## Abstract

Carbonates are the major hosts of carbon on Earth's surface and their fate during subduction needs to be known in order to understand the deep carbon cycle. Magnesite ( $\text{MgCO}_3$ ) is thought to be an important phase participating in deep Earth processes, but its phase stability is still a matter of debate for the conditions prevalent in the lowest part of the mantle and at the core mantle boundary. Here, we have studied the phase relations and stabilities of  $\text{MgCO}_3$ , at these  $P, T$ -conditions using Raman spectroscopy at high pressures ( $\sim 148$  GPa) and after heating to high temperatures ( $\sim 3600$  K) in laser-heated diamond anvil cell experiments (LH-DAC). The experimental Raman experiments were supplemented by X-ray powder diffraction data, obtained at a pressure of 110 GPa. Density functional theory-based model calculations were used to compute Raman spectra for several  $\text{MgCO}_3$  high pressure polymorphs, thus allowing an unambiguous assignment of Raman modes. By combining the experimental observations with the DFT-results, we constrain the phase stability field of  $\text{MgCO}_3$  (magnesite) with respect to the high pressure polymorph,  $\text{MgCO}_3$ -II. We further confirm that Fe-free  $\text{MgCO}_3$ -II is a tetracarbonate with monoclinic symmetry (space group  $C2/m$ ), which is stable over the entire  $P, T$ -range of the Earth's lowermost mantle geotherm.

## 1 I. INTRODUCTION

2 The Earth's mantle is believed to experience a carbon influx on the order of teragrams per year,  
3 due to the subduction of oceanic lithosphere [1, 2]. Carbonate minerals are considered to con-  
4 stitute the major carbon source during subduction processes [2–6]. In the mantle, decomposition  
5 reactions of carbonates and reactions with silicates are thought to lead to the formation of other  
6 carbon containing phases [7–10]. As silicates can only incorporate very minor amounts of carbon  
7 at mantle conditions [11, 12], the most prevalent carbon bearing phases are believed to be diamond  
8 [13], high  $P, T$  phases of  $\text{CO}_2$  [14], or metal carbides [15, 16]. However, carbonates may survive  
9 in the Earth's mantle in cold oxidized subducting slabs [17, 18] some of which might penetrate  
10 into the lowermost mantle [19]. This model is supported by the presence of carbonate inclusions  
11 ( $\text{CaCO}_3$ ,  $\text{MgCO}_3$ ,  $\text{CaMg}(\text{CO}_3)_2$ ) in mantle xenoliths and in super deep diamonds [20–25].

12 Magnesite ( $\text{MgCO}_3$ ) is thought to be stable under  $P, T$ -conditions of the Earth's mantle [9,  
13 26, 27]. While other carbonates undergo several phase transitions (e.g. calcite ( $\text{CaCO}_3$ )) [28],  
14 or decompose at  $P, T$ -conditions of the Earth's mantle (e.g. dolomite ( $\text{CaMg}(\text{CO}_3)_2$ ) and siderite

\* binck@kristall.uni-frankfurt.de

15 (FeCO<sub>3</sub>) [29, 30], magnesite remains stable up to at least 80 GPa and 3000 K [26, 31, 32]. Stud-  
16 ies of reactions of MgCO<sub>3</sub> with SiO<sub>2</sub> implied that high pressure, high temperature polymorphs  
17 of MgCO<sub>3</sub> might coexist with silicates in super cold slabs in the lower mantle [9]. Model cal-  
18 culations of reactions of MgCO<sub>3</sub>/CaCO<sub>3</sub> with MgO/MgSiO<sub>3</sub> under  $P, T$ -conditions of the Earth's  
19 lower mantle imply the possible existence of oxidized carbon in the form of MgCO<sub>3</sub> in the absence  
20 of iron [33, 34].

21 Based on in-situ powder X-ray diffraction, Isshiki *et al.* [26] showed that magnesite ( $R\bar{3}c$ ,  
22  $Z = 6$ ) undergoes a phase transition to 'magnesite-II' at deep lower mantle conditions ( $>115$  GPa  
23 and 2200 K). Shortly after these findings, DFT-based predictions reported the possibility of the  
24 existence of very high pressure (e.g., at pressures  $>80$  GPa) carbonate structures that are charac-  
25 terized by  $sp^3$ -hybridized bonding environments within CO<sub>4</sub><sup>4-</sup> tetrahedrons instead of triangular  
26  $sp^2$ -hybridized CO<sub>3</sub><sup>3-</sup> groups [35–39]. Within the last decade, the existence of so-called 'tetracar-  
27 bonates' has been confirmed by several experimental studies [30, 40–45].

28 Several theoretical structures have been reported for  $sp^3$ -MgCO<sub>3</sub> polymorphs [35, 38, 39].  
29 Combined results from DFT and X-ray powder diffraction suggested a MgCO<sub>3</sub> structure with  
30 space group  $C2/m$  and  $Z = 12$  formula units to be the most stable phase at pressures between  
31 82 – 138.1 GPa [38]. However, a comparison of powder X-ray diffraction data of the  $C2/m$ -phase  
32 with powder patterns published by Isshiki *et al.* [26] gave an unsatisfactory match. Further exper-  
33 imental evidence for the formation of the  $C2/m$ -phase around  $\sim 82$  GPa was given by Boulard  
34 *et al.* [40] and Maeda *et al.* [9]. However, their data analyses relied on Le Bail fits only. While  
35 X-ray powder diffraction data were fitted with the  $C2/m$ -phase between 85–152 GPa in the study  
36 by Maeda *et al.* [9], a lower symmetric structure with space group  $P2_1/c$  was proposed to be better  
37 suited for fitting X-ray diffraction patterns by Boulard *et al.* [40] at 82 GPa.

38 Using a sample with an initial composition of Fe<sub>0.15</sub>Mg<sub>0.85</sub>CO<sub>3</sub> at ambient conditions, Chariton  
39 *et al.* [46] have been able to solve the crystal structure of Fe<sub>0.4</sub>Mg<sub>2.6</sub>C<sub>3</sub>O<sub>9</sub> at 98 GPa and after  
40 heating to 2500 K from single-crystal data. This structure was shown to be identical to the  $C2/m$ -  
41 phase proposed by Oganov *et al.* [38].

