21

22 Capsule:

23 Effects of total N deposition and reduced and oxidised N deposition were studied across  
24 eight habitat types in the UK using data from the British Countryside Survey.

25 Highlights:

26 -N deposition was significantly related to species richness in all habitats except base-rich  
27 mires.

28 -Form of N in deposition was related to biodiversity in grasslands and woodlands.

29 -Reduced N deposition was related to higher Ellenberg N values in all but one habitat type.

30 -Reduced N was negatively related to species richness in acid and mesotrophic grasslands.

31

32 **Abstract**

33 Nitrogen (N) deposition impacts natural and semi-natural ecosystems globally. The  
34 responses of vegetation to N deposition may, however, differ strongly between habitats and  
35 may be mediated by the form of N. Although much attention has been focused on the  
36 impact of total N deposition, the effects of reduced and oxidised N, independent of the total  
37 N deposition, have received less attention. In this paper, we present new analyses of  
38 national monitoring data in the UK to provide an extensive evaluation of whether there are  
39 differences in the effects of reduced and oxidised N deposition across eight habitat types  
40 (acid, calcareous and mesotrophic grasslands, upland and lowland heaths, bogs and mires,  
41 base-rich mires, woodlands). We analysed data from 6860 plots in the British Countryside  
42 Survey 2007 for effects of total N deposition and N form on species richness, Ellenberg N  
43 values and grass:forb ratio. Our results provide clear evidence that that N deposition affects  
44 species richness in all habitats except base-rich mires, after factoring out correlated  
45 explanatory variables (climate and sulphur deposition). In addition, the form of N in  
46 deposition appears important for the biodiversity of grasslands and woodlands but not  
47 mires and heaths. Ellenberg N increased more in relation to  $\text{NH}_x$  deposition than  $\text{NO}_y$   
48 deposition in all but one habitat type. Relationships between species richness and N form  
49 were habitat-specific: acid and mesotrophic grasslands appear more sensitive to  $\text{NH}_x$   
50 deposition while calcareous grasslands and woodlands appeared more responsive to  $\text{NO}_y$   
51 deposition. These relationships are likely driven by the preferences of the component plant  
52 species for oxidised or reduced forms of N, rather than by soil acidification.

## 1 Introduction

2

3 There is widespread evidence across the globe, from both experiments and field surveys, of  
4 the significant ecological impacts of nitrogen (N) deposition on semi-natural ecosystems of  
5 low nutrient status (e.g. Bobbink et al. 2010), which also carries economic costs (Jones et al.  
6 2014). However, interpretation and quantification of these effects, and predictions of the  
7 benefits of emission control policies, need to consider the different components of N  
8 deposition (Brink et al. 2011). There are two main chemical forms – reduced N (ammonia,  
9  $\text{NH}_3$  and ammonium,  $\text{NH}_4^+$ ) emitted primarily from agricultural sources, and oxidised N  
10 (nitrogen oxides,  $\text{NO}_x$ , nitric acid,  $\text{HNO}_3$  and nitrate  $\text{NO}_3^-$ ) emitted primarily from fossil fuel  
11 combustion. In addition, N deposition may be in the form of dry deposition of gases and  
12 aerosols, which is most important close to sources, and in regions of the world with low  
13 rainfall, and as wet deposition as snow, dew, cloud or rainwater, which are important in  
14 more remote regions and in areas with high rainfall.

15 The mechanisms underlying the ecological effects of N deposition include direct toxicity,  
16 growth stimulation and competitive exclusion, soil acidification and increased susceptibility  
17 to other abiotic and biotic stresses (e.g. Bobbink et al. 1998, Roem and Berendse 2000).  
18 There are strong reasons, which have been recently reviewed by (Stevens et al. 2011), for  
19 expecting that there may be different effects of reduced and oxidised N deposition for each  
20 of these mechanisms. For example, foliar uptake of gaseous  $\text{NH}_3$  is more likely to be directly  
21 toxic than uptake of gaseous nitrogen oxides, while soil  $\text{NH}_4^+$  is more likely to be toxic to  
22 plant roots than soil  $\text{NO}_3^-$  (Sheppard et al. 2011, Sheppard et al. 2014). Plant species also  
23 differ strongly in their preference and tolerance for  $\text{NH}_4^+$  or  $\text{NO}_3^-$  uptake from soil solution  
24 with species of acidic habitats generally more tolerant of higher soil ammonium  
25 (Falkengrengrerup and Lakkenborgkristensen 1994). The soil  $\text{NH}_4^+/\text{NO}_3^-$  ratio is partly a  
26 function of the ratio in atmospheric deposition, but also of the degree of nitrification in  
27 soils; high rates of nitrification result in a lower soil solution  $\text{NH}_4^+/\text{NO}_3^-$  ratio, which may  
28 reduce the risk of direct  $\text{NH}_4^+$  toxicity but may increase acidification because of the greater  
29 oxidation to  $\text{NO}_3^-$ .

