<b>Abstract:</b>	<p>On October 3, 2013, a global failure occurred in one of the stabilized sections of a deep excavation in Shahrak-e gharb in Tehran. The excavation supported by ground anchors with enlarge reinforced concrete thrust blocks and sprayed concrete facing. The failure occurred despite the system passing conventional limit equilibrium design and satisfying requirements in terms of allowable displacements. This work aims firstly to model the case of Shahrak-e gharb using ABAQUS in order to understand the soil deformation leading to the failure condition. It is shown that a near-surface zone of weaker fill material was responsible for the failure. As displacements during construction and soil failure mechanisms are well matched in the numerical model, the case study is then considered to be a validation case for the numerical model, and a parametric study is performed on the extent to which anchoring bypasses the weaker surface soil. This shows that a proper embedment into the competent soils is important, as excessive strains can still develop if the anchor bond zone is insufficiently confined, potentially leading to progressive collapse.</p>

4 **Abstract**  
5

6 On October 3, 2013, a global failure occurred in one of the stabilized sections of a deep excavation in  
7  
8 Shahrak-e gharb in Tehran. The excavation supported by ground anchors with enlarge reinforced  
9  
10 concrete thrust blocks and sprayed concrete facing. The failure occurred despite the system passing  
11  
12 conventional limit equilibrium design and satisfying requirements in terms of allowable displacements.  
13  
14 This work aims firstly to model the case of Shahrak-e gharb using ABAQUS in order to understand the  
15  
16 soil deformation leading to the failure condition. It is shown that a near-surface zone of weaker fill  
17  
18 material was responsible for the failure. As displacements during construction and soil failure  
19  
20 mechanisms are well matched in the numerical model, the case study is then considered to be a  
21  
22 validation case for the numerical model, and a parametric study is performed on the extent to which  
23  
24 anchoring bypasses the weaker surface soil. This shows that a proper embedment into the competent  
25  
26 soils is important, as excessive strains can still develop if the anchor bond zone is insufficiently confined,  
27  
28 potentially leading to progressive collapse.

1   **1. Introduction**

2   Soil nail and ground anchored systems, respectively classified as passive and active anchorages, are  
3   efficient stabilization techniques for slopes and excavations and have been widely used throughout the  
4   world over the past three decades. Ground anchored walls, also referred to as “tieback walls”, can be a  
5   better method when a structure, sensitive to soil movement, exists near the excavation walls (Lazarte et  
6   al., 2015). This method involves the use of prestressed grouted ground anchors as structural elements  
7   that transmit applied tensile loads into the ground. The basic components of a grouted ground anchor,  
8   including the anchor head, the unbonded length, and the bond length, are presented in Figure 1.

9   The majority of research on stabilized slopes and excavations has focused on soil nail systems, using  
10   both physical model tests (e.g., Tei et al., 1998; Zhang et al., 2001; Hong et al., 2005; Zhang et al., 2013)  
11   and numerical studies (e.g., Smith and Su, 1997; Fan and Luo, 2008; Wei and Cheng 2010; Razavi and  
12   Hajjalilue Bonab 2017). There are also some studies in which the behavior of ground anchored systems  
13   has been investigated. Briaud and Lim (1999) conducted numerical modeling to study the effect of  
14   various design decisions for a 7.5 m tieback wall. The numerical model was calibrated against an  
15   instrumented case history. Their results provided some information about the impact of the anchor  
16   forces, the location of the anchor unbonded zone, the stiffness of the wood lagging, and the  
17   embedment of the soldier piles on the wall behavior. Finno and Roboski (2005) studied 3D ground  
18   deformations of a 12.8 m tieback excavation in which the support was provided by a sheet pile wall and  
19   three levels of ground anchors. A performance-based relationship as a function of safety factor against  
20   basal heave and excavation depth was proposed for the estimation of lateral ground displacement. Their  
21   empirical method was presented to predict the distribution of ground deformations parallel to the  
22   excavation wall. Kim et al. (2007) proposed a finite element method and a beam-column method to  
23   study the load transfer mechanism of ground anchors. Their numerical results were compared with field

24 measurements. It was reported that both methods could provide reasonable predictions on the load-  
25 displacement behavior of ground anchors.