42 While the existence of the  $C2/m$ -phase seems now to be established for pressures  $<100$  GPa  
43 and temperatures  $<2500$  K [46], significant gaps and inconsistencies remain in our understanding  
44 of the high  $P, T$  behaviour of Fe-free MgCO<sub>3</sub> [9, 26, 38, 39]. Currently, all experimental data  
45 above 100 GPa rely on poorly constrained indexing of X-ray powder diffraction patterns [9, 26,  
46 38], while theoretical calculations suggest several possible low energy structures [35, 38, 39]. The

47 strength of vibrational spectroscopy for the detection of high pressure, high temperature phases in  
48 the diamond anvil cell has recently been exploited for high pressure studies on different carbonates  
49 [28, 29, 42, 45, 47–49]. Raman spectroscopy is a very sensitive method, which may provide  
50 additional structural information for the particular high pressure, high temperature polymorphs of  
51  $\text{MgCO}_3$  thus complementing previous X-ray diffraction studies. However, studies that have been  
52 employing Raman spectroscopy on  $\text{MgCO}_3$  are limited to pressures  $<55$  GPa [32, 47, 50, 51].

53 In this study, we have investigated the  $\text{MgCO}_3$ -system in the entire pressure and temperature  
54 range reaching to the uppermost part of the Earth's outer core corresponding to pressures up to  
55  $\sim 148$  GPa and temperatures up to  $\sim 3600$  K. We combined Raman spectroscopy in the laser heated  
56 diamond anvil cell with DFT-based model calculations. Supplementary X-ray powder diffraction  
57 data were obtained at high pressures, which support our observations further.

## 58 II. METHODS

59 Syntheses, preparations of experiments, sample characterizations at ambient conditions, as well  
60 as Raman spectroscopy in the LH-DAC have been carried out at the Institute of Geosciences at  
61 the Goethe Universität Frankfurt, Germany. The high pressure X-ray diffraction experiments have  
62 been carried out at P02.2 at PETRA III (DESY) in Hamburg, Germany.

### 63 A. Synthesis

64 Single crystals of magnesite were synthesized according to the method described by Ni *et al.*  
65 [52]. All chemicals (magnesium acetate tetrahydrate, hexamethylenetetramine and sodium sul-  
66 fate) were analytical grade reagents purchased from Merck KGaA (Darmstadt) and used as re-  
67 ceived without further purification. 3 mmol magnesium acetate, 3 mmol hexamethylenetetramine,  
68 and 0.6 g sodium sulfate were dissolved in 40 ml bidistilled water. After stirring for 30 min, the  
69 obtained transparent solution was transferred into a 60 ml Teflon cup, which was filled to 60 %  
70 of its volume. Subsequently, the cup was put into a stainless steel autoclave and sealed tightly.  
71 After reaction at  $160^\circ$  for 48 h, the autoclave was slowly cooled down ( $160 - 100^\circ\text{C}$  in 48 h, then  
72  $100 - 25^\circ\text{C}$  in 12 h). The precipitate was filtered under vacuum, washed with distilled water re-  
73 peatedly and dried at  $60^\circ\text{C}$  in an oven. The slow cooling allowed us to grow crystals with edge  
74 lengths up to  $60\ \mu\text{m}$ .

## B. Characterization

The phase purity of the synthesized batch of single crystals has been characterized at ambient conditions by X-ray powder diffraction. Therefore, we separated the majority of single crystals from the synthesized batch and grounded a fine sample powder in an agate mortar. The grounded sample powder was measured using an X'Pert Pro diffractometer equipped with a linear position-sensitive detector from PANalytical (PIXcel<sup>3D</sup>) and a Johansson monochromator (Ge 111) using  $\text{CuK}\alpha_1$  radiation ( $\lambda = 1.5418 \text{ \AA}$ ) generated at 40 kV and 30 mA. A Rietveld refinement was carried out using the GSAS-II software [53] and a reported structure of magnesite [54] as a starting model (see appendix Fig. 1 and Tab. 1-2). The refined lattice parameters were  $a = b = 4.6375(1) \text{ \AA}$ ,  $c = 15.0268(2) \text{ \AA}$  and  $V = 279.876(1) \text{ \AA}^3$ , which are consistent with the parameters of the established structure of magnesite [54]. Additionally, Raman spectroscopy was carried out at ambient conditions on single crystals. The spectra confirmed the excellent sample quality (Fig. 1).

## C. Preparation of high-pressure, high-temperature experiments

High-pressure, high-temperature experiments were carried out using Boehler-Almax diamond anvil cells (DAC) [55]. Type Ia and IIa diamonds with low birefringence and ultra low fluorescence having either regular culets (200, 250 and 350  $\mu\text{m}$  diameter), or beveled culets (9° bevel, 100  $\mu\text{m}$  inner- and 220  $\mu\text{m}$  outer diameter) were inserted in WC seats. The opening angles of the cells were 48° or 70°. Depending on the culet size, sample chambers of 45 – 160  $\mu\text{m}$  in diameter were laser drilled in Re gaskets pre-indented to  $\sim 40 \mu\text{m}$ . Before loading, the sample material was dried at 150 °C for 24 h in an oven. Immediately after drying, three diamond anvil cells were loaded with single crystals and one cell with a compacted powder. The single crystals had edge lengths of  $\sim 15 \mu\text{m}$ . All cells were loaded with a ruby pressure marker. Neon served as a pressure transmitting medium for the single crystal cells, which was loaded by a custom built gas loading system. In order to obtain X-ray powder diffraction data without any interference by the pressure transmitting medium, no Neon gas was used for the DAC loaded with the compacted powder sample. No further thermal insulation was added to the loadings, in order to prevent possible chemical reactions.

#### 102 **D. Raman spectroscopy in the LH-DAC**

103 Raman spectra were measured in 0.5 – 4 GPa steps upon compression and decompression cov-  
104 ering a range between ambient pressure and  $\sim 148$  GPa. A frequency doubled 532.14 nm Nd:YAG  
105 Oxxius laser (LCX-532S) was focused on the sample with a spot size of 6  $\mu\text{m}$ . Spectra were col-  
106 lected in backscattering geometry, using a grating spectrometer (Acton, SP-2356) equipped with  
107 a CCD detector (Pixis 256E) and a microscope objective (Mitutoyo). The spectral resolution of  
108 the spectrometer is  $3\text{ cm}^{-1}$  [28]. The laser power was set to 430 mW and spectra were collected  
109 for 50 s in a frequency window of  $100 - 1500\text{ cm}^{-1}$ , using a grating of 1800 grooves/mm. The  
110 estimated laser power on the sample was around  $\sim 350$  mW. For measurements up to 95 GPa,  
111 the pressure was determined before and after the Raman measurement, using the ruby reference  
112 scales for non- [56] and quasi-hydrostatic conditions [57]. Pressures were further determined for  
113  $P \geq 45$  GPa using the diamond edge reference scale [58]. For  $P > 95$  GPa only the diamond  
114 edge reference scale was employed. According to Dewaele *et al.* [59], the uncertainty in pressures  
115 determined by Mao *et al.* [56] increases from 0.05 GPa at 1 GPa up to 2 GPa at 150 GPa. The  
116 accuracy of our pressure determination by the ruby and diamond reference scales was  $\leq 2$  GPa,  
117 while pressure gradients may have caused uncertainties up to 4 GPa during and after laser heating.

