectively) and the

10   transitions between the vibrationally excited states of the antisymmetric stretching

11   mode (2310 cm^{-1}) [19]. Except for weak carbonyls formed on the CeO$_2$, CO tends to

12   be chemisorbed at cerium sites to produce bidentate (1540 cm^{-1}) and monodentate

13   carbonates (1449 and 1346 cm^{-1}), which decrease slowly with temperature, and thus,

14   it is difficult to achieve CO$_2$ conversion [20]. A clear redshift of the carbonyl peak

15   (2113 cm^{-1}) with a high intensity and a blueshift of carbonates are observed for

16   CuO-CeO$_2$. The redshift might be induced by CO adsorption onto the oxygen

17   vacancies at the interface between the copper and cerium oxides to form Cu$^+$-[C≡

18   O]-Ce^{3+} species. Evidently, both π-back-bonding enhancement and σ-bond weakening

19   determine this IR signal shifting, which strengthens the Cu-C bonds but decreases the

20   C-O bond order, thus favoring CO oxidation. Therefore, under a 5%CO+10%O$_2$/N$_2$

21   atmosphere, Cu$^+$-[C≡O]-Ce^{3+} is a major contributor to CO ignition compared with

22   the carbonates and immediately reacts with active oxygen to produce CO$_2$ at

1 temperatures >100 °C. The IR peak intensity of CuO-CeO$_2$ catalyst under the

2 1%CO+1%O$_2$/N$_2$ and 5%CO+10%O$_2$/N$_2$ was calculated in Fig. S5, suggesting that

3 the CO-poisoned process occurs at low-temperature (20-100°C) for 5%CO, in

4 keeping with the kinetically limited regime data in Fig.5 although existing the

5 difference reaction conditions between IR experiments and activity tests.
7 **Fig. 6.** In situ infrared spectroscopy analysis of CuO (a), CeO$_2$ (b) and CuO-CeO$_2$ (c and d) under

8 1%CO+1%O$_2$/N$_2$ and 5%CO+10%O$_2$/N$_2$ atmospheres, and the curves are listed by 20 ºC intervals.

9 *3.5. Kinetic model of CO catalytic ignition*

10 *3.5.1 Steady state transformation induced by step-response runs*

11 The catalytic ignition process represents a convolution of the reaction kinetics

12 and heat generation since the heat produced is governed by the reaction rate that in

13 turn is determined by the reaction kinetics. However, the temperature triggers a

14 kinetic transition from a low-rate steady-state regime to a high-rate steady-state

15 regime, which should be well distinguished before the kinetic model of the CO

16 catalytic ignition is established. During the induction process, the reactivity of the

17 adsorbed [Cu$^+$-(C≡O)-Ce^{3+}] species with adsorbed oxygen species (O$_{ads}$) was

18 investigated by transient response runs at 60 °C, as presented in the insert of Fig. 7.

19 After CO saturation in 1 h, 5%CO/He (100 mL/min) was removed from the feed flow,

while the catalyst was continuously flushed with helium until the baseline was stable.

A switch to He→4%O_2/He permitted the oxidation of the Cu^+-[C≡O]-Ce^{3+} species

for a duration of O_2, where the molar fraction of CO_2 increased and passed through a

maximum. No CO signal was detected during the isothermal oxidation process,

indicating that CO adsorption to form Cu^+-[C≡O]-Ce^{3+} dominated over O_2

adsorption.

It has been previously shown that there is a large amount of lattice oxygen (O_{lat})

on the surface of the CuO phase that contributes to the self-sustained catalytic

combustion of CO, which was confirmed by the transient response run in Fig. 7. In

Part A, 1%CO+1.5%O_2/He was fed to the reactor at 300 °C, where the reaction

involving sufficient O_2 and CO led to 100% CO conversion. The CO_2 signal started at

a sharp step-response and then decreased with time until a steady state was achieved.

Then, after purging in helium (Part B) to remove the gas phase, a 1%CO/He mixture

was introduced into the reactor (Part C). Following another step-response of the CO_2

signal, which deceased with time, the CO outlet concentration showed a dead time,

i.e., a period during which the fed CO reacted with O_{lat} of the surface CuO, then it

increased with time, approaching the inlet value of 1% until all the O_{lat} was
completely consumed.

Fig. 7. Isothermal oxidation of CO over the CuO-CeO$_2$ catalyst.

3.5.2 Determination of the kinetic parameters

Based on the CuO-CeO$_2$ catalyst, the kinetics of CO oxidation during the induction process was simulated according to the reaction involving adsorbed CO and O$_2$ molecules under a 5%CO+10%O$_2$/N$_2$ (P_{CO}=5050 Pa, P_{O2}=10100 Pa) atmosphere. Considering CO adsorption as the rate-determining step of the oxidation, the CO adsorption, desorption and reaction steps are assumed at equilibrium. Hence, the kinetic relationships during the induction process can be written (M_i) [21] as

$$k_{ac}P_c(1 - \theta_c) - k_{dc}\theta_c - k_{r1}\theta_{oa}\theta_c = 0 \tag{1}$$

where θ_c and θ_{oa} denote the CO and O coverage arising from adsorbed CO and O$_2$, respectively; and P_c, k_{ac}, k_{dc} and k_{r1} are the partial pressures of CO, the rate constants of CO adsorption and desorption, and the CO+O surface reaction during the induction process, respectively. The exact solution of Eq. 1 is

$$\theta_c = \frac{K_c P_c}{1 + K_c P_c + (k_{r1}/k_{dc})\theta_{oa}} \tag{2}$$

$K_c=k_{ac}/k_{dc}$ is the adsorption coefficient of CO. Because the surface is primarily covered by CO during the induction process and a low reaction rate is observed at relatively high CO pressure, the O coverage (θ_{oa}) according to Langmuir's model [22] can be approximated as