26 The main purpose of most of these research works has been to study the effect of various components  
27 on the stability of the soil nail and ground anchored retaining systems, while the serviceability and  
28 deformation behavior of these retaining walls have received less attention. Furthermore, conventional  
29 soil nail reference manuals (e.g., Lazarte et al., 2015) and also ground anchored systems guides (e.g.,  
30 Sabatini et al., 1999), which are based on limit equilibrium methods, recommend just a simple equation  
31 as a function of wall height for the allowable displacements and provide little information about  
32 predicting the movement of these walls. Consequently, designers often conduct numerical simulations  
33 to estimate the wall movements. However, using the maximum lateral displacement as the outcome of  
34 the numerical analysis and its comparison with the allowable displacement cannot always make a  
35 comprehensive picture of the wall behavior. This is because the performance of ground anchored walls  
36 is significantly influenced by their complex interaction with soils. Furthermore, other factors, such as the  
37 grout injection method, the type of vertical support, the connection between the anchor head and the  
38 bond zone, the presence of weak soil layers, are also likely to affect the behavior of ground anchored  
39 walls. There is, therefore, a need for rigorous investigation regarding the effect of each component on  
40 the ground anchored wall performance.

41 In this research, a finite element procedure is proposed for deformation analysis of a deep post-grouted  
42 ground anchored excavation. Special attention is given to the precise simulation of contact interactions  
43 between the reinforcing elements and the surrounding soil. To verify the proposed numerical model,  
44 the computed deformations are compared with the measured lateral displacements of a case study  
45 ground anchored wall. Utilizing this verified FE model, the following issues are investigated. First, the  
46 reason behind the collapse that occurred in one of the sections of this case is discussed. Following this,  
47 the efficiency of the service limit state requirements for ground anchored excavations is investigated by

1  
2  
3  
4 48 comparing the maximum predicted displacement with the allowable value. Then, a true distance  
5  
6 49 between the bond zone of the uppermost anchors and the top fill layer is explored, particularly an  
7  
8  
9 50 extent to which the anchoring mechanism does not develop excessive strain around the embedded area  
10  
11 51 of the anchors.  
12  
13  
14

## 15 52 **2. Case study background**

16  
17  
18 53 On 3 October 2013, a failure occurred in one section of a deep excavation project known as Iran-zamin  
19  
20 54 Excavation, located in the Shahrak-e gharb in the heart of Tehran, the capital of Iran. As shown in Figure  
21  
22  
23 55 2(a), the project site had a triangle-shaped plan with an area of 16000 m<sup>2</sup>. The target excavation depth  
24  
25 56 was planned to be 40 m.  
26  
27

### 28 29 57 **2.1. Design considerations**

30  
31 58 To stabilize the excavation walls, a ground anchor system, including post-grouted ground anchors  
32  
33 59 supported by reinforced concrete blocks, was employed (S.E.S. Consulting & Contracting Co., 2013). In  
34  
35 60 this method, as can be seen in Figure 3(a), reinforced concrete blocks, located just behind each anchor  
36  
37  
38 61 head, were used rather than more conventional vertical connectors, e.g., soldier beams (Figure 3(b)) or  
39  
40 62 sheet-piles.  
41  
42

43  
44 63 In this project, the excavation support system was designed for short-term conditions with the allowable  
45  
46 64 stress design approach given in FHWA (Sabatini et al., 1999). The safety factor against overall stability  
47  
48 65 was checked to be at least 1.35 using limit equilibrium analysis by Geo-Slope software. The ultimate  
49  
50 66 displacement of the excavation walls was limited up to 0.005H, where H represents the wall height.  
51  
52  
53 67 Numerical modeling was also carried out using PLAXIS software to evaluate maximum displacements  
54  
55 68 (S.E.S. Consulting & Contracting Co., 2013).

69 As shown in Figure 2(a), the design of the support system was divided into 14 sections with similar  
70 stratification and height, named North-1, North-2, etc. A bond length of 6 m was considered for post-  
71 grouted ground anchors. The anchors were composed of six 15-mm-diameter steel strands having an  
72 ultimate strength of 260 kN. Using multiple high strength steel strand, provided the possibility of  
73 defining a design prestress load of 900 kN to achieve an adequate safety factor against overall stability  
74 and also reducing the lateral displacements of the excavation walls (S.E.S. Consulting & Contracting Co.,  
75 2013). The mechanical properties of the ground anchors, including bond length and unbonded length,  
76 are shown in Table 1. Just behind each anchor head, a cast-in-place reinforced concrete block was  
77 planned to transmit anchor prestress load to the soil mass and also to prevent punching shear of the  
78 anchor head. These blocks were designed like an isolated footing with length, width, and thickness of  
79 1.2 m, 1.2 m, and 0.45 m, respectively. Moreover, a 100-mm-thick layer of reinforced shotcrete facing  
80 was used to keep the soil from weathering and surficial failure (S.E.S. Consulting & Contracting Co.,  
81 2013). The mechanical parameters of the reinforced concrete blocks and facing are also presented in  
82 Table 1.

