Abstract

The space in which organisms live determines health and physicality, shaping the way in which they interact with their peers. Space, therefore, is critically important for species diversity and the function performed by individuals within mixed communities. The biotic and abiotic factors defined by the space that organisms occupy are ecologically significant and the difficulty in quantifying space-defined parameters within complex systems limits the study of ecological processes. Here, we overcome this problem using a tractable system whereby spatial heterogeneity in interacting fungal wood decay communities demonstrates that scale and patchiness of territory directly influence coexistence dynamics. Spatial arrangement in 2- and 3- dimensions resulted in measurable metabolic differences that provide evidence of a clear biological response to changing landscape architecture. This is of vital importance to microbial systems in all ecosystems globally, as our results demonstrate that community function is driven by the effects of spatial dynamics.

Introduction

Space determines the nature of and scale over which individuals meet and interact. The characteristics of the discrete spatial habitat which an organism occupies affects individual competitive success with a bottom-up effect on population-wide colonisation, speciation and extinction [1]. There is a dynamic link between spatial ecology and competitive success where transitive (where species A outcompetes B, which outcompetes C) communities with a strict competitive hierarchy become intransitive (A > B; B > C; C > A, like the game of rock-paper-scissors) when competing in a spatially more complex system [2], allowing individuals outcompeted under some scenarios to coexist with their competitors [3]. Dimensionality of habitat landscapes influences individual behaviour [4], and stochasticity of species interactions results in changes to the pool of community-produced metabolites [5], altering individual combative ability, community succession and structure between 2- and 3-dimensional landscapes [6]. Despite these findings, the mechanisms that influence stability and succession in the context of how communities occupy and exploit space are rarely adequately quantified as most ecological study systems are too complex and largely intractable. A model system is needed that allows such quantification, and understanding of how altered dynamics, coexistence and community-scale biodiversity in the context of space underpins changes in community function.

The functional diversity-area relationship, i.e. the correlation between increased habitat size and greater functional diversity, is one theory explaining how space mediates function in biodiverse communities [7]. However, the model does not account for effects of distributions and patch dynamics of species within habitats of varied area, yet these factors cause competitive communities to shift between hierarchical transitive and non-hierarchical intransitive relationship states [2,8]. Non-hierarchical intransitivity is an established mechanism of coexistence [9,10] and is thought to be associated with an intrinsically related functional-diversity mechanism [11,12]. Wood decay fungi offer an ideal ecologically relevant model for the study of these processes as they occupy columns of decay forming complex 3-dimensional communities in wood and, through their decomposition

activities release carbon and nutrients [13]. They typically form a hierarchical community structure (tertiary/late stage colonists outcompete secondary colonists which in turn outcompete primary/earliest colonists) [14] and competitive interactions between species can be easily observed [15]. In addition to compounds that primarily function in the exploitation and decomposition of lignocellulose [16,17], these fungi produce a plethora of potentially antagonistic compounds which function in changing territory, and differ in quantity and identity during interspecific competition [6,18,19,20].

Here, we used a tractable system of wood decay fungi to quantify the impact of space on the mechanisms of coexistence and community composition, in the context of its occupation and exploitation. We compared the combative abilities of fungi in linear 2-dimensional systems and species richer 3-dimensional systems. The study system allowed more detailed analysis of community dynamics between 3-dimensional systems where fungi were dispersed in evenly spaced patches and 3-dimensional systems where the weakest member of the community occupied the same volume but as a larger adjacent patch size. Previously, our data revealed an emergent property where intransitivity promoted biodiversity in more spatially diverse 3-dimensional systems where territory was less fragmented [2]. Here, we assess the underlying mechanisms causing community stability and coexistence dynamics to change. We do this by measuring the metabolic response of an individual to changing coexistence dynamics across spatial scales. Our large-scale untargeted metabolomics and other chemical methods analysed a comprehensive network of intracellular, extracellular and gas-phase metabolic products produced during community interactions. We hypothesised that stochasticity of species would influence functional biochemical processes, and that changes to metabolites involved in pathways for resource utilisation and antagonism would alter coexistence dynamics and community composition. Spatially heterogeneous systems containing non-hierarchical communities promote biodiversity [2,21], and here we deepen our understanding of this concept with the novel finding that space occupied alters metabolic function and coexistence, therefore moderating the diversity-function relationship.

