Keywords: Vulcanian explosions, Rhyolite, Chaitén, Vesiculation, Volcanic bombs

Highlights:

- Suite of high temperature bubble growth experiments performed on a rhyolitic bomb from the 2008 eruption of Chaitén volcano
- Hot-stage microscopy allowed the tracing of in-situ bubble growth at different temperatures
- Experimentally derived growth rates placed in context of a cooling volcanic bomb to determine the amount of post-fragmentation vesiculation
- Our model recreates textures observed in metre scale volcanic bombs

1 ABSTRACT

2 Bubble nucleation and growth dynamics exert a primary control on the explosivity of
3 volcanic eruptions. Numerous theoretical and experimental studies aim to capture the complex
4 process of melt vesiculation, whereas textural studies use vesicle populations to reconstruct magma
5 behaviour. However, post-fragmentation vesiculation in rhyolitic bombs can create final quenched
6 bubble (vesicle) textures that are not representative of the nature of fragmenting magma within the
7 conduit. To examine bubble growth in hydrous rhyolitic bombs, we have used heated stage
8 microscopy to directly observe vesiculation of a Chaitén rhyolite melt (with an initial dissolved
9 water content of ~0.95 wt. %) at atmospheric pressure and magmatic temperatures upon reheating.
10 Thin wafers of obsidian were held from five minutes up to two days in the heated stage at
11 temperatures between 575 °C and 875 °C. We found that bubble growth rates, measured through
12 changes in bubble diameter, increased with both temperature and bubble size. The average growth
13 rate at the highest temperature of 875 °C is ~1.27 $\mu\text{m s}^{-1}$, which is substantially faster than the
14 lowest detected growth rate of ~0.02 $\mu\text{m s}^{-1}$ at 725 °C; below this temperature no growth was
15 observed. Average growth rate V_r follows an exponential relationship with temperature, T and
16 inferred melt viscosity η , where $V_r = 5.57 \times 10^{-7} e^{0.016T}$ and $V_r = 3270.26 e^{-1.117\eta}$. Several stages of
17 evolving bubble morphology were directly observed, including initial relaxation of deformed
18 bubbles into spheres, extensive growth of spheres, and, at higher temperatures, close packing and
19 foam formation. Bubble deformation due to bubble-bubble interaction and coalescence was
20 observed in most experiments. We use our simple, experimentally-determined relationship
21 between melt viscosity and bubble growth rates to model post-fragmentation vesicle growth in a
22 cooling 1 m-diameter rhyolitic bomb. The results, which indicate negligible vesicle growth within
23 2-3 cm of the bomb surface, correspond well with the observed dense margin thickness of a

24 Chaitén bomb of comparable dimensions. The experiments described can be used to effectively
25 reconstruct the post-fragmentation vesiculation history of bombs through simple analytical
26 expressions which provide a useful tool for aiding in the interpretation of pumiceous endmember
27 textures in hydrous rhyolitic bombs.

31 **1. INTRODUCTION**

32

33 The nucleation and growth of bubbles in magma exerts a primary control on the dynamics of
34 explosive volcanism (Sparks, 1978). Once bubbles are nucleated in magma, either homogeneously,
35 or heterogeneously on crystal surfaces, they grow by diffusion of molecular volatiles through melt
36 in concert with the decompression and expansion of gas within bubbles. Diffusion produces a
37 volatile concentration gradient that drives continued volatile migration towards a growing bubble
38 (e.g. Toramaru et al., 1989; 1995; Proussevitch et al., 1993). Volatile diffusivity, within a melt,
39 then controls the ability of volatile species to diffuse through the melt into a bubble (e.g. Zhang et
40 al., 1991; Zhang 1999). However growth can be impeded by viscous forces, over natural
41 timescales, in the melt through melt cooling or degassing (e.g. Sparks, 1978; Gardner et al, 1996;
42 Proussevitch and Sahagian, 1996; Navon et al, 1998; Gardner et al, 2000). It has been shown that
43 when viscosity (η) reaches values of $>10^9$ Pa s gas exsolution is hampered and bubble growth is
44 significantly retarded, effectively quenching bubble growth (Thomas et al., 1994; Gardner et al,
45 2000). This viscous quench is important because it enables supersaturation of magma, producing
46 high internal bubble pressure that can cause explosive magma fragmentation (Gardner et al., 1996).