30 Experimental studies provide some evidence of the differential effects of reduced and  
31 oxidised N deposition. For example, van den Berg et al. (2008) showed that higher  
32  $\text{NH}_4^+/\text{NO}_3^-$  ratios in deposition to heathland mesocosms had significant adverse effects on  
33 acid-sensitive species but not on acid-tolerant species that were also tolerant of high soil  
34  $\text{NH}_4^+/\text{NO}_3^-$  ratios. This effect was lost in limed mesocosms, suggesting that acidification at  
35 higher  $\text{NH}_4^+/\text{NO}_3^-$  ratios was the key driving mechanism. By contrast, in Mediterranean  
36 maquis vegetation, the application of both  $\text{NH}_4^+$  and  $\text{NO}_3^-$  increased biomass but not plant  
37 diversity, while  $\text{NH}_4^+$  alone increased plant diversity but not biomass (Dias et al. 2014); these  
38 effects can at least partly be explained by the different responses of individual species to  
39 total N inputs or to reduced N deposition specifically.

40 A combination of targeted field surveys and analysis of nationwide surveillance data over  
41 the last decade have provided a strong body of evidence of the impacts of N deposition.  
42 Strong negative associations between N deposition and species richness have been reported  
43 in acid grasslands (Stevens et al. 2004, Duprè et al. 2010, Stevens et al. 2010a), grasslands,  
44 heathlands and bogs (Maskell et al. 2010, Caporn et al. 2014, Field et al. 2014) and sand  
45 dunes (Jones et al. 2004). In acid grasslands, this negative association is linked to declines in  
46 forb species richness and a corresponding increase in graminoids (Maskell et al. 2010) with  
47 differential responses of individual forb species to N deposition (Payne et al. 2013). In acid  
48 grasslands acidification rather than eutrophication may be the main driver of change  
49 (Stevens et al. 2010b), but the relative influence of sulphur versus nitrogen as the driver of  
50 acidification has not been separated .

51 However, in some other habitats; for example in calcareous grasslands, gradient surveys  
52 have shown no significant association between N deposition and species richness (Maskell  
53 et al. 2010). However, high rates of N deposition have been associated in calcareous  
54 grassland plots with an increase in grass:forb ratio (Maskell et al. 2010) and a decline in  
55 species diversity and in the frequency of characteristic species (van den Berg et al. 2011).  
56 This latter study suggests that, while direct effects of N deposition were responsible for  
57 shifts in diversity, effects on herb species number reflect indirect effects of both N and S  
58 deposition on soil acidity.

59 These and other findings from field surveys suggest that the responses to N deposition of  
60 vegetation characteristics in different habitats may be at least partly explained by  
61 differences in the underlying mechanisms of impact of reduced and oxidised N, mediated by  
62 soil pH, with acidification effects prevailing in poorly-buffered habitats and eutrophication  
63 effects in well-buffered habitats. Few field surveys have tried to separately evaluate the  
64 strength of associations with reduced and oxidised nitrogen but were only able to do so  
65 with relatively low number of samples/sites (Caporn et al. 2014, Field et al. 2014). Three  
66 studies have showed adverse changes in vegetation composition that were significantly  
67 correlated with reduced N deposition but not with oxidised N deposition: an increase in  
68 mean Ellenberg fertility index in semi-natural grassland and heaths/bogs between 1990 and  
69 1998 in UK Countryside Survey data (Smart et al. 2004); a loss of species with a low  
70 Ellenberg fertility index in UK national recording data between 1987 and 1999 (McClellan et  
71 al. 2011); and increases in graminoid cover and decreases in lichen cover in heathlands  
72 (Southon et al. 2013). A further study showed effects only of dry deposition of  $\text{NH}_x$  and no  
73 effect of wet reduced or oxidised N on abundance of N sensitive epiphytic lichens (Seed et  
74 al. 2013).