Methods

Experimental design and sampling

We constructed pair-wise interactions of 2 cm^3 *Fagus sylvatica* (beech) blocks that had been pre-colonised for 12 weeks by placing on agar (5 gL-1 malt extract, 15 gL-1 agar; Lab M, UK) cultures of *Hypholoma fasciculare*, *Trametes versicolor* and *Vuilleminia comedens* wood decay fungi at 20 °C (as in [2]). Interactions were performed in all combinations including, self-pairings (n = 10). We also constructed 3x3x3 27-block cubes containing 9 blocks of each species. 27-block cubes were arranged with all three species dispersed and no two blocks of the same species in contact (n = 10), and also so that all 9-blocks of the weakest competitor, *V. comedens*, occupied an adjacent volume while the other two fungi were dispersed (n = 10) (Fig. 1). Plus, entire 27-block assemblages containing each fungus solely were made [2]. Blocks in pair-wise interactions were arranged with cut vessel ends touching, and in 27-block cubes blocks were joined such that some cut vessel ends were touching but others were not, but all vessels were parallel (Fig. 1). Fungal species and specific strains were selected based on their successional order and expected combative hierarchy in the natural environment: *H. fasciculare* > *T. versicolor* > *V. comedens* [22,23,24] (Supplementary Table 1). Interacting combinations of wood blocks were incubated individually at 20 °C in 70 ml and 500 ml polypropylene pots for pair-wise and 27-block cubes respectively, and were laid upon a layer of perlite (20 ml and 85 ml) containing 2 ml and 12 ml of water respectively, as detailed in [2]. After 1 d and 28 d volatile organic compound (VOC) production was measured (described below), and we deconstructed n = 5 systems. Each individual block was split along the grain into quarters, and three of the quarters from each block were foil wrapped, flash frozen in liquid nitrogen and stored at -80 °C. These were subsequently analysed for enzyme activity and metabolomics (see below). For the remaining quarter, two chips (~2 mm^3) were taken from an inside face and inoculated onto 2 % malt agar, incubated at 20 °C, then emerging mycelia identified morphologically, to determine which species occupied the

106 wood (Fig. 2). We removed the chip excised face from the quarter by splitting with a chisel, and
107 determined final density as dry weight (80 °C for in excess of 72 h) per fresh volume (cm^3) (blocks
108 sampled at 28 d only), and the rate of decay estimated by comparison with density of blocks scarified
109 (n = 10) at the end of the pre-colonisation period.

110

111 *Overview of metabolite analysis*

112 To quantify changes to metabolic function (antagonistic chemicals and compounds for habitat
113 exploitation/wood decomposition) associated with different spatial dynamics in response to changing
114 community composition, we extracted and measured: the profile of VOCs from the headspace of
115 interactions, the activity of 12 targeted enzymes, chosen because they are directly involved in
116 interspecific competition [6,19]. We also conducted ultra-high performance liquid chromatography-
117 mass spectrometry (UHPLC-MS) metabolomics analysis. All analyses were conducted after 1 and 28 d
118 interactions in blocks originally colonised by *T. versicolor* (n = 5), and in 27-block interactions
119 'pseudo'-replicates representing different spatial locations within 3-dimensional cube arrays were
120 analysed (all n = 5). We chose to target *T. versicolor* since the fungus has been well characterised in
121 the past [16,19,25], and because it neither dominated systems (as did *H. fasciculare*) nor was it driven
122 to near extinction (as was *V. comedens*). There were no significant differences (ANOVA: $p > 0.05$) in
123 enzyme activity or small metabolite levels between pseudoreplicates of *T. versicolor* in 3-dimensional
124 cubes, so we pooled activities of all pseudoreplicates for each system (therefore, n = 15).

125

126 *VOC extraction and data-pre-processing*

127 We collected VOCs from the headspace of interactions after 1 d and 28 d (n = 3) by inserting pots
128 individually and lidless into a multi-purpose roasting bag (46 × 56 cm; Lakeland, UK), which was sealed
129 for 30 min to allow VOCs to equilibrate in the headspace. Then, 500 ml headspace gas was collected

onto thermodesorption (TD) tubes (Tenax TA & Sulficarb, Markes International Ltd.) using an EasyVOC manual pump (Markes International Ltd., UK).