83 **2.2. Subsoil conditions**

84 In terms of general geology, the project region represents the distribution of the Pliocene and  
85 Quaternary alluvial deposits in Tehran plain. Tehran alluvium formations are divided into four groups: A  
86 (Hezardarreh formation), B (Kahrizak formation), C (Tehran Alluvial formation), and D (Recent Alluvium).  
87 The main characteristics of Tehran alluvium formations are given in Table 2 (Sharifzadeh et al., 2013).  
88 The project region contained A formation in the middle, northern and western areas of the site while it  
89 contained younger C formation underlain by A formation in the southern and eastern areas (Z.S.A.  
90 Consulting Co., 2012).

91 To investigate underground conditions, nine boreholes (BH-1 to BH-9) were sunk to depths between 50  
92 m and 97 m. Besides, two 5.5-m-deep and 7.5-m-deep trial pits were excavated (Z.S.A. Consulting Co.,  
93 2012). Figure 2(a) shows the positions of the various boreholes and trial pits in the project plan. Detailed  
94 information from all the boreholes located on the site is presented in Figures 4 and 5. Figure 4 shows the  
95 profiles of the SPT-N values, fines, sand, and gravel contents with depth. As shown in Figure 4(a), the N  
96 values exceed more than 50 from depths of 4 m toward the end of boreholes, although there are some  
97 fluctuations until a depth of approximately 10 m below the ground surface. Figure 4(b) illustrates that  
98 the fine contents range from 20% to 80%, with more distributions below 50%. As shown in Figures 4(c)  
99 and (d), the coarse material mostly consists of sand. Figure 5 shows the distribution of moisture  
100 contents together with Atterberg limits and plasticity index with depth. The moisture contents range  
101 from 3% to 23%, and the liquid limits range between 29% and 48%, which indicates that the fine  
102 material in this site had low plasticity. The plasticity index is in the range of 10% to 28% showing that the  
103 fine contents are mainly from clay material. Site investigations revealed the existence of weak fill  
104 material at the top of soil profiles, with a variable depth between 4 m and 8.5 m in different sections.  
105 This is a common soil layer for many nearly developed areas in Tehran, where extensive leveling has  
106 resulted in a thick fill layer. The distribution of the fill layer in different sections is shown in Figure 2(b).  
107 Deeper soils below the fill layer were largely composed of dense to very dense clayey sand with gravel  
108 (SC), with more than 20% clay, and very stiff to hard lean clay with sand (LC) (Z.S.A. Consulting Co.,  
109 2012).

110 In terms of subsurface water conditions, geotechnical exploration and GPR (Ground Penetration Radar)  
111 tests showed only some local perched water zones at different depth surrounding the site. A dewatering  
112 and drainage system, including some deep vertical wells and prefabricated vertical drains behind the  
113 shotcrete facing, was designed to remove any risk induced by underground water (Z.S.A. Consulting Co.,  
114 2012).

115 To determine the shear strength parameters of the subsoil, an in situ direct shear test and several sets  
116 of lab direct shear tests and triaxial tests were carried out during the site investigation. The in situ direct  
117 shear test, which was conducted at the bottom of trial pit 2, showed a cohesion of  $c'=24$  kPa and a  
118 friction angle of  $\phi'=40.8$  for the clayey sand. According to the result of lab tests, the cohesion ranged  
119 from 0 to 30 kPa, and the friction angle ranged between  $22.9^\circ$  and  $42^\circ$  (Z.S.A. Consulting Co., 2012).

**2.3. Construction method**

121 The excavation support system was constructed in some main construction phases. Each phase was  
122 corresponding to an excavation lift. To stabilize the unsupported cut following each excavation lift, a  
123 staged-construction method was performed. Using the ODEX method, several 147-mm-diameter holes  
124 at an angle of  $10^\circ$  or  $13^\circ$  with respect to the horizontal plane were drilled into the excavated face to  
125 install the ground anchors. Parsapajouh et al., (2012) described the detail of installing the post-grouted  
126 anchors. Subsequently, a square opening, surrounding each anchor head, was dug down for each  
127 reinforced concrete block (Figure 3(a)) and followed by placing a special rebar mesh. After installing  
128 timber formwork and reinforcing bars, the openings were filled with concrete, and then the excavated  
129 face was covered with a 100-mm-thick reinforced concrete layer utilizing the shotcrete technique. At the  
130 final stage, following installing the bearing plate, the prestress load of each anchor was applied.