19

$$\theta_{oa} = \frac{(K_{oa}P_{oa})^{0.5}}{1+(K_{oa}P_{oa})^{0.5}} \approx (K_{oa}P_{oa})^{0.5} \tag{3}$$

1

2 where K_{oa} is the adsorption coefficient of O_2. Then, the reaction rate r_1 is calculated as

3 follows:

4
$$r_1 = k_{r1}\theta_c\theta_{oa} \tag{4}$$

5   The catalytic ignition of CO reflects the switching from a low-reactivity metallic

6 surface to a high-reactivity oxide surface; thus, the surface is mainly covered by

7 oxygen during the self-sustained combustion stage. Considering the dissociation of

8 oxygen, the rate equations during self-sustained combustion can be established based

9 on the conservation of adsorbed CO and O_{lat} species, (M_s):

10
$$K_cP_c(1-\theta_c) - \theta_c - \left(\frac{k_{r2}}{k_{dc}}\right)\theta_c\theta_{ol} = 0 \tag{5}$$

11
$$K_{ol}P_o(1-\theta_{ol})^2 - \theta_{ol}^2 - (k_{r2}/k_{dol})\theta_{ol}\theta_c = 0 \tag{6}$$

12 where θ_{ol} and k_{r2} denote the O coverage and the rate constants during CO

13 self-sustained combustion, respectively. The relevant kinetic parameters mentioned

14 above are determined in the supplementary information, with the description of

15 kinetic models, as illustrated in Fig. 8. Due to the self-poisoning of CO on the surface,

16 the induction step is depicted as a slow process, and both adsorbed CO and adsorbed

17 O_2 participate in the oxidation reaction. The θ_c decreases at a relatively slow rate to

18 0.98 until an ignition temperature of 72 °C (M_i), followed by the rate of CO oxidation

19 r_1 increasing to 1.1×10^4 s^{-1}. The catalytic ignition of CO leads to an abrupt decrease in

20 θ_c from 0.98 at 72 °C (M_i) to 0.006 at 197 °C (M_s) (see Section 3.3), which is

21 associated with a high CO conversion. The rate of CO oxidation r_2 (7.4×10^5 s^{-1}, M_s) in

22 the self-sustained combustion process is much higher than that (r_1) during the

1   induction process (1.1×10^4 s^{-1}, M_i). It is inevitable that the partially active O_{lat} species

2   of CuO contribute to CO oxidation, corresponding to θ_o decreasing to 0.44 at 197 °C.

3   However, the created oxygen vacancies are immediately replenished by the

4   dissociation of gaseous O_2 on the catalyst surface. According to the changes of bed

5   temperatures, the ignition curve of CuO-CeO$_2$ catalyst is well reproduced by the

6   kinetic model and shown in Fig.S6. Hence detailed reaction mechanism are as follows:

7   CO is preferentially adsorbed on Cu$^+$-[O$_v$]-Ce^{3+} to yield carbonyls in induction

8   process, which interact with adsorbed oxygen at vacancies to form CO$_2$; CO adsorbed

9   and reacted on cerium sites (carbonates) provides faint contribution to CO ignition.

10 Entering the ignition process, the fast heat/mass transport leads to the carbonyls

11 reacted with lattice oxygen of CuO, followed by a thermochemical runaway.
13 **Fig. 8.** Coverage of adsorbed CO and O as well as rates of CO oxidation in the induction and

14 self-sustained combustion processes.

4. Conclusion

16 CuO, CeO$_2$ and CuO-CeO$_2$ catalysts were prepared to investigate the

17 contribution of active sites over the CuO-CeO$_2$ to CO ignition. The activity test

18 demonstrated that CeO$_2$ is inactive for the ignition of CO. The CuO-CeO$_2$ catalyst

19 ignition temperature of 72 °C exhibits a higher low-temperature activity than that of

21

CuO corresponding to the ignition temperature of 117 °C. However, CuO provided enough copper sites to adsorb CO and abundant active lattice oxygen, and thus showed a higher hot zone temperature than that of $CuO\text{-}CeO_2$. During the induction process, the oxygen vacancies ($Cu^+\text{-}[O_v]\text{-}Ce^{3+}$) were analyzed by Raman, XPS, CO-TPD and in situ IR spectroscopy techniques and were the adsorption sites for the adsorption and activation of CO molecules. CO adsorption on the $Cu^+\text{-}[O_v]\text{-}Ce^{3+}$ sites dominated over O_2 adsorption, i.e., self-poisoning of CO. The formed $Cu^+\text{-}[C\equiv O]\text{-}Ce^{3+}$ species is a major contributor to CO ignition but results in a relative rate until entering the light-off stage as a function of temperature. Based on step-response runs and kinetic models, the kinetic phase transition, from a Cu^+ surface mainly covered by CO to that mainly covered by active lattice oxygen, occurs after the catalytic ignition, where the rate of CO oxidation during the self-sustained combustion process is much higher than that during the induction process. Although partially active lattice oxygen of CuO participates in CO oxidation, the oxygen vacancies created are immediately replenished by the dissociation of gaseous O_2 on the catalyst surface.