VOCs were desorbed using a TD100 thermodesorption system (Markes International Ltd., UK) with the following settings: tube desorption 10 min at 280 °C, at a trap flow of 40 ml min^{-1}; trap desorption and transfer 40 °C s^{-1} to 300 °C, with a split flow of 20 ml min^{-1} into gas chromatograph (GC; 7890A; Agilent Technologies Inc., USA). VOCs were separated over 60 m, 0.32 mm I.D., 0.5 µm Rx5ms (Restek, UK) with 2 ml min^{-1} helium as carrier gas under constant flow conditions using the following temperature program: 35 °C for 5 min, 5 °C min^{-1} to 100 °C, hold 5 min. Mass spectra were recorded from *m/z* 30 to 350 on a time-of-flight mass spectrometer (BenchTOF-dx, Markes International Ltd., UK). C8-C20 alkane standard (0.5 µl, Supelco) was loaded onto a blank thermodesorption tube as a retention standard and quality control (QC).

Enzyme assays

For enzyme assays, we freeze dried the *T. versicolor* frozen blocks for 48 h (Edwards Modulyo, UK), then ground them to sawdust using a spice and coffee grinder (Wahl James Martin, UK). 0.5 g of sawdust was added to 5 ml of 50 mM sodium acetate buffer and shaken overnight at 4 °C. For pair-wise interactions, *T. versicolor* blocks from all interactions and one block from its respective self-pairing were used (n = 5). In 27-block cubes, each fungus occupied 3 different spatial positions in both of the mixed-species assemblages, and *T. versicolor* occupied 4 spatial positions within the assemblage which it fully occupied. For each spatial position for *T. versicolor* blocks within 27-block systems (excluding the central-cube position which *T. versicolor* occupied when it was the sole occupant, as this was not represented in the mixed-species assemblages), 5 replicates were used for assays (full details in Supplementary Table 2).

153 The activities of the following terminal hydrolases were measured using 4 methylumbelliferol
154 (MUF)-based substrates: β-glucosidase (EC 3.2.1.21), α-glucosidase (EC 3.2.1.20), cellobiohydrolase
155 (EC 3.2.1.91), β-xylosidase (EC 3.2.1.37), N-acetylglucosaminidase (EC 3.2.1.30), phosphodiesterase
156 (EC 3.1.4.1), phosphomonoesterase (EC 3.1.3.2) and arylsulfatase (EC 3.1.6.1). Briefly, substrates
157 (40 µl in dimethylsulphoxide) at final concentration of 500 mM were combined with three technical
158 replicates of 200 µL of samples (diluted 1:10) in a 96 well plate. Background fluorescence was
159 determined by combining 200 µL sample (diluted 1:10) with 40 µl MUF standards. The 96 well plates
160 were incubated at 40 ^{o}C and fluorescence recorded at 5 and 125 min using a Tecan Infinite microplate
161 reader (Tecan, Switzerland) with an excitation wavelength of 355 nm and an emission wavelength of
162 460 nm. Quantitative enzymatic activities were calculated after blank subtraction based on a standard
163 curve of MUF. One unit of enzyme activity was defined as the amount of enzyme releasing 1 nmol of
164 MUF min-1.

165 Laccase (phenoloxidase; EC 1.10.3.2) activity was determined by monitoring the oxidation of 2,2'-
166 azino-bis(3-ethylbenzothiazoline-6-sulfonic acid) diammonium salt (ABTS) in citrate phosphate buffer
167 (100 mM citrate, 200 mM phosphate, pH 5.0), by monitoring the formation of green colouration
168 spectrophotometrically at 420 nm. Three technical replicates were performed for each sample.

169 Manganese peroxidase (MnP; EC 1.11.1.13) activity was determined by monitoring
170 spectrophotometrically at 595 nm the purple colouration from oxidative coupling of
171 3-methyl-2-benzothialone-hydrazone hydrochloride (MBTH) and 3-(dimethyl amino)-benzoic acid
172 (DMAB) in succinate-lactate buffer (100 mM, pH 4.5). Three technical replicates were performed for
173 each sample. The results were corrected by activities of samples without manganese, and with
174 ethylene diamine tetraacetate (EDTA) to chelate any Mn2+ present in the samples, allowing detection
175 of Mn^{2+}-independent peroxidases (versatile peroxidase). The results were also corrected by activities
176 of samples in the absence of H_2O_2, allowing detection of oxidase (but not peroxidase) activity.