118 The sample was heated from both sides with a pulsed  $\text{CO}_2$  laser (Diamond K-250 from Coher-  
119 ent,  $\lambda = 10.6\text{ }\mu\text{m}$ ) [28]. For the spectroradiometric temperature determination we used the same  
120 set-up as for the Raman measurements, while the grating was set to 150 grooves/mm. In order to  
121 achieve coupling of the  $\text{CO}_2$  heating laser from both sides of the sample, the laser power was typ-  
122 ically set in a range between 1 – 6 W, depending on the pressure and the loading of the diamond  
123 anvil cell. The heating laser was focused on the sample so that the diameter of the heated area  
124 was around 25  $\mu\text{m}$ , which nearly covered all of the single crystals. However, due to the poor to  
125 moderate coupling of the laser with the samples, heating was inhomogeneous. Hence, we moved  
126 the heating laser across the sample, while typically heating for about 5 min per position. The po-  
127 sition of the Raman laser with respect to the heated areas on the sample was controlled using an  
128 optical camera. The thermal emission of the sample, as well as the Raman signal was measured  
129 with a spatial resolution of around 5 – 6  $\mu\text{m}$ , i.e. the areas for the measurements were significantly  
130 smaller than the heating spots. The temperatures during laser heating were determined by the two-  
131 colour pyrometer method, employing Planck and Wien fits [60]. We assume a typical uncertainty  
132 associated with radiometric temperature measurements in LH-DACs of  $\sim 10\%$ .

### 133 E. High-pressure X-ray diffraction

134 High pressure X-ray powder diffraction measurements have been carried out at the extreme  
135 conditions beamline P02.2 at PETRA III (Desy, Hamburg, Germany). X-ray diffraction data were  
136 collected for a  $\text{MgCO}_3$  powder sample, which at first was pressurized to 110 GPa in a diamond  
137 anvil cell and temperature quenched after laser-heating to  $\sim 2500$  K. The diffraction patterns were  
138 acquired using a wavelength of  $0.2898 \text{ \AA}$ , a beam focused to  $8 \times 3 \mu\text{m}^2$  (full width at half max-  
139 imum), compound reflective lenses, and a Perkin Elmer XRD 1621 flat-panel detector. A grid  
140 of  $5 \times 5$  points with spacings of  $2 \mu\text{m}$  between each point was measured. The DAC was rotated  
141 by  $\pm 10^\circ$  with an exposure time of 40 s for every data point collection. The sample-to-detector  
142 distance of 402.78 mm and the wavelength were determined employing a  $\text{CeO}_2$  reference sample.  
143 The diffraction data were processed with the Dioptas software [61]. Rietveld refinements were car-  
144 ried out using the GSAS-II software [53] and the structure model based on an earlier description  
145 of the  $C2/m$ -phase [38].

### 146 F. Density functional theory

147 In order to obtain theoretical Raman spectra, density functional perturbation theory (DFPT)  
148 calculations were performed employing the CASTEP code [62]. The code is an implementation  
149 of Kohn–Sham DFT based on a plane wave basis set in conjunction with pseudopotentials. The  
150 plane wave basis set allows to achieve numerically converged results in a straightforward manner,  
151 as the convergence is controlled by a single adjustable parameter, the plane wave cut-off, which we  
152 set to 1020 eV. For calculations for pressures  $< 100$  GPa, the norm-conserving pseudopotentials  
153 were generated ‘on the fly’ from the information provided in the CASTEP data base. These pseu-  
154 dopotentials have been tested extensively for accuracy and transferability [63]. For calculations at  
155 pressures  $> 100$  GPa norm-conserving pseudopotentials with smaller core radii were constructed,  
156 in order to avoid overlap of ionic cores. The descriptors of these pseudopotentials are given in  
157 the appendix. All calculations employed the GGA-PBE exchange-correlation functional [64]. The  
158 Brillouin zone integrals were performed using Monkhorst–Pack grids [65] with spacings between  
159 grid points of less than  $0.037 \text{ \AA}^{-1}$ . Geometry optimizations were defined as being converged  
160 when the energy change between iterations was  $< 0.5 \times 10^{-6}$  eV/atom, the maximal residual force  
161 was  $< 0.01$  eV/ $\text{\AA}$ , and the maximal residual stress was  $< 0.02$  GPa. Phonon frequencies were ob-

162 tained from density functional perturbation theory (DFPT) calculations. Raman intensities were  
163 computed using DFPT in the ‘ $2n + 1$ ’ theorem approach [66].

### 164 III. RESULTS AND DISCUSSION

#### 165 A. $\text{MgCO}_3$ (magnesite) at high-pressures and high temperatures measured by Raman spec- 166 troscopy

167 The characteristic Raman phonon frequencies of  $\text{MgCO}_3$  (magnesite) were measured in four  
168 different experimental runs, covering a pressure range between ambient pressure and  $\sim 107$  GPa  
169 (Fig. 1 and 2). According to group theory, the following Raman and infrared active modes are  
170 expected for magnesite at ambient conditions:  $\Gamma = A_{1g}(\text{R}) + 3A_{2u}(\text{IR}) + 5E_u(\text{IR}) + 4E_g(\text{R})$ . All  
171 Raman active modes were observed at ambient conditions. Starting at ambient pressure with a fre-  
172 quency of  $1444 \text{ cm}^{-1}$ , the  $E_g(\nu_3)$  mode is obscured by the first order Raman mode of the diamond  
173 anvils in the DAC experiments. The frequencies of the symmetric stretching mode and the sym-  
174 metric in-plane bend allow a straightforward identification of the  $\text{CO}_3^{2-}$ -groups [50, 67, 68]. We  
175 observed the  $A_{1g}(\nu_1)$  and  $E_g(\nu_4)$  modes up to  $\sim 107$  GPa in a range between  $1095 - 1304 \text{ cm}^{-1}$   
176 and  $740 - 893 \text{ cm}^{-1}$  respectively. The two low frequency  $E_g$  modes ( $\nu = 213$  and  $331 \text{ cm}^{-1}$  at  
177 ambient pressure) were observed up to 45.5 GPa. At higher pressures these modes displayed a  
178 significant broadening, or disappeared completely. A similar behaviour for the low frequency  $E_g$   
179 modes was reported by Williams *et al.* [50] and Gillet [51], who observed the  $213 \text{ cm}^{-1}$  Raman  
180 band at pressures between 13 – 20 GPa and the  $331 \text{ cm}^{-1}$  Raman band up to 26 GPa.