47

48 Bubble nucleation and growth dynamics in explosively erupted volcanic bombs have received
49 comparatively little attention; however, it has been shown that vesiculation does not necessarily
50 cease when pyroclastic material is explosively ejected (Thomas et al. 1994; Kaminsky and Jaupart,
51 1997). Bubbles in pyroclasts with water contents ~0.4-3.1 wt.% continue to grow through
52 coalescence and diffusional processes at atmospheric pressure (Hoblitt and Harmon, 1993;
53 Giachetti et al., 2010; Wright et al., 2007), as highlighted schematically in Fig. 1. Significant post-
54 fragmentation pyroclast vesiculation may occur if melt viscosity is sufficiently low and clast size
55 sufficiently large such that cooling rates can remain low in pyroclast interiors (Thomas et al. 1994;
56 Soriano et al., 2009; Clarke et al., 2019). Post-fragmentation bubble nucleation, growth and
57 coalescence is likely, hence, to occur in bombs erupted in Vulcanian explosions (e.g. Wright et al.
58 2007; Castro et al., 2012a; Saubin et al. 2016). These processes continue where cooling is slow,
59 such that clasts remain above the glass transition (T_g) temperature (~600-700°C, for rhyolites,
60 depending on wt. % H₂O) for sufficient time (Giachetti et al., 2010). T_g is a temperature range that
61 marks the transition from a liquid-like to a solid-like state (e.g. Dingwell, 1998; Dingwell and
62 Webb, 1989; Webb, 1997), and is defined either calorimetrically or in terms of a viscosity of 10^{12}
63 Pa s (Stevenson et al., 1995). Given the possibility of post-fragmentation vesiculation in pyroclasts
64 it is important to disentangle the relative contributions of pre- and post- fragmentation vesiculation
65 on final clast textures, in order to interrogate processes occurring in the conduit and in ejected
66 pyroclasts. This is especially relevant to breadcrust bombs and tuffisite veins, where local melt
67 H₂O concentration also appears to strongly affect vesiculation rates (Wright et al. 2007; Saubin et
68 al. 2016). However, the timescales of bubble nucleation, growth and coalescence within post-
69 fragmentation pyroclastic material remain poorly constrained (Giordano et al., 2005; Ryan et al.,

70 2015; Clarke et al., 2019). Understanding these systematics is important for understanding porosity
71 and permeability development within shallow conduit magmas at the moment of fragmentation
72 (Giordano et al., 2005; Mueller et al., 2008; Ryan et al., 2015; Clarke et al., 2019). At Chaitén,
73 clast textures record repeated welding and re-opening of a conduit plug, partly overprinted by late-
74 stage vesiculation (Castro et al. 2012; Saubin et al. 2016).

75

76 To illuminate bubble growth dynamics in post-fragmentation volcanic bombs, we use a series of
77 high temperature, atmospheric pressure vesiculation experiments to investigate in-situ bubble
78 nucleation, growth and interactions in natural samples of H₂O-rich rhyolitic glass from the 2008
79 eruption of Chaitén, Chile. Being the only closely observed eruption of high-silica (75 wt. %) rhyolite, Chaitén provides a unique source of fresh rhyolitic glass for which there are excellent
80 constraints on eruption dynamics (Castro and Dingwell, 2009; Forte and Castro, 2019). Our
81 atmospheric pressure experiments simulate vesiculation processes following explosive
82 fragmentation from a conduit. The aim is to understand the extent of post-ejection bubble growth
83 occurring in pyroclasts. Although previous studies have addressed vesiculation dynamics in H₂O-
84 poor melts (<0.5 wt. % H₂O) (i.e. Bagdassarov et al., 1996), we have investigated more water-rich
85 melt (~1 wt. % H₂O) that is typical of bombs ejected in explosive rhyolitic eruptions (Forte and
86 Castro, 2019). Such bombs preserve volatile contents and textures indicative of upper conduit plug
87 formation, partially overprinted by post-fragmentation vesiculation (Saubin et al. 2016).