For each enzyme, n = 3 technical replicates were performed and enzyme activities were normalised to the protein content of each sample, which was determined using Qubit™ fluorometric assays (ThermoFisher Scientific Inc., UK).

Metabolomics analysis

As for enzyme assays, we selected blocks pre-colonised by *T. versicolor* (n = 5) upon which to perform UHPLC-MS (Supplementary Table 2). 0.5 g of sawdust was added to 1666 µl of each of H_2O, methanol and chloroform, vigorously vortexed and sonicated for 15 min (Elmasonic S150, Singen, Germany). The extracts were allowed to sit until the polar (containing H_2O and methanol) and non-polar (containing mostly chloroform) layers separated, then removed 1500 µl of the upper layer containing the polar metabolite extracts. The extracts were centrifuged for 5 min at 17,000 x g (Biofuge, Thermo Fisher Scientific, MA, USA), and 200 µl of supernatant removed and dried *in vacuo* (Thermo Savant, NY, USA) for ca. 3 h. We then stored extracts at -80 ^{o}C until metabolomics analysis.

An intrastudy quality control (QC) sample was prepared by pooling small aliquots of all samples, and the single extract was removed and dried down by centrifugation (20,000 x g for 10 min at 4 °C, Biofuge). UHPLC-MS based metabolomics was performed (20 µl per sample) on a Thermo Dionex Ultimate 3000 RS system with a Thermo Scientific Q Exactive Orbitrap mass spectrometer. Samples (20 µl) were separated over a 100 x 2.1 mm, 1.9 µm particles, C18 column (Thermo Hypersil Gold) at a flow rate of 400 µl min^{-1} using a 14 min linear gradient programme from 0.1 % formic acid in water to 0.1 % formic acid in methanol. MS acquisition started at 0.1 min, with the flow up to 0.45 min directed towards waste. We acquired data in positive ion and profile mode from *m/z* 100-1000 at 70,000 resolution. Samples were analysed in a controlled randomised order, with the intrastudy QC sample repeatedly analysed equidistantly between the biological samples.

Metabolomics data processing

To process the UHPLC-MS data, the Thermo.raw data files in profile mode were converted into mzML format in centroid mode using MSConvert (Proteowizard 3.0.7665). Data were then aligned using an R (3.2.0) based XCMS and CAMERA script (both R packages [26,27]) which resulted in a csv file intensity matrix (containing 9309 features, i.e. peaks in the mass spectra). This matrix was imported into MatLab and inserted into a direct infusion mass spectrometry (DIMS) SIMStitch workflow [28] where a blank filter of > 2x sample over blank signal was applied, and a sample filter of peak-presence of at least 50 % of all samples [29]. The matrix was further processed by probabilistic quotient normalisation (PQN) and subsequently missing values were imputed using K-nearest neighbour (KNN) with $k = 5$. The imputed data matrix was used as an input to univariate statistics, including calculation of fold-changes. For multivariate statistics, a g-log transformation of the imputed data matrix was additionally applied, using an assessment of the technical variance across the repeated measurements of the intrastudy QC sample [29].

We putatively annotated UHPLC-MS features by inputting *m/z* values and their associated mean intensities into MI-Pack software version 2 beta [30], where metabolites were compared against the Kyoto Encyclopaedia of Genes and Genomes (KEGG) database. A set of highly significant metabolites (ANOVA: $p < 0.001$) were further searched against the KEGG database to determine possible roles within metabolic pathways.

Statistical analysis

To analyse the rate of decay and progression of interactions, we used R statistical software [31]. For each interaction, we assigned every species an individual score of combative ability, expressed as the percentage of the total system that it finally occupied. Briefly, each competitor scored between 0 and 2 for each block within a system (since two regions of every block were isolated; no outgrowth of a

competitor from either isolation point scored 0, outgrowth from one isolation point scored 1, outgrowth from both isolation points scored 2). Scores for all blocks within a system were combined for each competitor individually, normalised to the number of replicates and converted to a percentage of the total system colonised. The data were analysed using a General Linear Model combined with Tukey *post hoc* tests, with individual block position (i.e. number of faces of that block involved in direct combat) and access to water (water was added to the perlite, as such, in 27-block interactions the layer laid on the perlite has greatest access to water) factored into the model. The rate of decay of wood in all interactions was compared using a one-way ANOVA followed by Tukey *post hoc* tests.