181 We were able to detect all Raman active modes that are observable in a diamond anvil cell up  
182 to 87.8 GPa by carefully thermally annealing the single crystal at nearly each pressure step up to  
183 82 GPa and measuring the Raman signal after temperature quenching (Fig. 1). The temperatures  
184 during the thermal annealing by the laser were estimated to be  $< 1000$  K, since no visible thermal  
185 radiation was observed. An offset for especially the low frequency Raman modes may be observed  
186 for some of the high pressure Raman spectra due to the non-hydrostatic pressure on the sample.  
187 These effects disappeared after heating was applied and hydrostatic conditions on the sample were  
188 increased.

FIG. 1. High pressure Raman spectra of  $\text{MgCO}_3$  (magnesite) from ambient pressure to  $\sim 88$  GPa as obtained for a single run. For most of the pressure steps between 15.9 and 82.1 GPa, the crystal was slightly annealed at temperatures  $< 1000$  K. All Raman measurements were conducted after quenching the sample to ambient temperature.

FIG. 2. Pressure dependence of the characteristic Raman modes of magnesite (black symbols) and  $\text{MgCO}_3\text{-II}$  (yellow symbols). Triangles and circles correspond to single crystal and powder samples respectively. Open symbols correspond to data obtained under cold-decompression. DFT-calculated phonon frequencies of  $\text{MgCO}_3\text{-II}$  at 85 and 140 GPa are shown for comparison (green diamond symbols). The black dashed line marks the phase boundary of the  $\text{MgCO}_3$  polymorphs at 85 GPa. Data points were fitted using linear or quadratic fits. (color online)

189 **B. Phase transition of MgCO<sub>3</sub> (magnesite) to MgCO<sub>3</sub>-II identified by Raman spectroscopy, XRD**  
190 **and density functional theory**

191 At 83 GPa and after heating to  $\sim 2400$  K, our Raman spectra still indicate the presence of  
192 MgCO<sub>3</sub> (magnesite) at these conditions, while a drastic change in the spectra is observed at around  
193 85 GPa and after heating to  $\sim 2000$  K, where new characteristic Raman bands were observed be-  
194 sides those of MgCO<sub>3</sub> (magnesite) (appendix Fig. 2). At 87.9 GPa and after heating to maximum  
195 temperatures of  $\sim 3100$  K, Raman spectra yielded at least 23 strong intense modes covering a fre-  
196 quency range between 250 and 1250 cm<sup>-1</sup> (Fig. 3). These changes are due to a phase transition  
197 from MgCO<sub>3</sub> (magnesite) to a second phase, which we have labeled MgCO<sub>3</sub>-II here. We com-  
198 puted the Raman spectra for the monoclinic  $C2/m$ -phase [38, 46] and for a hypothetical triclinic  
199  $P\bar{1}$ -phase [39], which has been suggested to be stable between 85 – 101 GPa. The experimental  
200 Raman spectrum at 87.9 GPa can very satisfactorily be explained by a combination of the theoret-  
201 ical Raman spectra of magnesite and the  $C2/m$ -phase, while no indication for the  $P\bar{1}$ -phase was  
202 found (Fig. 3).

203 We continued measuring Raman spectra up to 148 GPa (Fig. 2 and 4). For most of the  
204 pressure steps, the sample was heated up to maximum temperatures of  $\sim 3600$  K prior to the  
205 measurement, in order to achieve a hydrostatic pressure distribution on the sample. A com-  
206 parison of theoretical spectra with experimental data at 115 and 140 GPa shows an excellent  
207 match of frequencies and intensities (Fig. 5). Characteristic modes of MgCO<sub>3</sub> (magnesite) are  
208 no longer observed in the experimental spectrum at these conditions. According to group the-  
209 ory, the irreducible representations of the  $C2/m$ -phase for the Raman and infrared-modes are  
210  $\Gamma = 25A_g(\text{R}) + 18A_u(\text{IR}) + 20B_g(\text{R}) + 24B_u(\text{IR})$ . The tetrahedral CO<sub>4</sub><sup>4-</sup> groups of the  $C2/m$ -  
211 phase are polymerized and form corner sharing C<sub>3</sub>O<sub>9</sub><sup>6-</sup> rings [38]. Between 85 and 148 GPa,  
212 characteristic vibrations of those rings are frequencies in the ranges 1023 – 1095 cm<sup>-1</sup>, 1026 –  
213 1128 cm<sup>-1</sup>, 1050 – 1146 cm<sup>-1</sup>, and 1065 – 1173 cm<sup>-1</sup>, respectively. Further characteristic fea-  
214 tures are the intense A<sub>g</sub> and B<sub>g</sub> modes at 733 – 781 cm<sup>-1</sup> and 444 – 463 cm<sup>-1</sup>, respectively. Both  
215 modes are due to relative movements between the C<sub>3</sub>O<sub>9</sub><sup>6-</sup> rings and the Mg<sup>2+</sup> cations. Two modes  
216 in MgCO<sub>3</sub>-II at 189 cm<sup>-1</sup> ( $\leq 105$  GPa) and 1050 cm<sup>-1</sup> ( $\geq 120$  GPa) have no correspondence in the  
217 DFT-calculations. The origin of these modes is currently unexplained.

218 There have been suggestions that the  $C2/m$  polymorph transforms into another phase at  
219  $P \geq 138$  GPa. For this phase, structures with space group  $P2_1$  [38], or  $P2_12_12_1$  [39] have been

220 suggested. Theoretical Raman spectra of the hypothetical  $P2_1$ -phase [38] at 120 and at 140 GPa  
 221 were computed and compared to our experimental observations (see appendix Fig. 3). Although  
 222 the comparison between experimental and theoretical spectra exhibits some similarities at higher  
 223 frequencies, significant differences are observed in the lower frequency range. Hence, we con-  
 224 clude that this phase has not been formed in our experiments. Computation of the Raman spectra  
 225 of the  $P2_12_12_1$ -phase [39] was beyond the available computation resources.