89

90

 92 *conduit. Individual pyroclasts of pumice may continue to vesiculate past the point of initial*
 93 *fragmentation although this process is dictated by cooling rates within the pumice clast, modified*
 94 *after Gonnermann and Manga (2007).*

95

96 **1.1 Previous experimental bubble growth studies**

97

98 Several studies involving decompression and heating experiments on silicic melts have sought to
 99 gain an understanding of the effects of magma ascent and decompression on bubble nucleation
 100 and growth (e.g. Gardner et al. 2000, Hamada et al. 2010, Lavallée et al. 2015; Ryan et al. 2015;
 101 Forte and Castro, 2019). Whilst the vast majority of previous bubble growth experiments utilised
 102 a heat (and/or decompression) and quench technique whereby the end-member product of
 103 vesiculation was recorded in terms of vesicle size distributions (e.g Gardner et al, 1999; 2000; Lui

104 and Zhang, 2000; Hamada et al., 2010); continuous measurements of in-situ bubble growth are
105 rare (Baker et al., 2012; Masotta et al., 2014; Polacci et al., 2018). End-member analysis of
106 experimentally treated samples have been used to infer mechanisms of bubble growth and
107 coalescence (Burgisser and Gardner, 2004; Gardner, 2007a; Kennedy et al, 2016), as well as shape
108 ideas concerning the efficiency of crystal surfaces for sites of heterogeneous bubble nucleation
109 (Gardner and Denis, 2004; Gardner, 2007b). Bubble growth experiments can be broadly
110 categorised into those that directly measure in-situ growth (e.g. Bagdassarov et al., 1996; Bai et
111 al., 2008; Baker et al., 2012; Masotta et al., 2014; Ryan et al., 2015) and those that use a heat and
112 quench technique to record final bubble sizes (i.e. Hamada et al., 2010). In addition we can
113 differentiate between experiments that induce bubble growth by keeping pressure constant but alter
114 temperature (e.g. Bagdassarov et al, 1996; Lui and Zhang, 2000; Masotta et al., 2014; and our
115 study) and those that keep temperature constant but alter pressure (e.g. Lyakhovsky et al., 1996).
116 Many of the experiments were conducted on real silicic materials with a range of H₂O contents,
117 so comparisons can also be made through experiments on low and high water content material and
118 those that invoked high (>700 °C) or low (<700 °C) temperatures. In one of the first experimental
119 bubble growth studies, samples of Newberry Rhyolite obsidian with a water content ~0.2 wt.%
120 were heated at 0.1 MPa to temperatures of 800-1100 °C (Murase and McBirney, 1973). It was
121 found that bubbles grew at a sluggish rate of around $1-2 \times 10^{-8} \text{ cm s}^{-1}$ and nucleated rapidly near
122 the beginning of the experiments but both growth and nucleation were significantly reduced by the
123 end of their 50 minute long experiments. Lui and Zhang (2000) found the rate of observed bubble
124 growth in their experiments on basalt, increased with both temperature and initial H₂O content.
125 Masotta et al., (2014) also directly recorded bubble growth in basaltic, andesitic and rhydacitic
126 magmas during heating experiments and found growth rates ranging from $3.4 \times 10^{-6} \text{ mm/s}$ to $5.2 \times$

127 10^{-7} mm/s. They noted the faster growth rates in the primitive magmas. In a conduit setting, it has
128 been hypothesized that the level or amount of supersaturation significantly affects both the timing
129 and distribution of bubble nucleation on crystal surfaces (e.g. Gardner and Denis, 2004) during
130 non-equilibrium degassing as magma ascends (Gardner et al., 1999; Mangan and Sisson, 2000).
131 Permeability and porosity development through interconnecting bubbles greatly accelerates the
132 rate of gas escape, encouraging equilibrium conditions and efficient degassing (Gardner et al.,
133 1999; Larsen and Gardner, 2000; Okumura et al., 2009; Okumura et al., 2010; Kennedy et al.,
134 2016). More recently, Castro et al. (2012) used decompression experiments and tomographic
135 observations of natural Chaitén obsidian with 0.6-1.0 wt. % H_2O to characterise timescales and
136 mechanisms of bubble coalescence. Forte and Castro (2019) conducted 1 atm vesiculation
137 experiments on variably hydrous Chaitén obsidian, finding melt vesiculation for $H_2O \leq 1$ wt.% but
138 explosive decrepitation at $H_2O > 1.4$ wt.% and $T > 874$ °C. Sample failure occurred as the induced
139 strain rate during rapid vesiculation led to non-relaxed melt deformation and stress accumulation.
140 Bubble nucleation and growth in hydrous rhyolitic pyroclasts at low pressure has been additionally
141 observed experimentally during isobaric foaming experiments using a peralkaline rhyolitic melt
142 from Olkaria, Kenya (Bagdassarov et al., 1996). This rhyolite contained ~ 0.14 wt.% H_2O and was
143 heated to temperatures between 625-925 °C, with bubble growth recorded using a video camera
144 (Bagdassarov et al., 1996) and considered in terms of volume expansion with an exponent of 2-
145 2.5 in the Avrami equation.