75 However, interpretation of such field surveys is difficult due to problems of spatial  
76 autocorrelation, and the confounding effects of other environmental and land use changes.  
77 The levels of reduced and oxidised N deposition are often highly correlated (areas of low  
78 reduced N usually have low oxidised N, etc); in addition, the range and spatial variability of

79 reduced N deposition is often greater than that of oxidised N deposition, thereby increasing  
80 the probability of detecting a statistically significant association with vegetation  
81 characteristics (e.g. Smart et al. 2012). In this paper, we present new analyses of national  
82 surveillance data in the UK to provide a more rigorous evaluation of whether there are  
83 differences in the effects of reduced and oxidised N deposition that are more robust to  
84 statistical limitations. The data that are used here provide a greater sample size and spatial  
85 scope that includes almost the complete N deposition range in the UK and allows us to  
86 evaluate our mechanistic understanding of the differential effects of the two forms of N  
87 deposition in different habitats and on different groups of species. In our analysis we focus  
88 on species richness of vascular plants as a measure of biodiversity, Ellenberg N as a measure  
89 of nutrient status (Diekmann and Falkengren-Grerup 2002) and grass:forb ratio as a  
90 measure of competitive dominance effects. We hypothesise that:

91 -The form of N (oxidised  $\text{NO}_y$ , or reduced  $\text{NH}_x$ ) in deposition has an effect on vegetation  
92 composition that is independent of, and additional to, that of total N deposition.

93 -Reduced N deposition has a greater impact on vegetation composition than oxidised N  
94 deposition.

95

96

## 1 **Methods**

### 2 *Vegetation data*

3 The effect of N deposition on vegetation was assessed using vegetation data obtained from  
4 6860 plots (2x2m) from the UK Countryside Survey 2007 (Carey et al. 2008). For each plot,  
5 total species richness, grass:forb ratio and mean Ellenberg N values were calculated. Species  
6 richness was defined as the sum of all vascular plants in each 2x2 m plot. Grass to forb ratio  
7 was based on the cover of grass species (*Poaceae*) divided by the cover of forb species.  
8 Cover-weighted average Ellenberg N numbers (Ellenberg et al. 1991) that were modified for  
9 the UK (Hill et al. 2004) were calculated based on the cover per 2x2m plot to obtain strong  
10 correlates of species responses to nutrient availability and succession (Vile et al. 2006).

11 The vegetation in each plot was classified according to the UK National Vegetation  
12 Classification (NVC) and plots were pooled into broad groups of similar habitat (see table in  
13 supplementary material). Earlier studies have shown that soil pH or base saturation can  
14 explain species richness and can affect the responses of the vegetation and the ecosystem  
15 to N deposition (van den Berg et al. 2005, Stevens et al. 2006). Therefore, habitats that  
16 belong to a similar broad NVC classification but differ strongly in average soil pH and/or  
17 base cation content (heaths, mires and grasslands) were subdivided according to pH for  
18 analysis. The resulting broad habitat types in this study were: bogs and mires (acidic), base  
19 rich mires and fens, upland dry heaths, lowland dry heaths, calcicolous grasslands,  
20 mesotrophic grasslands, calcifugous grasslands and woodlands. Bogs and mires comprise  
21 the NVC classes: M1 to M21 (mires) and H3, H4 and H5 (wet heaths). Base rich mires and  
22 fen habitat consist of the NVC classes M22 to M38. Upland dry heaths are NVC classes H10  
23 to H22, lowland dry heaths are H1, H2, H6 to H9, calcicolous grasslands are CG1 to CG14,  
24 mesotrophic grasslands are MG1 to MG13, calcifugous grasslands are U1 to U21 and  
25 woodlands are W1 to W25. All sub-communities were included.

### 26 *Atmospheric deposition and climatic data*

27 Climatic factors such as precipitation and temperature were included in our models as these  
28 are known to affect species richness (Cleland et al. 2013). Average annual temperature (°C)  
29 and average annual precipitation (mm), calculated over a 5 year period 2000-2005 were  
30 obtained from UK Meteorological Office ([www.metoffice.co.uk](http://www.metoffice.co.uk)). Sulphur (S) deposition, that  
31 peaked in the UK in the 1970s can have an acidifying effect on the soil (Kirk et al. 2010) and  
32 may thereby affect species richness (McGovern et al. 2011). Historical data on S deposition  
33 was therefore included in our models to account for potential legacy of soil acidification  
34 effects due to sulphur. Modelled N deposition data for each plot were obtained from the  
35 Centre of Ecology and Hydrology (CEH) for the year 2007; data from 1987 were used for  
36 historical S deposition. Climate and pollution data were all at 5x5km resolution. Total N  
37 deposition ranged from 5.1 to 54.2 kg N ha<sup>-1</sup>yr<sup>-1</sup> while S deposition ranged from 5.0 to 43.5  
38 kg S ha<sup>-1</sup>yr<sup>-1</sup>. Oxidised and reduced N were included in our models as the sum of wet and dry

39 NO<sub>y</sub> or NH<sub>x</sub> deposition and expressed in kg N ha<sup>-1</sup>yr<sup>-1</sup>. NO<sub>y</sub> deposition ranged from 2.5 to  
40 25.6 kg N ha<sup>-1</sup>yr<sup>-1</sup>, NH<sub>x</sub> deposition ranged from 2.3 to 36.1 kg N ha<sup>-1</sup>yr<sup>-1</sup>. The ranges of N and  
41 S deposition for each habitat are different and depend on their geographical distribution.