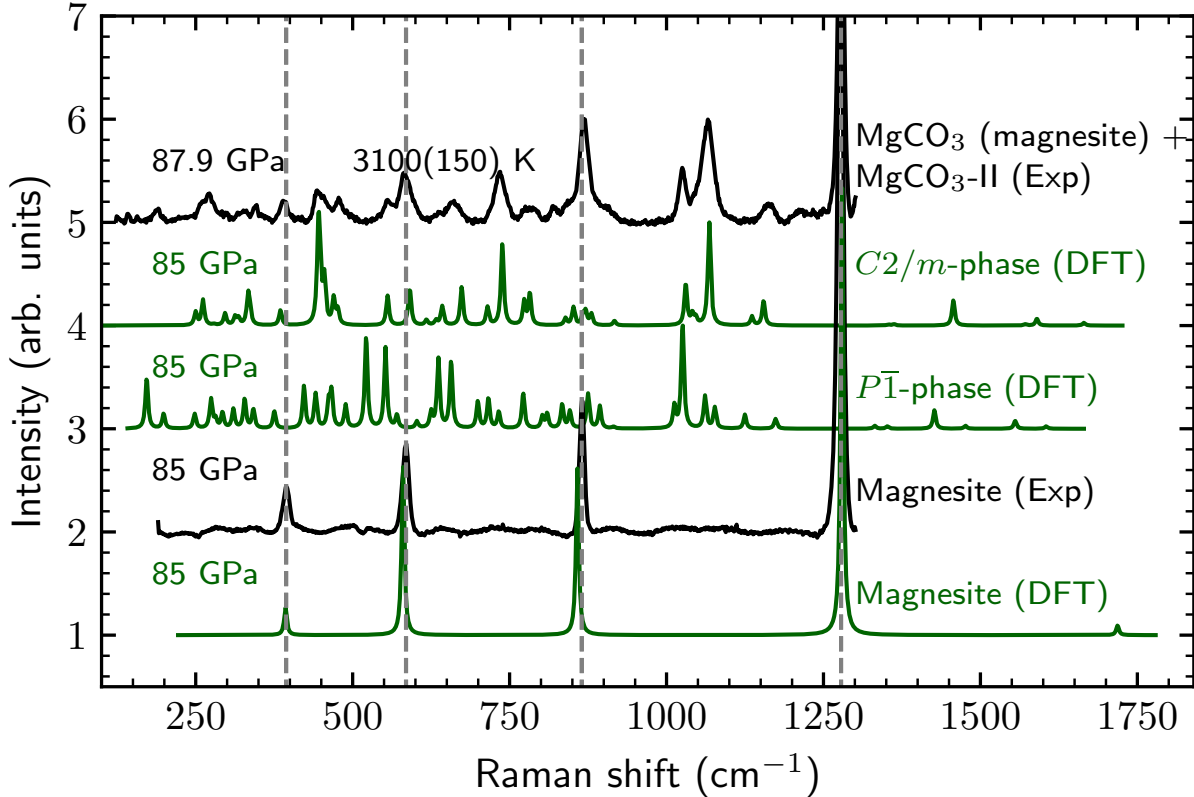

FIG. 3. Experimental Raman spectra of  $\text{MgCO}_3$  (magnesite) and a mixture of  $\text{MgCO}_3$  (magnesite) and  $\text{MgCO}_3$ -II ( $C2/m$ -phase [38]) are shown in black. DFT-calculated Raman spectra of magnesite, the  $C2/m$ -phase and the  $P\bar{1}$ -phase [39] are shown in green. DFT frequencies were calculated with a FWHM broadening of  $5 \text{ cm}^{-1}$ . The calculated frequencies were multiplied by a scaling factor of 1.02. The characteristic Raman modes of  $\text{MgCO}_3$  (magnesite) at 85 GPa are indicated by dashed grey lines. (color online)

226 Our combined results from Raman spectroscopy and DFT-calculations are supported by syn-  
 227 chrotron X-ray powder diffraction measurements, which have been conducted on  $\text{MgCO}_3$  powder  
 228 at 110 GPa and after heating to  $\sim 2500 \text{ K}$ . We were able to successfully carry out a Rietveld refine-  
 229 ment, which allowed the identification of the  $C2/m$ -phase (Fig. 6 and appendix Tab. 1-2). Since

FIG. 4. Raman spectra of  $\text{MgCO}_3\text{-II}$  ( $C2/m$ -phase) [38] in a pressure range from 87 to 148 GPa for a single run. For most of the pressure steps, the sample was heated to maximum temperatures between 3000 and 3600 K and measured after quenching to ambient temperature. For the present data, the grating of the Raman spectrometer was centered towards higher Raman shifts, which resulted in obscuration of the  $\text{CO}_3$ -stretching mode ( $\nu = 1278 \text{ cm}^{-1}$ ) by the diamond anvils.

230 Rietveld refinements are usually hard to conduct for high pressure data especially after heating,  
 231 intensities of a grid of 25 diffraction images were summed at each particular 2 theta angle, in order  
 232 to achieve an accurate ratio of intensities for the refinement (appendix Fig. 4-5). Profile parameters  
 233 including scaling, Gaussian and Lorentzian terms, as well as the unit cell were initially refined.  
 234 The background was manually fitted, using a Chebychev function with twenty terms. In order to  
 235 reduce the number of parameters, we constrained the isotropic atomic displacement parameters  
 236 to be the same for symmetrically independent atoms of the same chemical species. Further, we  
 237 employed restraints on the atomic distances and refined the atomic positions. Refined lattice pa-  
 238 rameters were  $a = 8.117(4) \text{ \AA}$ ,  $b = 6.510(1) \text{ \AA}$ ,  $c = 6.911(2) \text{ \AA}$ ,  $\beta = 103.858(9)^\circ$ ,  $V = 354.64(5) \text{ \AA}^3$ .  
 239 Our refined structural model is in excellent agreement with the structure of the  $C2/m$ -phase re-

FIG. 5. Comparison between Raman bands of experimental data (black) and theoretical data (green) of  $\text{MgCO}_3\text{-II}$  ( $C2/m$ -phase [38]) at 115 and 140 GPa. Experimental data have been obtained on the temperature quenched sample after heating to  $\sim 3000$  and  $\sim 3200$  K, respectively. The experimental spectrum reveals the complete transformation of  $\text{MgCO}_3$  (magnesite) to  $\text{MgCO}_3\text{-II}$  at these conditions. DFT frequencies were calculated with a FWHM broadening of  $5 \text{ cm}^{-1}$ . The calculated frequencies were multiplied by a scaling factor of 1.02. (color online)

240 ported by Oganov *et al.* [38] and lattice parameters are well in agreement with those from Le Bail  
 241 refinements for the same pressure range as reported by Maeda *et al.* [9].