For enzyme activities, we used a one-way ANOVA with Tukey *post hoc* tests to compare mean activity (from five replicates), or Kruskal-Wallis tests followed by a Dunn's test *post hoc* procedure when data were non-normally distributed, in R statistical software [31].

For GC-MS (VOCs) data, mass spectra of the entire data set were analysed by principal components analysis (PCA) to check for clustering of the QCs and, therefore, robustness of the data set (see Supplementary Fig. 2 for QC clustering), using MetaboAnalyst 3.0 [32]. We then removed QCs from the matrix, and orthogonal projection to latent structures-discriminant analysis (OPLS-DA) ($Q^2 = 0.93$, $R^2 = 0.96$), chosen for its cross-validation method which reduces false-positive results [33], was applied to the standardised binned data to determine the degree of separation between the four major sample groups: pair-wise samples 1 d and 28 d after interaction set up, and 27-block samples 1 d and 28 d after interaction set up. Next, we separated the data and applied OPLS-DA to pair-wise ($Q^2 = 0.57$, $R^2 = 0.61$) and 27-block ($Q^2 = 0.37$, $R^2 = 0.55$) sample groups separately. The modelled covariance and correlation were used to identify the compounds contributing most to the discriminant model separation, and one-way analysis of variance (ANOVA) with a 5 % Benjamini-Hochberg false discovery rate (FDR) correction for multiple comparisons [34], and Tukey *post hoc* tests were applied to those compounds.

Lastly, for UHPLC-MS data we applied PCA to the g-log transformed data to explore the separation between control samples (*T. versicolor* growing alone), interaction samples and QCs. The median Relative Standard Deviation (RSD) for the intrastudy QC samples was 11.15 %, indicating that the MS data were of sufficiently high quality for further statistical analysis (see Supplementary Fig. 3 for QC clustering). After removing the QCs, analysis of variance simultaneous components analysis (ASCA) was applied, and the model was permutation tested (5000 permutations) to determine the significance of factors (sample day, and block position within systems) [35,36]. An additional ASCA model was tested to determine the significance of species distribution patterns within cubes, i.e. species being dispersed, *V. comedens* occupying a larger adjacent volume, or *T. versicolor* comprising the entire system, but did not include spatial location within assemblages as a factor. Pair-wise comparisons using ASCA were carried out for *post hoc* testing of significant effects, and the *p*-values were adjusted for multiple testing using a 5 % Bonferroni-Hochberg multiple testing correction [37]. Univariate analysis of variance (ANOVA) was applied to the whole normalised matrix with a 5 % FDR correction [34] to test for significant metabolites. Finally, we determined fold changes (FC) between significant groups.

Network analytics

We investigated the synergy of metabolites produced by *T. versicolor* during all interactions by creating a co-occurrence Force Atlas2 [38] network analysis plot using Sci2 [39] and Gephi [40]. Data were filtered such that only significantly abundant compounds (ANOVA/ASCA: adjusted $p < 0.05$) relative to the baseline were included in the analysis, and abundancies of < 10 % the maximum were removed from the matrix, resulting in 908 retained variables. The weighted degree of nodes was calculated, and nodes were partitioned based on their weighting to facilitate removal of those which did not cluster into a discrete module. A final network was constructed from the refined dataset, with edges weighted by count of occurrence and clusters coloured by weighted degree. The average

abundance of all compounds within a cluster was calculated, and we used a one-way ANOVA with Tukey *post hoc* tests with a 5 % FDR correction [34] to compare mean abundance between interacting systems after 28d, in R statistical software [31].