#### 42 *Linear models*

43 Multicollinearity is common between variables such as N deposition and the different forms  
44 of N in deposition, S deposition and climatic variables. In our dataset, NH<sub>x</sub> and NO<sub>y</sub>  
45 deposition were highly correlated ( $r=0.69$ ,  $p<0.001$ ) and could therefore not be analysed  
46 simultaneously. In addition, total N deposition and either NH<sub>x</sub> or NO<sub>y</sub> deposition were highly  
47 correlated ( $r=0.95$ ,  $p<0.001$  and  $r=0.89$ ,  $p<0.001$  respectively). Analysis to determine the  
48 effect of N form was therefore performed using linear models taking two different  
49 approaches that each overcome problems typically associated with multicollinearity and that  
50 each test specific hypotheses. Linearity of the relationship between the predictor factors  
51 and the dependent variables were tested in single linear regressions. If needed, data were  
52 transformed to meet assumptions of linearity.

53 In the first method (models coded with A), the effect of NH<sub>x</sub>/NO<sub>y</sub> ratio in deposition was  
54 tested against the effects of total N deposition. For this analysis, multiple regressions were  
55 performed with dependent variables: species richness, cover weighted Ellenberg N  
56 (hereafter Ellenberg N) and grass:forb ratio that were regressed on the explanatory  
57 variables: total N deposition, NH<sub>x</sub>/NO<sub>y</sub> ratio, S deposition, precipitation and temperature. All  
58 models were at first explicitly tested for spatial autocorrelation in the response variable and  
59 residuals by inspection of semi-variograms using generalized linear mixed-effect models  
60 (GLMM). In these models, a correlation structure was added to correct for spatial  
61 autocorrelation. Correlation structures such as corExp, and corSpher were used with the  
62 “form=~Easting+Northing” argument in the correlation option to calculate the Euclidean  
63 distances (using Pythagoras theorem) between sites with coordinates given by Easting and  
64 Northing. When spatial autocorrelation was not present or not severe, multiple linear  
65 regression models were used.

66 In the second method (models coded with B), the additional effects of either NH<sub>x</sub> or of NO<sub>y</sub>  
67 on species richness, Ellenberg N and grass:forb ratio were tested after taking into account  
68 the variation explained by S deposition, precipitation, temperature and the other form of N.  
69 In this analysis, the residuals of a model that regresses a predictor against NH<sub>x</sub>, S deposition,  
70 precipitation and temperature were regressed in a second model against NO<sub>y</sub>. i.e. the  
71 relationship between NO<sub>y</sub> deposition and the unexplained variance of the model was tested.  
72 The calculation was then repeated for an analysis of NH<sub>x</sub> on the residuals of a model that  
73 included NO<sub>y</sub>. Given that the data cover a substantial range of NO<sub>y</sub> and NH<sub>x</sub> deposition, and  
74 making the assumption that the observed responses with N deposition are linear, any  
75 differential effect of reduced and oxidised N deposition is independent of the range of the  
76 length of the deposition gradient. In this way, the slope coefficients (effect sizes) that are

77 derived allow a comparison of the independent effects of either NH<sub>x</sub> and NO<sub>y</sub>, after  
78 accounting for other sources of (co-correlated) variation.

79

80 Multicollinearity in the models was detected by calculating the Pearson correlation  
81 coefficient among pairs of the predictors and by calculating the variance inflation factors  
82 (VIF) for each predictor in the model. Predictors with VIF of less than 4 were maintained in  
83 the models since these indicate that problems with multicollinearity are not severe (Gujarati  
84 1995). Predictor variables that were highly correlated (VIF>4) were not analysed in the same  
85 model. In an additional step, multicollinearity was explored by comparing the beta-  
86 coefficients of the explanatory variables that were obtained in a multiple regression with  
87 the beta coefficients from single regressions of these explanatory variables. In this analysis,  
88 major changes in beta coefficient or changes in sign indicate multicollinearity between  
89 explanatory variables that needs to be accounted for.

90 Statistical analysis were performed using the 'nlme' package in the 'R' (version 2.9.0)  
91 statistical and programming environment (R\_Development\_Core\_Team 2008) and SPSS  
92 version 21 (IBM statistics).