242 Raman spectra of  $\text{MgCO}_3$  (magnesite) and  $\text{MgCO}_3\text{-II}$  ( $C2/m$ -phase) were measured upon  
 243 pressure release (Fig. 7 and 2). The pressure unexpectedly dropped during the first step of the  
 244 release from 85 GPa down to 64 GPa. The pressure was then released in small steps down to am-  
 245 bient conditions, while Raman spectra were measured. During pressure release, the characteristic  
 246 Raman bands of  $\text{MgCO}_3$  (magnesite) and those of  $\text{MgCO}_3\text{-II}$  ( $C2/m$ -phase) could concomitantly  
 247 be observed in the pressure range between 39.6 – 85 GPa. At lower pressures, only the  $A_{1g}(\nu_1)$   
 248 and  $E_g(\nu_4)$  modes of  $\text{MgCO}_3$  (magnesite) remained. The low frequency  $E_g$  modes reappeared at

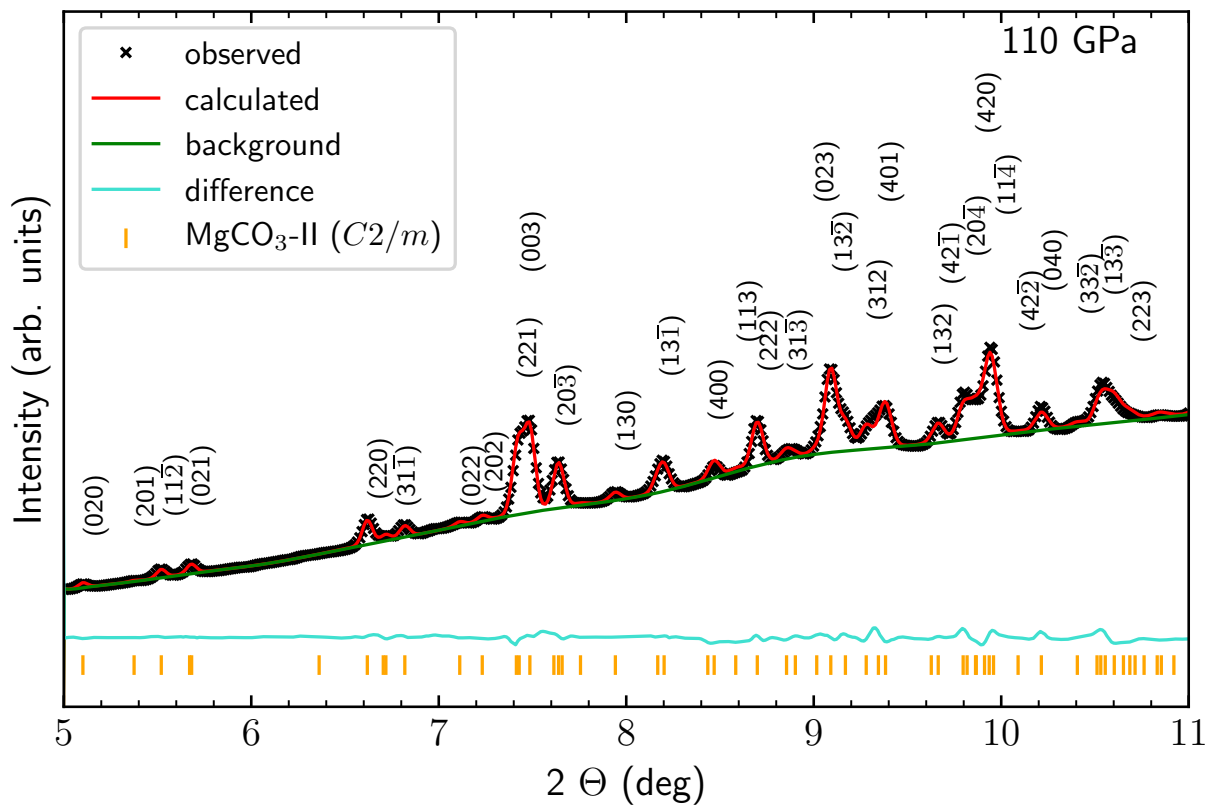

FIG. 6. Rietveld refinement of diffraction data collected at 110 GPa. The structural model by Oganov *et al.* [38] for  $\text{MgCO}_3\text{-II}$  ( $C2/m$ -phase) was used for the refinement ( $\lambda = 0.2898 \text{ \AA}$ ). Refined structural parameters are listed in the appendix (Tab. 1-2). (color online)

249 around 5 GPa.  $\text{MgCO}_3$  (magnesite) was eventually recovered at ambient conditions, unequivocally  
 250 showing that no decomposition occurred after laser heating at high pressures.