146

147 In addition to experimental studies, many increasingly sophisticated numerical models of bubble
148 growth have been developed. Bubble growth in an infinite melt has been shown to follow a
149 parabolic growth law, where bubble size increases with the square root of the diffusion coefficient

150 × time (Sparks, 1978). Later models additionally treat volatile diffusion to the growing bubble
151 (Proussevitch et al., 1993a), and thermal effects related to the heat of volatile exsolution (Sahagian
152 and Proussevitch, 1996). Subsequent work numerically demonstrated that bubble interactions also
153 affect growth rates (Proussevitch and Sahagian, 1998). These different effects play differing roles
154 during magma evolution. Three stages of bubble growth have been postulated in high viscosity
155 melts (Navon et al., 1998). In the first stage, diffusion into a small bubble is efficient in keeping
156 internal pressure in the bubble close to its initial value, and the viscous resistance of the melt limits
157 growth at this stage. During the second stage, bubble pressure is greater than the surrounding melt
158 and growth is then limited by diffusion. In the final stage, which was independently confirmed by
159 Lyakhovsky et al. (1996), bubble growth is influenced by neighbouring bubbles and all
160 supersaturated water diffuses until a final bubble radius is reached. In silicic bombs with >0.95
161 wt.% H₂O that are rapidly ejected into the atmosphere, ΔP can exceed 7 MPa, as calculated using
162 the H₂O solubility-pressure relationship at 825°C and 0 wt. % CO₂, given the VolatileCalc
163 programme (Newman and Lowenstern, 2002).

164

165 The principle aim of the current paper is to provide an empirically derived bubble growth law from
166 direct experimental observations that can be used to provide 1st order approximations of the time
167 scales of vesiculation in post-fragmented pyroclasts in hydrous rhyolitic magmas.

168

169 **2. METHODOLOGY**

170

171 **2.1 Sample characterisation**

172

173 The material used during vesiculation experiments was a 2 cm fragment of dense, high-silica (76
174 wt.%) rhyolitic obsidian (Chaitén obs 3) ejected in the early explosive stage of the 2008-2009
175 Chaitén eruption. It was collected from close to the caldera edge in July 2008, from amongst bomb-
176 rich pyroclastic fragments thought to derive from Vulcanian explosions in the transitional phase 2
177 of the eruption, which began in mid-June 2008 (Castro and Dingwell, 2009; Pallister et al. 2013;
178 Saubin et al. 2016). The Chaitén obsidian was chosen as a suitable material for vesiculation
179 experiments due to the hydrous nature of the melt and the minimal microlite crystal content.
180 Additionally, a partially vesiculated rhyolitic bomb ~1 m in diameter was observed and sampled
181 in January 2014 (BOMB-1). This was located within the Chaitén caldera (42°49'38.62" S,
182 72°39'32.51" W), in pyroclastic deposits emplaced during Vulcanian activity in June 2008 (Saubin
183 et al. 2016).

184 From the original 2 cm fragment we made much smaller millimetric fragments of the Chaitén obs
185 3 obsidian sample which were double-polished by hand using sandpaper in order to create wafers
186 with thicknesses ranging from about 125 μm (+/- 5 μm) to 212 μm (+/- 13 μm). Inspection of these
187 wafers with a petrological microscope revealed the presence of fresh glass, bearing <2-5 % of
188 small (<20 μm) biotite and pyroxene microlites, in agreement with other studies of Chaitén rhyolite
189 (Castro and Dingwell, 2009). The resolution of our imaging meant that it was not possible to
190 discern nanolites or speculate on their influence (Hajimirza et al., 2020). A small proportion (<5
191 %) of vesicles were observed, which were largely elongate, <55 μm in length, and preferentially
192 occur in flow bands hundreds of μm to <1 mm in width. Similarly, wafers were created from the
193 dense margin of BOMB-1, with thickness of 132 +/- 5 μm .