**2.4. The behavior of ground anchored excavation walls**

132 As shown in Figure 2(a), 14 monitoring sections (named NP1, NP2, ..., WP1, and so on) were planned in  
133 this project. In each monitoring section, from 2 to 5 points on the wall face (in total, more than 50  
134 points) were monitored using survey equipment during the construction. The construction had been  
135 carried out for 12 months without incident. However, in early October 2013, when the section North-2  
136 was being excavated at a depth of approximately 32 m, the lateral displacement of this section  
137 substantially increased, ending in global collapse. Figure 6 illustrates the wall failure had an extent of 18

1  
2  
3  
4 138 m down the face of the wall (Figure 6(a)) and 12 m perpendicular to the wall (Figure 6(b)). Figure 7  
5  
6 139 shows some cracks, induced by such failure, on the neighboring buildings located in the north of the  
7  
8  
9 140 collapsed section. After the wall failure, it was observed that the depth of fill soil layer around this  
10  
11 141 section was approximately 10 m rather than 6.8 m used in the design process. Figure 8 indicates the  
12  
13  
14 142 stratification of section North-2, based on the site investigation as well as the post-collapse  
15  
16 143 observations. The properties of each soil layer used in the design of the excavation support system are  
17  
18 144 shown in Table 3. The reliability of these values was again confirmed through further site investigations  
19  
20  
21 145 conducted after the collapse.

22  
23  
24 146 In this section, ten rows of ground anchors had been used, all of which had a lock-off load of 900 kN.  
25  
26 147 The first row of anchors was inclined at 13° with respect to the horizontal plane, and the other rows  
27  
28  
29 148 were inclined at 10°. Figure 8 shows the schematic positions of the ground anchors and their unbonded  
30  
31 149 length for the same section. The vertical distance between the head of the ground anchors is also shown  
32  
33 150 in Figure 8. The horizontal distance between the ground anchors in the first row, in the second to the  
34  
35  
36 151 ninth rows, and in the tenth row were 3.1 m, 3.4 m, and 1.8 m, respectively. In the design of section  
37  
38 152 North-2, the computed factor of safety against overall stability was predicted to be 1.371, and the  
39  
40 153 maximum lateral and vertical displacement were estimated to be 57 mm and 62 mm, respectively (S.E.S.  
41  
42  
43 154 Consulting & Contracting Co., 2013). The predicted values, including safety factor and maximum  
44  
45 155 displacements, had satisfied the requirements specified by FHWA (Sabatini et al., 1999).

46  
47  
48 156 Despite the collapse in section North-2, most of the other wall sections showed a sensible and safe  
49  
50  
51 157 performance during construction. Monitoring results of section North-4, which was undamaged, is used  
52  
53 158 as a part of validation assessment for the following numerical simulation. In this section, all ten rows of  
54  
55  
56 159 ground anchors had a prestress load of 900 kN and were inclined at 10° with respect to the horizontal  
57  
58 160 plane. The unbonded length of ground anchors and the vertical distance between the anchors head are  
59  
60 161 shown in Figure 9(a). The horizontal distance between ground anchors in the first nine rows was 3.4 m

1  
2  
3  
4 162 while it was 1.8 m in the tenth row (lower row). Figure 9(a) also shows the thickness of different soil  
5  
6 163 layers in section North-4, where the fill soil layer had a depth of 4.3 m. In the design process of section  
7  
8  
9 164 North-4, the computed factor of safety against overall stability was predicted to be 1.456, and the  
10  
11 165 maximum lateral and vertical displacement were estimated to be 51 mm and 61 mm, respectively (S.E.S.  
12  
13  
14 166 Consulting & Contracting Co., 2013). All the predicted values had satisfied the requirements specified by  
15  
16 167 FHWA (Sabatini et al., 1999). Figure 9(b) shows that this section had a height of 31 m in which lateral  
17  
18 168 displacements at three points (NPA, NPB, and NPC), located at a distance of 1.5 m, 4.4 m and 16.3 m  
19  
20  
21 169 below the crest of the wall, respectively, were monitored.

22  
23  
24 170 In the design process, all the wall sections were predicted to be safe, while global collapse occurred in  
25  
26 171 one of the sections. Therefore, the current study is further conducted to explore the actual reason for  
27  
28  
29 172 the collapse, utilizing the finite element method. This case study can further help to explore the effect of  
30  
31 173 different system variables.