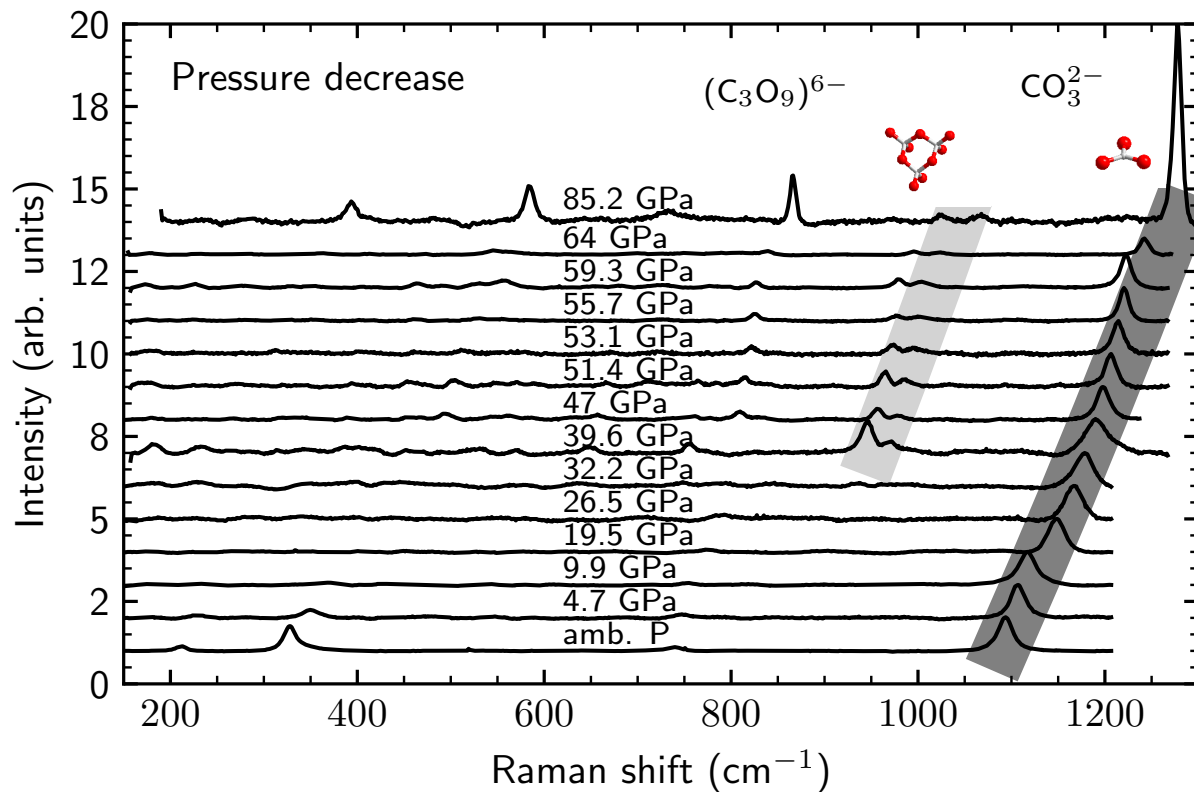

FIG. 7. Raman spectra of  $MgCO_3$  (magnesite) +  $MgCO_3$ -II ( $C2/m$ ) obtained during decompression down to ambient conditions. Frequencies of the  $(C_3O_9)^{6-}$  ring bending (light grey) are observed down to  $\sim 40$  GPa. The concomitant presence of a characteristic mode ( $CO_3^{2-}$ -stretching mode) of  $MgCO_3$  (magnesite) indicated in dark grey shows the coexistence of magnesite and metastable  $MgCO_3$ -II.  $MgCO_3$  (magnesite) is recovered at low pressures and ambient conditions. (color online)

### 251 C. Phase diagram of MgCO<sub>3</sub>

252 Based on the results from this study in conjunction with data from the literature [9, 26, 31, 32,  
253 40, 69] we revise the phase diagram of MgCO<sub>3</sub> (Fig. 8). A first phase diagram of MgCO<sub>3</sub> was  
254 given by Isshiki *et al.* [26] in which phase boundaries were drawn for the magnesite to ‘magnesite-  
255 II’ phase transition and the decomposition behaviour of MgCO<sub>3</sub>, determined by Fiquet *et al.* [31],  
256 was extended to higher  $P, T$ -conditions. Another phase diagram at lower  $P, T$ -conditions was  
257 reported by Solopova *et al.* [32], where the melting- and decomposition behavior of magnesite  
258 was described. The slope of the melting curve was discussed to be less steep than that reported by  
259 Katsura and Ito [69]. Also, for pressures below 50 GPa the decomposition of MgCO<sub>3</sub> (magnesite)  
260 was shown to happen at significantly lower temperatures than reported by Fiquet *et al.* [31], while  
261 at higher pressures both curves are approaching one another. We combined the contents of the  
262 phase diagrams from both studies [26, 32] and added data points obtained in this study (large filled  
263 circles in Fig. 8) along with datapoints of the available high pressure high temperature studies  
264 on MgCO<sub>3</sub> beyond 50 GPa [9, 26, 32, 40]. It should be borne in mind that our data and those  
265 by Solopova *et al.* [32] were obtained after temperature quenching and at high pressures, while  
266 all other data from the literature were measured in-situ at high pressures and high temperatures  
267 [9, 26, 40].

268 In the present phase diagram, data points of MgCO<sub>3</sub> (magnesite) are indicated by black circles  
269 (Fig. 8). According to Solopova *et al.* [32] our data points of heated MgCO<sub>3</sub> (magnesite) fall  
270 within the conditions for magnesite as a solid phase. Our data points of MgCO<sub>3</sub>-II (yellow circles)  
271 and MgCO<sub>3</sub>-II associated with MgCO<sub>3</sub> (black-yellow circles) are in very good agreement with  
272 the observations by Maeda *et al.* [9] and Boulard *et al.* [40]. Hence, we present the MgCO<sub>3</sub>-  
273 MgCO<sub>3</sub>-II phase boundary (yellow dashed line) with a negative slope of  $dT/dP = -940 \text{ K GPa}^{-1}$   
274 towards higher temperatures. Due to a lack of data, the phase boundary is only drawn up to the  
275 maximum available  $P, T$ -conditions [40]. Our data points reveal that no decomposition is to be  
276 expected for MgCO<sub>3</sub>-II at  $P, T$ -conditions suggested by the decomposition lines of the previous  
277 phase diagrams [26, 32] (see appendix Fig. 6). As a consequence, the decomposition boundary  
278 of MgCO<sub>3</sub>-II ( $C2/m$ -phase) by Isshiki *et al.* [26] is not shown in the revised phase diagram (Fig.  
279 8). Further, MgCO<sub>3</sub> (magnesite) is observed to transform into MgCO<sub>3</sub>-II rather than decomposing  
280 into MgO + C + O<sub>2</sub> at pressures and temperatures above 85 GPa and  $\sim 3000 \text{ K}$ , respectively.

281 In our experiments, no other phase transition was found for pressures and temperatures up to

282 148 GPa and  $\sim 3600$  K. Our conclusion is consistent with the interpretation of Le Bail fits by  
283 Boulard *et al.* [40] and Maeda *et al.* [9] who conducted in-situ powder X-ray diffraction in the  
284 same  $P, T$ -range. These combined observations suggest that the magnesite-II phase, found by  
285 Isshiki *et al.* [26], was very likely the  $C2/m$ -phase ( $\text{MgCO}_3$ -II).