Results

Hierarchy and coexistence dynamics

Typical transitive hierarchy of the focus decay species, *T. versicolor*, was established in paired block interactions (Fig. 1), i.e. *H. fasciculare* > *T. versicolor*, *H. fasciculare* > *V. comedens* and *T. versicolor* > *V. comedens* (Fig. 3). This hierarchy reflected the general niche occupied in wood decomposition: least competitive *V. comedens* an early/primary decay species, *T. versicolor* a secondary colonising species, and *H. fasciculare* a late/tertiary decay species, the most competitive. Transitivity was also exhibited when the three fungi were dispersed throughout more spatially heterogeneous 3-dimensional systems (Fig. 1e): 15 % of the original territory (defined as the relative proportion of a block occupied by a single fungus) of *T. versicolor* was captured by *H. fasciculare*, and 69 % of the original territory of *V. comedens* was captured by its competitors. However, when spatial dynamics within the 3-dimensional cubes were changed such that *V. comedens* occupied a larger adjacent, but same total, volume as its competitors (Fig. 1f), *V. comedens* was displaced from just 6 % of its original territory, and *T. versicolor* was displaced from 46 % of its original territory. The three species coexisted without *V. comedens* being driven to near extinction (within a closed community network loop) as it was when territory was patchy, which is a characteristic of an intransitive relationship (Fig. 3).

Metabolite network function

In addition to our 12 targeted enzyme assays, our untargeted analyses yielded 67 VOCs, and 2825 LC-MS signals of which 1597 were putatively annotated against existing compound libraries (Supplementary Table 3). Univariate ANOVA analysis (with false discovery rate correction of p-values) and ASCA multivariate analyses provided evidence of significant differences in the quantity of individual functional metabolites from blocks originally colonised by *T. versicolor* between interactions with divergent coexistence dynamics, which are summarised in Supplementary Information. Network analysis of the detectable metabolome, VOCs and enzymes throughout all interactions (average weighted degree = 3230), revealed 10 distinct clusters of synergistic metabolites (both antagonistic and lignocellulose decaying), plus an additional 11 independently functioning compounds with a high network degree. Namely, toluene (VOC: C66), an undefined oxidase enzyme, manganese peroxidase (MnP), manganese independent peroxidase (peroxidase), arylsulfatase, phosphodiesterase, and five unidentified small metabolites (Fig. 4; Cluster Identity Table 1).

By comparing the average abundance of individual clusters of metabolites produced in blocks pre-colonised by *T. versicolor* in pair-wise competitive systems, we found that production of 7 clusters of antifungals was induced in significantly greater quantities when *H. fasciculare* was *T. versicolor's* opponent, compared to 3 clusters when it was paired against the weaker *V. comedens*, relative to single species controls (Fig. 5). This particular response was consistent, and in 3-dimensional community interactions there was a stronger competition response shown in *T. versicolor* pre-colonised blocks when *V. comedens* was more combative when occupying a larger adjacent patch size (Clusters 6 and 9 were significantly more abundant (ANOVA: $p < 0.05$)), compared to when all fungi were dispersed in 3-dimensions. Cluster 6 contained the putatively annotated metabolite swainsonine, which functions in the biosynthesis pathway of piperdine- and pyridine-based antimicrobial alkaloids, and isolongifolene, a sesquiterpene with known antifungal properties, featured in Cluster 9 (Table 1). Although only putatively identified, the increased abundance of these combative/defensive compounds in *T. versicolor*-colonised blocks correlates with the increased

combative ability of competitor *V. comedens* and longer coexistence of the three fungi within an intransitive relationship loop (Fig. 3).

In addition to our findings in competitive systems, we found distinct metabolic differences between 2-dimensional and more spatially complex 3-dimensional controls where *T. versicolor* was the sole occupant of these resource habitats. For example, the unclustered enzyme arylsulfatase and Cluster 10, which comprised another six similarly functioning enzymes (Table 1), were significantly more highly abundant (ANOVA: $p < 0.05$) when *T. versicolor* solely occupied a 3-dimensional cube compared to when it was solely paired in 2-dimensions (Fig. 5).

The presence of other species affected metabolic function, as for example Clusters 7 and 8, amongst others, comprising compounds such as antifungal sesquiterpenes (Table 1), were significantly more abundant (ANOVA: $p < 0.05$) when *T. versicolor* was paired in an interaction compared to when it decayed wood alone. Similarly, when we compared whole *T. versicolor* 3-d cubes with 3-d community interactions, clusters 2, 3 and 4 which contain metabolites such as ankorine and fortimicin involved in antibiotic biosynthesis pathways, were significantly more abundant (ANOVA: $p < 0.001$) in the more species-rich systems. Within this experimental time frame the process of decomposition was not affected by spatial dynamics or species diversity (ANOVA: $p > 0.05$; Supplementary Fig. 1).