### 35 174 **3. Numerical modeling of the post-grouted ground anchored walls**

36  
37  
38 175 The behavior of the anchor-stabilized walls is investigated using a stress-deformation analysis. The  
39  
40 176 construction sequence of post-grouted ground anchored walls, as well as contact interactions between  
41  
42 177 reinforcing elements surfaces and the surrounding soil, are dominant factors which can affect the result  
43  
44  
45 178 of a numerical analysis. In this study, a numerical analysis procedure is conducted to reasonably cover  
46  
47 179 these issues.

#### 50 180 **3.1. Finite element modeling**

51  
52  
53 181 The two wall sections studied in the current study are long enough and far from the corners of the site  
54  
55 182 plan. Due to the satisfaction of the plane strain condition, a 2D numerical model is adopted to perform  
56  
57  
58 183 the numerical analysis using the ABAQUS software. The motivation for employing this software is its  
59  
60 184 successful results, obtained in various geotechnical issues (Helwany, 2007) especially numerical

185 simulation of soil-nailed slopes (Zhou et al., 2009), ground anchored slopes (Kim et al., 2013) and ground  
186 anchored walls (Briaud and Lim, 1999). Moreover, the connection between model components has a  
187 significant effect on the result of numerical simulation, and ABAQUS is able to accurately simulate  
188 discrete elements of a model (Hibbitt et al., 2016).

189 In the present study, soil and concrete blocks are simulated by the homogeneous solid section, facing is  
190 modeled using the beam section, and ground anchors are simulated by the truss section. The properties  
191 of the reinforcing elements and soil layers (Table 1 and Table 3) have been used to specify the section  
192 characteristics in numerical modeling. The linear-elastic behavior is used for the ground anchors, the  
193 reinforced concrete blocks, and the facing in the numerical modeling. The Mohr-Coulomb constitutive  
194 model using non-associated flow rule is employed for the surrounding soil. This model is believed to be  
195 suitable since the system is largely governed by frictional failure, and also it has been previously used for  
196 similar subjects (Kim et al., 2013). The parameters of the Mohr-Coulomb model are Young's modulus  
197 ( $E'$ ), and Poisson's ratio ( $\nu$ ) for soil elasticity; angle of shearing resistance ( $\varphi'$ ), and cohesion ( $c'$ ) for soil  
198 plasticity, and angle of dilation ( $\psi$ ).

199 The FE mesh used in the analysis is shown in Figure 10. The mesh pattern is symmetrically designated for  
200 the left and right sides of the wall face. A relatively fine mesh is used in the zone of anchors, and the  
201 mesh size becomes coarser farther from the reinforced area. The four-node bilinear plane strain  
202 quadrilateral element, known as CPE4, with full integration is used to mesh the soil and the concrete  
203 blocks. The two-node linear two-dimensional truss element (T2D2) and the two-node linear beam in a  
204 plane element (B21) are employed to mesh the anchor bond length and the facing, respectively.

205 As is shown in Figure 10, the distance from the right and left boundaries to the wall face are chosen  $2H$ ,  
206 where  $H$  is the height of the wall. The bottom boundary is selected at a distance of  $H$  from the  
207 excavation subgrade. Kim et al., (2013) employed similar distances for the side and bottom boundaries

208 to study the stability of a ground-anchored slope using finite element modeling. These dimensions are  
209 assumed to be adequate to eliminate the boundary effects on the wall performance. The side  
210 boundaries are constrained against the horizontal movement while the bottom boundary is constrained  
211 against the horizontal and vertical movements.

**3.2. Numerical procedure for simulating the interaction between reinforcing elements and surrounding soil**

213 In practice, the bond zone in post-grouted ground anchors is performed using multiple grout injections  
214 under high-pressure to enlarge the grout body of straight-shafted gravity grouted ground anchors. Due  
215 to this installation method, there would be no distinctive interface between the anchor bond zone and  
216 the surrounding soil, as shown in Figure 11(b). To properly model this, any slippage on the interface  
217 between these two components should be restricted in numerical modeling. The embedded-region  
218 constraint, which allows a part of the model to be embedded within a host area of the model, is  
219 employed to confine anchor bond length inside the soil. As a result, the translational degrees of freedom  
220 of the embedded elements (anchor bond zone) are constrained to the surrounding soil, and the  
221 reinforcement mechanism of post-grouted anchors is appropriately simulated.