93

## 1 **Results**

### 2 *N deposition and NH<sub>x</sub>/NO<sub>y</sub> ratio*

3 Our analysis shows that species richness was negatively affected by total N deposition for all  
4 habitats apart from base rich mires (no significant effect) and calcareous grasslands (a  
5 significant positive effect) (Table 1 and 2; Figure 1). Coefficients were comparable for the  
6 habitats mesotrophic grasslands, bogs and mires, woodlands, acidic grasslands and dry  
7 upland heaths. The strongest negative coefficient was found for dry lowland heath.

8 Species richness of all three grassland habitats was negatively related to NH<sub>x</sub>/NO<sub>y</sub> ratio in  
9 deposition when effects of total N deposition were accounted for (Table 1 and 2; Figure 2).  
10 For woodlands a positive relationship between species richness and NH<sub>x</sub>/NO<sub>y</sub> ratio was  
11 found, while there was no significant effect of N form on the upland and lowland heathlands  
12 and the base-rich mires, bogs and mires. Analyses of residuals against NH<sub>x</sub> and NO<sub>y</sub> (Models  
13 B) in all cases were consistent with responses shown by NH<sub>x</sub>/NO<sub>y</sub> ratio (Models A). These  
14 analyses showed that the negative effects on species richness in all three grassland habitats  
15 were driven by strong negative effects of NH<sub>x</sub>. Species richness in calcareous grasslands was  
16 also positively related to NO<sub>y</sub> (Table 2). In woodlands in contrast, the negative effects on  
17 species richness were strongly related to NO<sub>y</sub> deposition.

18 Total N deposition increased Ellenberg fertility index for bogs & mires, base rich mires,  
19 mesotrophic grasslands and calcareous grasslands, but decreased fertility index in dry  
20 lowland heath and acidic grasslands (Table 1 and 2; Figure 3). There was no significant effect  
21 on fertility index in upland heaths or woodlands. In all habitats apart from the base rich  
22 mires, there was a significant positive relationship of comparable size between NH<sub>x</sub>/NO<sub>y</sub>  
23 ratio and the Ellenberg fertility index (Figure 4). However, the form of N responsible and the  
24 nature of the relationship differed among the habitats. For dry lowland heath and acidic  
25 grassland, this ratio effect was driven by a strong negative relationship with oxidised N, i.e.  
26 NO<sub>y</sub> reduced fertility index. In the case of the bogs & mires, mesotrophic grasslands and  
27 woodlands, the ratio effect was caused by a positive relationship with reduced N, i.e. NH<sub>x</sub>  
28 increased fertility index. For calcareous grassland there was both a negative relationship for  
29 oxidised N and a positive relationship for reduced N with Ellenberg fertility scores.

30 Grass:forb ratios increased with greater N deposition in upland and lowland heathland, bogs  
31 & mires and acidic grasslands (Figure 5). Only in calcareous grasslands, grass:forb ratio was  
32 found to be lower with increased N deposition. There was no effect on grass:forb ratio in  
33 base rich mires, mesotrophic grasslands or woodlands. In acidic and calcareous grasslands  
34 the increased grass:forb ratio was associated with increased NH<sub>x</sub>/NO<sub>y</sub> ratio (Table 2, Figure  
35 6), but separate relationships for either reduced N or oxidised N were not significant and  
36 could not be used to infer which form of N was more responsible.

### 37 *Additional environmental factors*

38 Climate variables were frequently a significant explanatory variable for total species richness  
39 and Ellenberg fertility score (Table 1 and 2). Precipitation was negatively associated with  
40 species richness in the acidic and calcareous grasslands but positively associated with  
41 species richness in mesotrophic grasslands, dry upland heath and bogs & mires. A higher  
42 precipitation was associated with a lower Ellenberg fertility score in most habitats.  
43 Temperature was positively associated with Ellenberg fertility scores. Past sulphur  
44 deposition also showed some significant effects. Sulphur deposition showed a significant  
45 relationship with species richness in acidic grasslands (negative), Ellenberg fertility scores for  
46 mesotrophic and calcareous grasslands (positive) and grass:forb ratio for bogs & mires  
47 (negative). This highlights the importance of factoring out these co-correlated variables to  
48 genuinely extract any relationships due to N deposition or N form.