Discussion

Our results indicated that coexistence dynamics and metabolic function are directly affected by spatial occupation and patchiness of territory and can be translated into mechanistic functional processes. Furthermore, we provide evidence of a metabolic response to shifts in community structure as a result of altered connectivity. Landscape architecture changes combative mechanisms [2] and in return may cause variation in expenditure of metabolic products between systems of varied levels of spatial

heterogeneity. Community composition may be altered by a change in combative mechanisms as a result of landscape structural complexity [2], possibly due to stochastic effects within community assemblages [3] or different gaseous regimes throughout 3-dimensional structures and altered edge effects in 2-dimensions vs 3-dimensions. A study in which individuals of a community were paired against each other in artificial media [21], found negligible effects of species diversity alone on community function, but that a diverse community comprising weak competitors with high intransitivity exhibited a positive diversity-function relationship, i.e. the structure of a competitive network impacts community-level function. The more realistic complexity of the model system used in the present study revealed very different relationships: *T. versicolor* changed its mechanism of combat in systems where *V. comedens* occupied a larger adjacent volume, as clusters of metabolites functioning in the biosynthesis pathways of antagonistic antimicrobial compounds were produced in greater abundance. Presumably this emergent property was as a result of the greater combative strength of *V. comedens* (i.e. more antifungals were needed to attack the connected *V. comedens*), or as a result of a change of strategy by *H. fasciculare* which focused its attention on antagonising the now weakest competitor with whom it shared the most antagonistic-fronts, *T. versicolor*, which responded to this change with increased antimicrobial compound production, or, the emergent property could have resulted from both simultaneously. Additionally, in this scenario *H. fasciculare* was able to capture some of the territory of *T. versicolor* which would result in a change to species-specific biochemical production. When *V. comedens* was dispersed it was less stable than when connected, and connectivity of *V. comedens* altered the community dynamic such that the usually stronger competitor, *T. versicolor*, came under survival pressure. The change in mechanisms led to coexistence of the three species with more similar relative abundancies and a closed community network loop (characteristic of intransitivity), compared to transitive community dynamics when the individuals were dispersed, where *V. comedens* was outcompeted to near extinction. It is worth noting that in natural deadwood species diversity would be far greater than that presented here, and the presence of other fungal species as well as bacteria would influence interactions outcomes and,

373 therefore, metabolism [41]. Fungal-bacterial interactions have been shown to be mutualistic [42],
374 which could give individual fungal species a competitive advance against their competitors, and
375 further alter expected community hierarchies.

376 In the present study, production of seven cellulolytic enzymes functioning in resource exploitation was
377 boosted when spatial scale was increased from linear 2-dimensions to more heterogeneous
378 3-dimensions. The differences in functional metabolic processes across spatial scales, and between
379 the more diverse community exhibiting intransitive characteristics and the transitive community is,
380 therefore, reflective of a relationship between diversity and function that is regulated by space. The
381 impact of the nature (space occupancy) of communities in directing community structure should be
382 considered when looking at complex communities where outcomes are less predictable, and
383 metabolic quantification to potentially inform predicted outcomes is, therefore, very useful.

384 That species diverse communities promote coexistence and positively impact community function is
385 well known [21,43,44,45]. Our results confirm this relationship between function and diversity, i.e.
386 metabolic function changed significantly between systems with different numbers of species (single
387 species assemblages vs multi-species assemblages), but we also show that spatial scale and
388 distribution of species (patch dynamics) affect metabolic function as well. While these effects were
389 not directly translated into ecosystem services (i.e. the rate of wood-decay was not significantly
390 affected), decay in the natural environment occurs over much larger time-scales than used here [46].
391 So it might be predicted that given a greater length of time spatial heterogeneity and species diversity
392 would have resulted in changes to the rate of decomposition, since substrate utilisation was affected
393 over the short time-scale measured in this study. The decomposition activities of wood decay fungi
394 determine the rate of nutrient cycling in forest ecosystems which impacts forest function [47]. The
395 relationship between spatial dynamics, species diversity and function highlighted in our study is,
396 therefore, a key mechanism in the release of carbon from organic substrates into the carbon cycle,
397 which drives global change [48]. Microbial communities in every global ecosystem carry out an array

398 of functions as important as that of wood decayers [49,50,51], but the effects of spatial dynamics and
399 species diversity on these functions have not previously been measured and quantified by
400 experimental studies. The ecologically pertinent systems presented here are pioneering in their
401 quantitative capture of 3-dimensional spatial dynamics into the experimental study of microbial,
402 community and landscape structural ecology, which can be adapted, reconfigured and reimagined for
403 the study of communities with a range of interaction types (e.g. neutral, mutualistic, facilitative). Our
404 3-dimensional experimental design, and the finding that spatial dynamics directly impact coexistence,
405 diversity and function, are not only translatable to the understanding of diversity in existing
406 microbiomes but may also provide key insights into extinctions and predictions of future ecological
407 trends and community-level evolution.