222 As can be seen in Figures 1 and 11, the unbonded length is that portion of the prestressed steel that is  
223 free to elastically elongate and transfer the resisting force from the bond length to the structure  
224 (Sabatini et al., 1999). Therefore, if a one-dimensional linear elastic relationship between the anchor  
225 head (point “A” in Figure 11(b)) and the beginning point of anchor bond length (point “B” in Figure  
226 11(b)) is developed, it can simulate the real performance of the anchor unbonded length. This idea is  
227 performed in a three-stage process throughout the FE modeling. First, a virtual wire is created between  
228 points A and B, and these points are defined as the reference points. Following this, one transitional  
229 degree of freedom along the wire is established utilizing the axial connector. The process culminates  
230 with specifying the linear elastic behavior between points A and B along the wire.

231 The reinforced concrete blocks do not slide relative to soil surfaces because these blocks are placed  
232 inside the cut. The tie constraint is used to constrain the blocks into the soil. The use of this type of  
233 constraint permits two separate surfaces to be fused together to avoid any relative movement between  
234 them.

235 Finally, based on the performed construction method of facing, it is assumed that relative movement  
236 between the facing and the adjacent soil does not take place. Thus, the interface between the shotcrete  
237 facing and the soil is described as perfectly rough by implementing the embedded-region constraint,  
238 which can accurately model beam elements (like facing) lying embedded in solid elements.

239 **3.3. Numerical procedure of stress-deformation analysis**

240 The stress-deformation analysis, including the construction sequence of ground anchored walls, is  
241 performed to obtain the wall movements. The numerical techniques for simulating interactions between  
242 the reinforcing elements and the surrounding soil, described in the previous section, are implemented in  
243 the FE modeling. The following steps, as shown in Figure 12, are required for the stress-deformation  
244 analysis:

245 Step1: The 2D FE mesh, including the ground anchors, facing, and reinforced concrete blocks, is  
246 generated. The whole excavation zone is divided into ten partitions corresponding to the real  
247 construction phases (excavation lifts) in the field (Figure 12(a)). The depth of the excavation lifts is 1m  
248 below the elevation where the relevant row of anchors is installed. These elevations were presented  
249 earlier in Figures 8 and 9(a) for sections North-2 and North-4, respectively.

250 Step 2: The natural condition of ground layers is modeled by deactivation of all the reinforcing elements.  
251 The properties of soil layers are assigned, and the boundary conditions are applied to the model (Figure  
252 12(b)).

1  
2  
3  
4 253 Step 3: The initial ground stresses are applied to the FE model using the geostatic analysis procedure in  
5  
6 254 which in situ stresses are generated without any deformation (Figure 12(c)).  
7  
8  
9  
10 255 Step 4: The first layer of soil, corresponding to the initial excavation lift, is removed (Figure 12(d)).  
11  
12  
13 256 Step 5: The relevant reinforcing elements of the current phase, including the bond length of the ground  
14  
15 257 anchor, the reinforced concrete block, and the facing, are activated with their material properties. The  
16  
17 258 interaction between the reinforcing element and the soil is generated. During this step, the gravity  
18  
19  
20 259 forces are applied to the new reinforcing elements added to the system (Figure 12(e)).  
21  
22  
23 260 Step6: The simulated feature for modeling the anchor unbonded length is generated (Figure 12(f)).  
24  
25  
26 261 Step 7: The prestress load of the related anchor is applied along the wire between the first reference  
27  
28 262 point (anchor head), and the second reference point (starting point of the anchor bond length), (Figure  
29  
30 263 12(g)).  
31  
32  
33  
34 264 Step 8: The stress-deformation analysis is performed. This step experiences the static-general analysis  
35  
36 265 procedure in which changes in stress and corresponding displacements are produced (Figure 12(h)).  
37  
38  
39 266 As the ground anchored support system was constructed in ten excavation phases, steps 4-8 of the  
40  
41 267 above are repeated ten times to obtain the wall deformation at the end of each construction phase. This  
42  
43 268 approach provides the possibility of comparing numerical results with those measured in the site at the  
44  
45  
46 269 end of each construction phase.  
47  
48  
49

274 wall movements are shown with negative quantities. The observed lateral displacements of point NPA at  
275 the end of construction phases as well as the numerical results are presented in Figure 13(a). Since  
276 monitoring of point NPA was started at the end of the third construction phase, the field deformations  
277 are compared with the numerical data from this phase. Comparison of the field lateral displacements of  
278 point NPB as well as their computed results are shown in Figure 13(b). Similarly, this point was  
279 monitored from the end of phase 3, so both the measured data and the predicted movements are  
280 presented from this phase. As is shown, the calculated values for both NPA and NPB are in good  
281 agreement with the recorded data except those lateral displacements that are computed at the end of  
282 the third and fourth steps. The computed lateral displacements of both NPA and NPB, at the end of the  
283 third and fourth phases, predict a slight inward movement. This movement is due to the huge prestress  
284 loads applied to the anchors at each phase, causing the points close to the crest of the wall (like NPA  
285 and NPB) to show marginal inward movements, as long as the excavated depth is less than about 12 m  
286 (end of step 4).