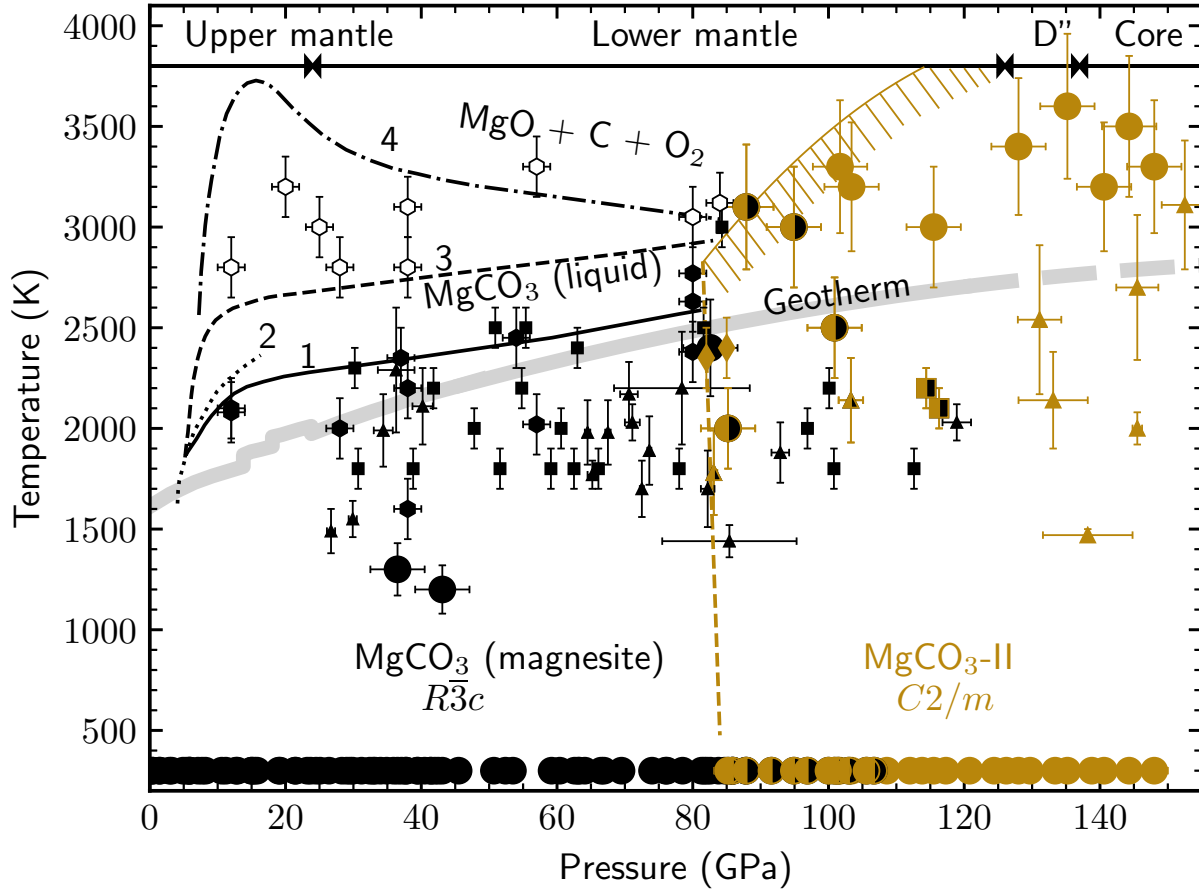

FIG. 8. Phase relations in the  $\text{MgCO}_3$  system with respect to the depth profile of the Earth's mantle and outermost core. Markers correspond to studies, while colours denote distinct phases (black = magnesite, yellow =  $C2/m$ -phase [38], white = magnesite +  $\text{MgO}$ ). Data from this study are shown as large circles and were obtained after temperature quenching at high pressures. Data obtained by Solopova *et al.* [32] are shown as hexagons, which have also been obtained after temperature quenching at high pressures. Squares, triangles, and diamonds correspond to the in situ data obtained in the studies by Isshiki *et al.* [26], Maeda *et al.* [9], and Boulard *et al.* [40], respectively. A typical mantle geotherm is shown as grey solid line [70]. The solid (1) and dashed (3) lines represent liquidus and decomposition for magnesite as reported by Solopova *et al.* [32]. The dotted line (2) represents the liquidus for magnesite as reported by Katsura and Ito [69]. The dash-dotted line (4) represents the decomposition of  $\text{MgCO}_3$  as reported by Fiquet *et al.* [31]. The dashed yellow line corresponds to the phase boundary of magnesite into the  $C2/m$ -phase derived here. The broad dashed yellow band presents a boundary above which we have not observed decomposition, but solid or liquid  $\text{MgCO}_3\text{-II}$ . (color online)

#### 286 IV. CONCLUSIONS

287 This study provides the first Raman spectra of pure  $\text{MgCO}_3$  at pressures and temperatures up to  
288 148 GPa and 3600 K. Our spectra allowed the identification of  $\text{MgCO}_3$ -II-tetracarbonate and the  
289 location of the phase boundary between  $\text{MgCO}_3$  (magnesite) and  $\text{MgCO}_3$ -II ( $C2/m$ -phase). Based  
290 on our observations from Raman spectroscopy, XRD and density functional theory calculations,  
291 we propose a revised phase diagram for  $\text{MgCO}_3$ . At  $P, T$ -conditions of Earth's upper mantle and  
292 upper part of the lower mantle (e.g. pressures up to  $\sim 80$  GPa and temperatures up to  $\sim 2500$  K),  
293  $\text{MgCO}_3$  is stable as magnesite ( $R\bar{3}c$ ) [26, 32]. At  $P, T$ -conditions of Earth's lowermost mantle  
294 and outermost core (e.g. 85-148 GPa and at temperatures above 2500 K) the stable polymorph  
295  $\text{MgCO}_3$ -II is a monoclinic  $C2/m$ -tetracarbonate as predicted by Oganov *et al.* [38]. In the present  
296 study we observe that  $\text{MgCO}_3$ -II can exist on pressure release down to  $\sim 40$  GPa. This is similar  
297 to an earlier observation of the existence of  $\text{CaCO}_3$ -tetracarbonate on pressure release down to  
298 57 GPa [45].

#### 299 V. ACKNOWLEDGEMENTS

300 The authors acknowledge funding by the Deutsche Forschungsgemeinschaft (DFG)-Germany  
301 (FOR2125/CarboPaT, BA4020, WI1232) and BMBF (05K16RFA). Chris J. Pickard is supported  
302 by the Royal Society through a Royal Society Wolfson Research Merit Award and the EPSRC  
303 through Grant No. EP/P022596/1. Sergey S. Lobanov acknowledges the support of the Helmholtz  
304 Young Investigators Group CLEAR (VH-NG-1325). The ' $2n+1$ ' Raman theorem in CASTEP was  
305 developed under grant EP/I030107/1. DESY (Hamburg, Germany), a member of the Helmholtz  
306 Association (HGF) is acknowledged for the provision of experimental facilities. We would like to  
307 thank Hanns-Peter Liermann and his team for assistance in using beamline P02.2.