194 Water concentrations in the Chaitén obs 3 sample were determined using a Thermo Nicolet infra-
195 red spectrometer at the University of Lancaster, with a Continuum Analytical microscope, KBr

196 beamsplitter, and a MCT-A detector. Four maps were produced to test for H₂O heterogeneity
197 within the wafer, comprising 162 analyses in total. 128 spectra were collected across wavenumbers
198 of 6000 to 1000 cm⁻¹, at a resolution of 4 cm⁻¹. Raw spectra were processed using an 18-point
199 linear baseline correction that allowed the 5230 cm⁻¹ (H₂O_m), 4520 cm⁻¹ (OH⁻), 3550 cm⁻¹ (H₂O_t),
200 2350 cm⁻¹ (CO₂) and 1630 cm⁻¹ (H₂O_m) peak heights to be discerned. Spectra that showed
201 additional peaks were dismissed, being affected by partial analysis of a mineral phase. No
202 discernible CO₂ was detected, in common with other studies of Chaitén obsidian (Castro and
203 Dingwell 2009; Castro et al. 2012), indicating concentrations less than the detection limits of ~30
204 ppm. Water content (C) was calculated using the Beer-Lambert Law:

$$C_i = \frac{M_i Abs}{d \rho \varepsilon} \quad (1),$$

207
208 where *i* refers to the volatile species of interest, *M* is the molecular weight of substance *i* (18.02 g
209 mol⁻¹ for H₂O), *Abs* is absorbance (measured peak height), *d* is sample thickness, *ρ* is glass density
210 and *ε* is the absorption coefficient. Absorption coefficients of 1.42 l mol⁻¹ cm⁻¹ (Okumura and
211 Nakashima, 2005), 80 l mol⁻¹ cm⁻¹ (Leschik et al., 2004) and 55 l mol⁻¹ cm⁻¹ (Newman et al., 1986)
212 were used for the 4520 cm⁻¹, 3550 cm⁻¹ and 1630 cm⁻¹ peaks respectively. A glass density of 2275
213 g l⁻¹ was used, in accordance with density measurements for similar Chaitén obsidian (Saubin et
214 al. 2016). Maps were re-run in reflectance mode to determine wafer thickness, with reflectance
215 spectra displaying interference fringes collected between 2050 and 2310 cm⁻¹, and wafer thickness
216 given by

$$d = \frac{m}{2n(v_1 - v_2)} \quad (2),$$

218

219 (von Aulock et al., 2014), where m is the number of fringes that occur between two selected
220 wavenumbers; ν_1 and ν_2 (in cm^{-1}) and n is the refractive index; 1.5 for rhyolite (Hodder, 1978). A
221 unique sample thickness was thus acquired for every transmission point. The absolute error in
222 water concentration determined by infra-red spectroscopy is approximately 10% (e.g. Dixon et al.,
223 2002; von Aulock et al. 2014; Saubin et al. 2016). The mean measured total H_2O concentration in
224 the wafer was 0.95 wt. %, with <0.1 wt.% variation. Domains of slightly higher H_2O generally
225 coincided with bubble-rich flow bands. All analyses have low $\text{H}_2\text{O}_m/\text{H}_2\text{O}_t$ ratios that are indicative
226 of high-temperature magmatic speciation followed by rapid quenching, with negligible post-
227 eruptive hydration (e.g. Owen et al., 2012). Water concentrations in the BOMB-1 obsidian were
228 determined at beam B22 of the Diamond Light Source, Harwell, UK, using analytical techniques
229 described in von Aulock et al., (2014) and Saubin et al. (2016). An aperture of $10 \times 10 \mu\text{m}$ was
230 used, and 174 points were collected at a spacing of $10 \mu\text{m}$ along a traverse 1.73 mm in length. It
231 was not possible to measure water concentrations in the vesiculated samples after they had been
232 heated, owing primarily to the prohibitively thin glass septa between vesicles. The physical nature
233 of such samples precludes both sample preparation and achievement of good FTIR signal (von
234 Aulock et al., 2014).

235

236 **2.2 Hot stage and analytical techniques**

237

238 A Linkam TS1500 hot-stage connected to a Zeiss AxioScope A1 microscope was used as the
239 apparatus for heating experiments (Fig. 2). Temperature calibration experiments conducted by
240 Applegarth et al. (2013), using the known melting points of several metal standards, suggest that
241 recorded temperatures match those of the actual temperature in the sample to within ± 2 °C, over
242 the range 157 °C to 1064 °C. A sample wafer was placed onto a sapphire slide where light passes

243 through a 0.8 mm diameter basal aperture and time-lapse images were captured with a digital
244 camera connected to a PC, at a rate of one image every two seconds. Image resolution was
245 determined with a micrometer and gave a pixel size of 0.6 μm (20 \times objective lens).