287 Figure 13(c) draws a comparison between the recorded lateral displacements of point NPC and the  
288 computed results. As monitoring of point NPC was begun at the end of phase 6, the comparison is  
289 illustrated from this phase. The calculated lateral movements at various construction phases agree well  
290 with the measured data with the predicted values slightly higher than the displacement monitored in  
291 the site.

292 **4.2. Numerical simulation of the collapse**

293 To simulate the wall behavior in section North-2, the depth of the top soil layer has been modified  
294 according to the in situ observation after the collapse. Figure 14 indicates the contours of computed  
295 lateral displacement following complete construction. The deformed shape of the wall face due to  
296 lateral movements is also presented in Figure 14. As is shown, a maximum lateral movement of 103 mm

297 is predicted in the middle of the wall height (at the base of the fill soil layer). Besides, a significant lateral  
298 displacement of about 70 mm can be seen around the bond zone of the two top rows of ground anchors  
299 located in the top soil layer of fill material. The predicted wall deformations are less than the allowable  
300 limit (160 mm). However, failure still occurred, suggesting that judging the stability of a deep ground  
301 anchored wall by just comparing the numerically predicted displacement with the allowable value may  
302 be insufficient as a comprehensive assessment of the wall serviceability. In this study, the potential  
303 failure surfaces are located where the greatest total strain occurs. Figure 15 illustrates two developed  
304 failure surfaces from the maximum total strain distribution plot. The first surface is located in the bond  
305 zone of two top anchors, extending toward the lower anchors and the ground surface. This interior  
306 failure surface seems to play a significant role in the expansion of the second failure surface, located  
307 close to the wall facing. When this shallow failure surface is noticed, it can be seen that the computed  
308 depth of failure surface is 18.1 m compared to the depth of 18 m measured on the site, and the  
309 predicted breadth of the failure surface is 11.5 m compared to the measured 12 m, which gives  
310 confidence that the FE model is capable of properly modeling the observed failure. To draw a clear  
311 reason for the collapse, based on numerical analysis, it can be concluded that since the bond length of  
312 two top anchors were placed in the weaker fill soil layer, when the excavation reached to a depth of 32  
313 m they failed to transfer the developed bond stress into the soil. This is because the load of anchors at  
314 the excavated depth of 32 m had increased to more than their initial lock-off load. Thus, these anchors  
315 were pulled out of the soil, and a large lateral displacement was created in their bond zone, leading to a  
316 shallow failure.

317 **4.3. Effect of top fill layer on the occurrence of failure**

318 Since the numerical model has matched the observed failure as well as the recorded wall displacements  
319 during the construction phases, it is a suitable model for further investigation. If the depth of fill soil  
320 layer around section North-2 had been accurately estimated, the occurred failure would have been

321 avoided. This is particularly important for the areas where past activities have created a thick layer of  
322 loose fill material near the ground surface. Thus, this section aims to discuss what kind of considerations  
323 should be taken into account concerning the position of bond zone of the uppermost anchor to reach an  
324 adequate level of serviceability when a thick loose fill layer exists at the top of the soil profile.

325 Accordingly, the following six models are considered. Model 1 represents the section North-2 in which  
326 the depth of the fill layer is modeled based on the initial estimation in the original design of the ground  
327 anchored excavation. In this model, all the ground anchors are located in competent soil. However, the  
328 vertical distance between the center of the uppermost anchor bond zone and the fill layer,  $d$ , is  
329 approximately 1.6 m. Figure 16(a) indicates the position of the bond zone of the uppermost anchor in  
330 Model 1. To evaluate the effect of “ $d$ ” on the wall behavior, this distance is increased in the next  
331 models. Such an increase is performed by enlarging the unbonded length of the anchor, with an  
332 increment of 1 m, while keeping all other parameters constant. Figure 16(b) illustrates Model 6, in which  
333 “ $d$ ” is increased to 2.8 m.