Acknowledgements

This work was supported by a Natural Environment Research Council (NERC) GW4+ DTP studentship (JO'L: NE/L002434/1), and NERC Biomolecular Analysis Facility (R8-H10-61) through an NBAF award (NBAF-977). We thank Dr Clement Heude for training in small metabolite extraction technique.

Author contributions

LB, DCE, CTM and JO'L designed the experiment. JO'L and KJ set up the experiment, KJ, JO'L and CTM analysed VOCs, JO'L analysed enzymes. JO'L, US and MRV analysed small metabolites (LC-MS). J'OL, JE and KH contributed to analysis of the untargeted LCMS data, and J'OL analysed the block interactions data, enzymes data and VOC's data. J'OL, LB, DCE and CTM drafted the paper, and all authors had editorial input.

The authors declare no competing interests.

Figure Legends

Fig. 1: Spatial distribution of species in pair-wise (a-d) and 3-dimensional 27-block (e-g) interactions. a-d: pair-wise interactions in all conceivable combinations, plus *T. versicolor* self-pairing; e: dispersed cube (fungi were dispersed throughout the system and arranged so that no two blocks containing the same species had adjacent faces); f: "wall" distribution cubes (all fungi occupied the same total volume of wood but the adjacent territory occupied by *V. comedens* was larger; the other two competitors were arranged so that no two blocks containing the same species were adjacent); g: single species, *T. versicolor* 27-block cube. Cut vessels in pair-wise interactions and rows within 27-block layers were touching so that the wood grain ran in the same parallel direction as denoted by arrows.

Fig. 2: Sampling and deconstruction of wood blocks. Individual blocks were split along the grain into quarters, and three of the quarters from each block were foil wrapped, flash frozen in liquid nitrogen and stored at -80 ^{o}C. For the remaining quarter, two chips (~2 mm^3) were taken from an inside face and inoculated onto 2 % malt agar, then emerging mycelia identified morphologically.

Fig. 3: Interaction progression after 28 d in pair-wise interactions (*T. versicolor* (Tv) against *V. comedens* (Vc); *T. versicolor* against *H. fasciculare* (Hf); *H. fasciculare* against *V. comedens*), and 3-dimensional cubes in which all three species were evenly dispersed (Fig. 1e), and where *V. comedens* occupied a larger adjacent volume (Wall; Fig. 1f). Bars show the proportion of territory occupied by each species at the end of the experiment (mean of n = 5, SEM = ± 12.2).

Fig. 4: Metabolic network of the full complement of significant compounds produced by *T. versicolor* throughout all interactions. Synergistic clusters of putatively annotated metabolites are clearly visualised and grouped based on their weighted degree (WD) (number of weighted edges, i.e. connections to other nodes, for a node. Average WD = 3230) and grey nodes labelled with compound

names denote metabolites that did not form clusters (note that unlabelled grey nodes lack putative identifications). Clusters and their WD are detailed in Table 1. Edges are weighted by the count of occurrence of synergistic metabolites within samples, and node sizes and cluster colours represent weighted degree.

Fig. 5: Significant differences in the average abundance of metabolic clusters (details of composition of clusters in Table 1) between interactions. Orange denotes cluster abundance is significantly higher (ANOVA: $p < 0.05$) in the interaction on the left of the colon; Blue denotes significantly lower (ANOVA: $p < 0.05$) cluster abundance in the interaction on the left; and no colour denotes no significant difference (ANOVA: $p > 0.05$) between a pair of interactions. Tv, *T. versicolor*; Vc, *V. comedens*; Hf, *H. fasciculare*; Wall, 3-dimensional cube where *V. comedens* occupied a larger adjacent volume; Dispersed, 3-dimensional cube where all three species were dispersed; TvCube, 3-dimensional cube colonised entirely by *T. versicolor*.