246 All of the samples were heated at the same rate (200 $^{\circ}\text{C min}^{-1}$) to isothermal temperatures spanning
247 575–875 $^{\circ}\text{C}$, at which they were held for between 8 minutes and 48 hours, with longest dwell times
248 for the lowest isothermal temperatures (Supporting information table 2). The different durations
249 of the experiments represent the time available until bubble growth ceased. These temperatures
250 were chosen to range from below the glass transition temperature T_g ($\sim 600^{\circ}\text{C}$) and to above the
251 inferred eruptive temperature of 825 $^{\circ}\text{C}$ (Castro and Dingwell, 2009). After the isothermal phase,
252 samples were quenched to room temperature ($>200^{\circ}\text{C min}^{-1}$ cooling above 400 $^{\circ}\text{C}$). To assess
253 whether there would be any significant lag between the temperature of the furnace and the rhyolite
254 wafers we consider a simple model for conductive heat transfer, in which the thermal diffusion
255 time of a particle with diffusivity K and thickness d is given by

$$256 \quad \tau = \frac{d^2}{4K} \quad (3)$$

257 (e.g. Turcotte and Schubert, 1982). In our case, d is the water thickness (125-212 μm) and K the
258 thermal diffusivity of rhyolite ($\sim 5.4 \times 10^{-7} \text{ m}^2\text{s}^{-1}$; Romine et al., 2012). The maximum thermal
259 diffusion time, which approximates that of thermal equilibration, is therefore 0.02 s, which
260 corresponds to a lag of 0.07 $^{\circ}\text{C}$ at the maximum applied heating rate of 200 $^{\circ}\text{C}/\text{min}$. This is
261 negligible compared to the uncertainty of furnace temperature ($\pm 2^{\circ}\text{C}$), and thus we can assume
262 that the wafers effectively retained thermal equilibrium throughout all experiments.

263

264 During experiments, care was taken to ensure growing vesicles remained in focus; however non-
265 uniform vesicle growth drove variable expansion within the field of view, compromising the
266 ability to capture fully-focused images.

267

268

269

270 *Figure 2. Hot-stage microscope setup. Sample is placed inside a ceramic furnace (c), temperature*
271 *is set by a Linkam TSI500 heated stage mounted on a Zeiss Axioscope (b). In-situ observations*
272 *are made on a connected PC (a).*

273

274 **2.3 Bubble growth measurements**

275

276 To calculate bubble growth rates, individual bubbles were tracked with a time-lapse image
277 sequence using ‘Pointcatcher’ (<http://tinyurl.com/pointcatcher>), a Matlab-based time-lapse analysis

278 software (James and Robson, 2014). The code enables bubble growth to be measured by tracking
279 individual points, manually identified on the bubble perimeter and measuring the distance between
280 points. Bubbles were chosen for measurement based upon the quality of focus in individual
281 frames, and the initial distance from other bubbles or the sample edge. Ideal bubbles with which
282 to obtain growth rates were those with sufficient space (many tens of microns) for free growth
283 before the onset of inter-bubble interactions in an expanding foam. All of the measurements are
284 two-dimensional and we could not account for growth in the 3rd dimension, into the sample.
285 However, since the sample diameter is approximately 1000 times the sample thickness we assume
286 that the growth and dynamics observed in the dimension and field of view is representative. We
287 monitored the growth of 14 bubbles in the tests at 725°C, 16 bubbles at 775°C, 22 bubbles at
288 825°C, and 23 bubbles at 875°C, which we used to determine the growth rates for each different
289 test. Each individual bubble was marked, manually, with four separate points, two corresponding
290 to the maximum diameter (b-axis) and the other two for the minimum diameter (a-axis). In the
291 vesiculation experiments bubbles are identified as black patches within a yellow (false colour)
292 melt (Figure 2). Measurements were made on the edge of bubbles where there was a clear contact
293 between bubble and melt. However, at the edge of these dark patches the melt-bubble boundary
294 can be unclear. The accuracy of measurements is dictated largely by image focus, it is noted that
295 changes in focus can contribute to an additional +/- 5 µm uncertainty in bubble edge locations,
296 estimated at room temperature defocussing. The smallest bubbles measured had a diameter of 8
297 µm (+/- 5 µm), and the largest a diameter of 202 µm (+/- 10 µm). The bubble-melt boundary is
298 defined by a clear colour contrast; however, the contrast between bubble-bubble boundaries is
299 much less clear. Quantitative bubble measurements are made up until the a and b diameters can no
300 longer be discerned due to interaction with neighbouring bubbles (Fig. 4). Uncertainty with respect