334 Figure 17 shows the lateral wall displacements of all six models as a function of wall height. As can be  
335 seen, a maximum lateral movement of 66 mm, which takes place in the middle third of the wall height,  
336 is predicted for Model 1. This value is less than the allowable limit, and the wall is assumed to have an  
337 acceptable serviceability level. To determine possible failure conditions, the result of the maximum total  
338 strain distribution in Model 1 is presented in Figure 18(a). As is shown, a partial failure surface can be  
339 distinguished behind the bond zone of the uppermost anchor, developing to the two lower anchors and  
340 also the ground surface. This observation confirms that the potential failure surfaces may not be  
341 detected using predicted deformations during wall design. In addition, if Figure 18(a) is compared with  
342 Figure 15, it can further support the idea that the interior failure surface has an important effect on the  
343 formation of the shallow failure surface. In other words, it can be concluded that the occurred failure

344 was progressive collapse starting from the bond zone of two top ground anchors and then led to the  
345 shallow collapse.

346 More attention in Figure 17 indicates that when “d” increases from 1.6 m (in Model 1) to 2.8 m (in  
347 Model 6), the maximum lateral wall movement experiences a marginal decline of 7 mm. At first glance,  
348 such an increase in the magnitude of “d” may be regarded unimportant. However, a comparison  
349 between the maximum total strain contour plots in Models 1, 4, and 6 (Figures 18(a)-(c), respectively)  
350 reveals that such an increase for “d” causes gradual elimination of any potential interior failure surfaces.  
351 If Model 1 is compared with Model 6, it can be seen that the strain values have experienced a moderate  
352 decrease and the local failure surface behind the bond zone of the uppermost anchor has been perfectly  
353 removed. As a result, although the predicted value of maximum displacement in Model 1 meets the  
354 requirement limit, to eliminate any partial failure surface that may lead to progressive collapse, it is  
355 recommended that the uppermost anchors bypass the top fill layer into the competent soil to the extent  
356 that anchoring mechanisms no longer cause excessive strain around the embedded area of the anchors.

**5. Conclusion**

The following findings can be drawn from the current study:

- 359 1. It was found out that the wall failure was progressive collapse starting from the bond zone of two top  
360 rows of ground anchors located in the top soil layer of fill material.
- 361 2. Stress-deformation analyses revealed the possibility of the collapse for two following circumstances:  
362 actual soil layer conditions after the collapse and soil layer conditions based on the initial subsurface  
363 investigation. However, the maximum displacements in both cases, obtained by numerical modeling,  
364 satisfied the allowable limit, 0.005H. Thus, meeting this requirement cannot always guarantee the wall  
365 serviceability.

366 3. Studying the distribution of generated maximum total strains in the soil surrounding the anchor bond  
367 zone can be regarded as a further desirable criterion for analyzing the performance of post-grouted  
368 ground anchored walls. This is because such observation can exhibit the potential local failure surfaces  
369 in weaker soils where anchoring mechanisms may develop excessive strain around the embedded area  
370 of the anchors.

371 4. In the case of the existence of a thick layer of fill material at the top of the soil profile, the  
372 embedment of the bond zone of the uppermost anchors into the competent soil can reduce the  
373 maximum lateral wall displacement, while this might not be sufficient by itself for the safe wall  
374 performance. The uppermost anchors should be adequately confined into the competent soil to the  
375 extent that eradicates local failure from the confined area that can lead to progressive collapse. For a  
376 6.8-m-thick fill layer at the top of the soil profile, increasing the vertical distance between the bond zone  
377 of the uppermost anchor and the top fill layer by 1.2 m (from 1.6 m to 2.8 m) could eliminate the cause  
378 of concern of any local failure.

379 5. Unlike the passive ground anchored walls in which the maximum lateral deformation takes place at  
380 the top of the wall, for a deep ground anchored wall (32 m high) supported by active reinforcement  
381 systems, the peak movement was observed in the middle third of the wall height. This issue is  
382 specifically crucial when critical points need to be selected for the performance-monitoring plan during  
383 the wall construction.

384 6. In the design process of the ground anchored walls, wall deformations are considered as service limit  
385 states. These limit states refer to the conditions which do not involve collapse. This case shows that wall  
386 movements may be the primary design issue (strength limit state) for an excavation support system  
387 located in a major urban area. Besides, more experimental and numerical works should be performed to  
388 investigate the tolerable deformation limits for deep ground anchored walls.

Table 3. Geotechnical parameters of soil layers used in design (S.E.S. Consulting &amp; Contracting Co., 2013)

Layer	Type	Geotechnical parameters					
		$\gamma$ (kN/m <sup>3</sup> )	E' (MPa)	Poisson's ratio	c' (kPa)	$\phi'$ (deg)	$\psi$ (deg)
Top layer	Fill material	18	15	0.3	10	25	0
Middle layer	Coarse material with caly	21	80	0.3	40	40	0
Base layer	Coarse material with caly	21	125	0.3	100	40	0