## 1 Discussion

### 2 *Total N deposition effects on species richness*

3 Almost all habitats showed a negative relationship between total N deposition and species  
4 richness, largely corroborating previous gradient studies for acid grasslands, heathlands and  
5 bogs (Stevens et al. 2004, Duprè et al. 2010, Henrys et al. 2011, Caporn et al. 2014). In a  
6 previous study using 1998 Countryside Survey data, as opposed to the 2007 data used in our  
7 analysis, Maskell et al. (2010) found significant negative relationships for acid grassland and  
8 heathlands, but not for calcareous or mesotrophic grassland, a pattern consistent with our  
9 findings. Although woodlands showed a negative relationship for species richness in this  
10 study, Verheyen et al. (2012) suggest that species richness changes in woodlands are more  
11 attributable to management than to N deposition. The positive relationship in calcareous  
12 grasslands runs contrary to findings in most other habitats and may reflect differences in the  
13 types of grassland included in this category that are due to a combination of glacial history,  
14 biogeographical regions, altitude and management. The calcareous grasslands include the  
15 species rich CG1 and CG2 and the relative species poor CG10 and CG11. These habitat types  
16 are different with respect to species numbers, management and altitude. Separate analysis  
17 of the most abundant communities within the dataset (95% of the calcareous grassland  
18 records), the relatively species rich communities (UK NVC classes CG1 and CG2) and  
19 relatively species-poor communities (CG10 and CG11) showed no significant relationship  
20 with N deposition in either case, which is in line with other surveys in calcareous grasslands  
21 showing no effect of N (Bennie et al. 2006, van den Berg et al. 2011) and similar to Maskell  
22 et al (2010) who used a subset of NVC classes (CG2,3,4,6,8,10,11).

23 A lack of significant relationships with N deposition may be caused by differences in local  
24 management that is aimed specifically at the conservation of high species diversity and in  
25 which grazing regimes are implemented to prevent the dominance of eutrophic species. In  
26 this study, local management was not taken into account. Base rich mires showed no  
27 relationship, but there are no other studies in this habitat against which to compare a  
28 response. However, negative effects of N on species richness have been shown in  
29 calcareous dune grasslands (Jones et al. 2004, Field et al. *in press*), suggesting that base-rich  
30 habitats are not immune to N impacts.

31

32 The decline in species richness was accompanied by an increased grass:forb ratio in the  
33 acidic, open habitats (acidic grasslands, dry upland and lowland heaths and bogs and mires).  
34 In contrast, the highly buffered alkaline habitats base rich mires and calcareous grasslands,  
35 showed no or even a negative relationship between grass:forb ratio and N deposition. These  
36 results are in agreement with previous studies on acidic habitats that showed an increased  
37 grass:forb ratio with increasing N deposition due to either loss of forb species richness  
38 (Maskell et al. 2010, Payne et al. 2013) or increased grass encroachment (Remke et al. 2009,  
39 Friedrich et al. 2011, Provoost et al. 2011). Grass encroachment and a decline in forb species  
40 in acidic ecosystems are often attributed to accelerated acidification of the soil leading to a

41 depletion of base cations and increased availability of potential toxic metals such as iron and  
42 aluminium (De Graaf et al. 1997, Horswill et al. 2008). Both (historical) deposition of sulphur  
43 and N deposition are known causes for acidification (RoTAP 2012) and N deposition also  
44 results in eutrophication. However, our data does not allow us to disentangle the effects of  
45 eutrophication and acidification due to N deposition. Note that grass:forb ratio only  
46 increased in 4 of the 8 habitats, and therefore is not a consistent indicator of N impact.  
47

48 Base rich habitats and, to a lesser extent, bogs and mires increased in Ellenberg fertility  
49 index with increasing N deposition which was not necessarily accompanied with a loss in  
50 species richness suggesting that elevated N deposition in these habitats results in a shift in  
51 species composition favouring more nutrient-loving species. In contrast, acid grasslands and  
52 lowland heaths show a small decline in fertility index with increasing N deposition. Others  
53 have also reported lower Ellenberg N values with higher N deposition in acid grasslands  
54 (Maskell et al. 2010) and heathlands (Caporn et al. 2014) and these relationships may be  
55 linked to the high correlation between Ellenberg N and Ellenberg R, suggesting mechanisms  
56 such as acidification to operate in these systems. The exact mechanisms for these  
57 relationships are however not known and need further exploration at the species level of  
58 both vascular plants and bryophytes; studies have shown much greater effects of N  
59 deposition on bryophyte species richness than vascular plant species richness (e.g. Caporn  
60 et al. 2014).