301 to user measurement error (σ_d) was reduced by conducting three repeat measurements on each
302 bubble in a single original image (measurement uncertainties were of order +/-5 μm). The error
303 with respect to growth rates was calculated from the measurement uncertainty through error
304 propagation. Minimum and maximum bubble diameters (d_a and d_b respectively) are used to
305 calculate aspect ratios (AR) to assess bubble shape evolution and relationship with growth rate,

$$306 \quad AR = \frac{d_b}{d_a} \quad (4)$$

307 The uncertainty in aspect ratio, σ_{AR} , is dictated largely by measurement error,

$$308 \quad \frac{\sigma_{AR}}{AR} = \frac{\sigma_a}{d_a} + \frac{\sigma_b}{d_b} \quad (5)$$

309 Where σ_a and σ_b are the standard deviation about the mean of length measurements along the a
310 and b axes of each bubble. Equation 7 has the condition that $\sigma_a \ll d_a$ and $\sigma_b \ll d_b$, which is fulfilled
311 because, although the smallest measured bubbles are $\sim 10 \mu\text{m}$ and the maximum measurement error
312 on these bubbles is $\sim 5 \mu\text{m}$, the largest bubbles ($> 50 \mu\text{m}$) have larger measurement errors,
313 particularly when neighbouring bubble walls touch (e.g. at least +/-10 μm). This error results from
314 defocussing as samples expand and the effects of neighbouring bubble walls where the error on
315 measurements is difficult to quantify but at least +/- 10 μm .

316

317 The growth-temperature relationship was determined using the average growth rate (\bar{v}_r) of
318 different bubbles at each temperature within the elapsed period of isothermal free bubble growth.

319 Average growth rates were obtained by

$$320 \quad \bar{v}_r = \frac{d_f - d_i}{t_f - t_i} \quad (6)$$

321 where subscript f denotes the final and i the initial values within the section of free growth as
322 previously described, d is bubble diameter in either the a or b axis and t is time. The calculation
323 considers two dimensional bubble growth rather than volumetric changes. Error in growth rate
324 (σ_{vr}) was calculated based upon the maximum measurement error (σ_d) where

$$325 \quad \sigma_{vr} = \left(\frac{1}{t_2 - t_1} \right) (\sigma_{d_2} + \sigma_{d_1}) \quad (7)$$

326 Maximum growth rate error of +/- 0.18 $\mu\text{m s}^{-1}$ was calculated in the highest temperature
327 experiments but reduced to <0.05 $\mu\text{m s}^{-1}$ in lower temperature experiments. This growth rate error
328 is smaller in lower temperature experiments because bubble sizes were generally smaller and there
329 were less bubble interactions.