#### 61 *N form and the relative influence of reduced versus oxidised N*

62  $\text{NH}_x$  deposition and  $\text{NO}_y$  deposition are highly correlated. In addition,  $\text{NH}_x$  was highly  
63 correlated to total N deposition. Separate analysis of  $\text{NH}_x$  and  $\text{NO}_y$  effects in models that  
64 allowed us to factor out the variance that was explained by either one of the N forms was  
65 therefore considered the best method to compare effects of these N forms, after taking  
66 account of other variables and the multicollinearity that existed in the datasets. Since both  
67 forms are correlated the variance that is explained by one N form, and which is factored out,  
68 is likely to contain some degree of variance that in fact should be attributed to the other  
69 form. The method that we employed here is therefore considered conservative in its  
70 estimation of effect sizes and significance levels.

71 The range of  $\text{NH}_x$  (2.3 - 36.1  $\text{kgNha}^{-1}\text{y}^{-1}$ ) exceeds that of  $\text{NO}_y$  (2.5 - 25.6  $\text{kgNha}^{-1}\text{y}^{-1}$ ) over all  
72 habitats together. Although the gradient length of explanatory variables may affect the  
73 outcome of the analysis in small data sets (Smart and Scott 2004), large datasets such as the  
74 CS data capture a good proportion of the relationship (i.e. not just a small segment), even  
75 with smaller ranges of the explanatory variable. Our analysis is based on the assumption  
76 that the relationships are linear (transformations were applied when necessary) between  
77 the response variable and either  $\text{NH}_x$  or  $\text{NO}_y$  and estimations of the effect sizes of the  
78 relationships are therefore considered relatively unaffected by the length of the gradients.  
79 Plots of beta coefficients of the regressions for  $\text{NO}_y$  and  $\text{NH}_x$  against N-gradient length

80 confirm that the beta coefficients were indeed not affected by gradient length in the N  
81 ranges that we tested (data not shown). In addition, the modelled  $\text{NH}_x$  data may be more  
82 prone to error in predicting the actual  $\text{NH}_x$  deposition at each site. Although this increased  
83 scatter reduces the likelihood of finding a significant relationship with  $\text{NH}_x$ , the longer  
84 gradient length partly offsets this problem. Therefore the effect sizes give a good indication  
85 of the relative influence of  $\text{NH}_x$  or  $\text{NO}_y$ .

86  
87 The form of N in deposition independent of N load did affect species richness, but only in  
88 certain habitats. N form altered species richness in all grasslands and in woodlands but not  
89 in the mires and heaths. The lack of response of species richness and also grass:forb ratio, to  
90 N form in heaths and mires may be due to the prevailing acidic conditions, restraining  
91 nitrification rates with naturally high soil  $\text{NH}_4^+/\text{NO}_3^-$  ratios and low base cation  
92 concentrations (e.g. De Graaf et al. 2009). Many species of acidic habitats, such as ericoids,  
93 are generally adapted to elevated  $\text{NH}_4^+$  concentrations and tolerate high  $\text{NH}_4^+$   
94 concentrations (De Graaf et al. 1998, Britto and Kronzucker 2002, Sheppard et al. 2014).

95  
96 Where N form was important, in the acidic and mesotrophic grasslands  $\text{NH}_x$  appeared to be  
97 more important than  $\text{NO}_y$  as a driver of species richness decline, corroborating an  
98 experimental study on N form in acid grasslands (Dorland et al. 2013). However, in the  
99 woodlands and in calcareous grassland,  $\text{NO}_x$  was more important than  $\text{NH}_y$ , having a positive  
100 effect on species richness in the grassland but a negative effect in the woodland.  
101 Nitrification and mineralisation in woodlands can be very high (Falkengrengrerup and  
102 Lakkenborgkristensen 1994, Falkengren et al. 1998). Atmospheric deposition of oxidised N  
103 may therefore favour nitrophilous species such as bramble and nettle that outcompete  
104 slow-growing forb and shrub species that are more adapted to ammonium nutrition (such as  
105 *Vaccinium myrtillus*), corroborating a recent simulation study (Stevens et al. this volume).  
106 The positive impact of  $\text{NO}_y$  on calcareous grassland species richness may relate to the  
107 preference of many calcareous species for available N in oxidised rather than in reduced  
108 form.

109  
110 The question remains why the species richness and composition of only some habitats are  
111 sensitive to N form, even though the fertility index of almost all habitats responded to N  
112 form. N form may alter species composition through preferences of the component species  
113 for oxidised or reduced N, through direct toxicity of  $\text{NH}_3$  and  $\text{NH}_4^+$  (Britto and Kronzucker  
114 2002, van den Berg et al. 2005, Sheppard et al. 2011), or through indirect effects mediated  
115 by N-induced acidification (e.g. Bobbink et al. 1998, Stevens et al. 2011), which would be  
116 more apparent in acidic habitats. The lack of significance of N form in the more acidic  
117 habitats suggests that acidification is not the main cause. However, experimental studies  
118 have shown that elevated  $\text{NH}_4^+/\text{NO}_3^-$  ratios in deposition result in a decline of acid-sensitive  
119 species but not of acid-loving species tolerant of high soil  $\text{NH}_4^+/\text{NO}_3^-$  ratios (Paulissen et al.

120 2004, van den Berg et al. 2008). The response in acidic and mesotrophic grasslands may  
121 therefore reflect the abundance of species that are sensitive to reduced N in these neutral  
122 to moderately acidic habitats compared with the more strongly acidophile vegetation in  
123 heaths, bogs and mires. Clearly responses to N form are habitat-specific, and may be driven  
124 by the preference or tolerance of the component species for N in oxidised or reduced forms.

125

126 In conclusion, this study has shown that N affects species richness in almost all habitats,  
127 after correlating factors such as temperature, rainfall and historical sulphur deposition have  
128 been factored out. The form of N is important, with fertility index increasing with  $\text{NH}_x/\text{NO}_y$   
129 ratio in almost all habitats. However, the effects of the ratio on species richness were only  
130 found in certain habitats (grasslands and woodland), not in others (mires and heaths). In  
131 habitats where there were differential effects of one N form or the other, acidic and  
132 mesotrophic grassland were more sensitive to  $\text{NH}_y$ , while calcareous grassland and  
133 woodland were more sensitive to  $\text{NO}_x$ . This study suggests that, contrary to our original  
134 hypothesis, sensitivity to N form is more likely due to the inherent preferences of  
135 component species for oxidised or reduced N, rather than linked to soil acidification.  
136 However, those preferences are related to soil pH with  $\text{NH}_4$ -loving species generally more  
137 prevalent on acidic soils.

138

### 139 **Acknowledgements**

140 We thank Lindsay Maskell for her help with the CS-data and David Fowler for making the N  
141 deposition data available.

1 **Figure legends**

2 **Figure 1** Effect sizes (slopes) of total N deposition on the number of species for UK habitats.  
3 Only significant effects are shown. Actual ranges of N deposition covered by each vegetation  
4 type differs but slopes are shown for a range between 5 and 45 kgNha<sup>-1</sup>y<sup>-1</sup>.

5 **Figure 2** Effect sizes (slopes) of NH<sub>x</sub>:NO<sub>y</sub> ratio in deposition on the number of species for UK  
6 habitats. Only significant effects are shown. Actual ranges of NH<sub>x</sub>:NO<sub>y</sub> ratio covered by each  
7 vegetation type differs but slopes are shown for a range between 0.5 and 3.5.

8 **Figure 3** Effect sizes (slopes) of total N deposition on the Ellenberg N number for UK  
9 habitats. Only significant effects are shown. Actual ranges of N deposition covered by each  
10 vegetation type differs but slopes are shown for a range between 5 and 45 kgNha<sup>-1</sup>y<sup>-1</sup>.

11 **Figure 4** Effect sizes (slopes) of NH<sub>x</sub>:NO<sub>y</sub> ratio in deposition on the Ellenberg N number for  
12 UK habitats. Only significant effects are shown. Actual ranges of NH<sub>x</sub>:NO<sub>y</sub> ratio covered by  
13 each vegetation type differs but slopes are shown for a range between 0.5 and 3.5.

14 **Figure 5** Effect sizes (slopes) of total N deposition on the Grass:Forb ratio for UK habitats.  
15 Only significant effects are shown. Actual ranges of N deposition covered by each vegetation  
16 type differs but slopes are shown for a range between 5 and 45 kgNha<sup>-1</sup>y<sup>-1</sup>.

17 **Figure 6** Effect sizes (slopes) of NH<sub>x</sub>:NO<sub>y</sub> ratio in deposition on the Grass:Forb ratio for UK  
18 habitats. Only significant effects are shown. Actual ranges of NH<sub>x</sub>:NO<sub>y</sub> ratio covered by each  
19 vegetation type differs but slopes are shown for a range between 0.5 and 3.5.

1 **Table 1** Coefficients and their significance for the habitats dry upland heaths, dry lowland heaths,  
2 bogs & mires and base rich mires. Results of a multiple regression (A) and regression analysis of the  
3 residuals of models containing either NH<sub>x</sub> or NO<sub>y</sub> with respectively NO<sub>y</sub> and NH<sub>x</sub> to separate N form  
4 (B) (see methods for details). Results are shown for the response variables: species richness,  
5 Ellenberg N fertility score and grass:forb ratio. Grass:forb ratio was log transformed.