330

331 **2.4 Magma viscosity and melt diffusivity**

332

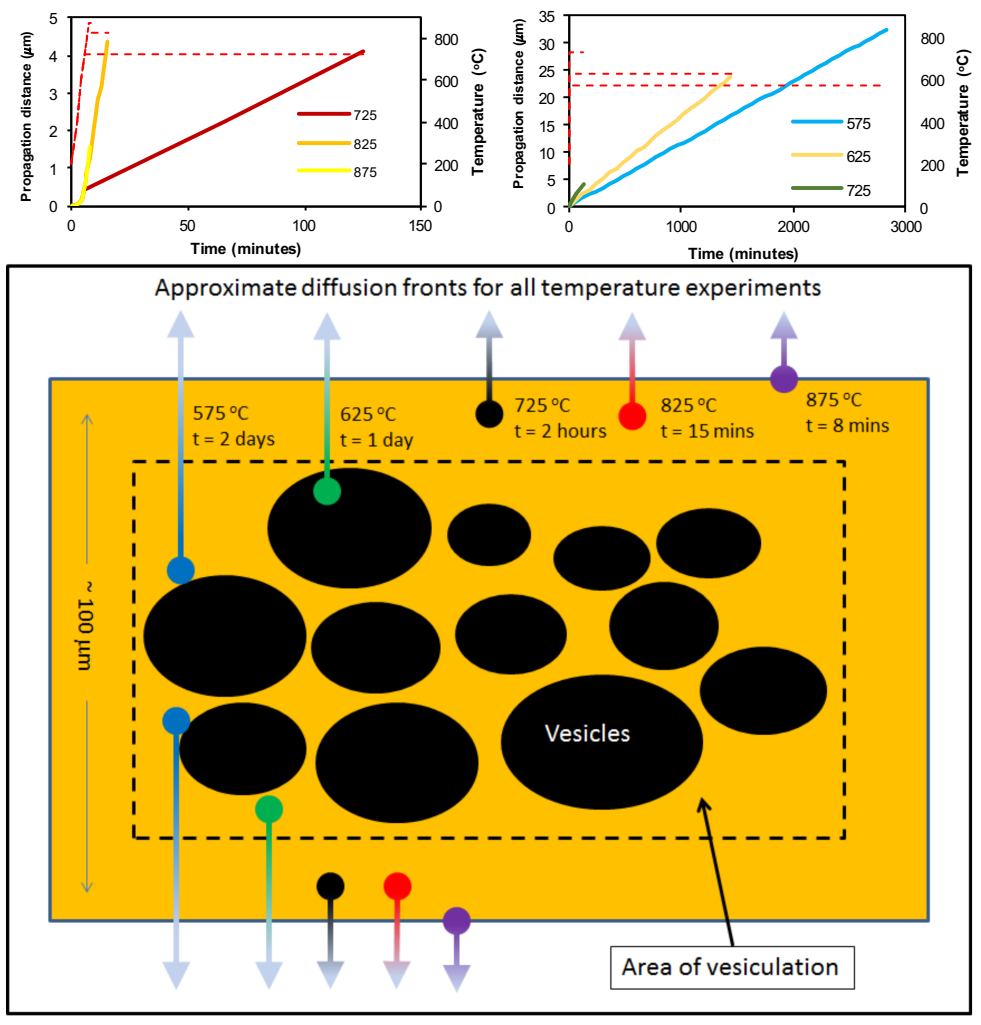

333 Magma viscosity for each temperature tested was calculated using the method of Giordano et al
334 (2008), based upon the composition of Chaitén rhyolite (from Castro and Dingwell 2009), the
335 measured H₂O concentration of our sample, with 0 ppm CO₂. CO₂ was not detected in our samples
336 and is therefore not incorporated into the viscosity calculations. The effect of crystals on effective
337 viscosity (η) was estimated using the Einstein-Roscoe equation (Einstein, 1911; Roscoe, 1952;
338 1953)

$$339 \quad \eta = \eta_o (1 - \phi C)^{-2.5} \quad (8),$$

340 where η_o is the viscosity of crystal free melt, ϕ is a constant (1.67) and C is the volume fraction of
341 suspended crystals. Due to the low crystal content of analysed samples, the effect of crystals on
342 viscosity is negligible: the addition of 10% crystals at 875°C raises the magma viscosity from

343 $10^{7.05}$ to $10^{7.24}$ Pa s. None of the experiments induced noticeable crystallization and therefore the
 344 crystal fraction remained constantly low.

345

346

347 *Figure 3. Diffusional front propagation as a function of time and temperature (above), where*
 348 *dashed lines represent the imposed temperature and solid lines are the modelled diffusion*
 349 *distance. Below, a schematic diagram of a cross section through a ~100 μm thick vesicular*
 350 *obsidian wafer showing the approximate distances that the diffusional front propagated into the*
 351 *sample. Maximum diffusion propagation is 32 μm over a period of ~ 2 days held at 575 °C (top).*
 352 *In contrast the diffusional front for the highest temperature experiment (875 °C) only propagated*
 353 *1.5 μm into the sample; however this occurred over a much faster timescale (~ 8 minutes).*

354

355 One of the complexities of the atmospheric pressure hot-stage method is diffusive loss of H₂O
356 from the sample surfaces. Thus, even without vesiculation, sample water content will vary through
357 time and space throughout an experiment, potentially influencing estimates of the viscosity and
358 H₂O content of vesiculating melt. This could be particularly important in longer-duration
359 experiments. As we were not able to directly measure the water concentration of samples after the
360 heating experiments a model based on Zhang (1999) was used to estimate the timescale of diffusive
361 dehydration ($D_{H_2O_t}$) where C_o and C are water concentration inside and outside of the sample
362 respectively

363

$$364 \quad D_{H_2O_t} = \left(\frac{C}{C_o}\right) \exp\left(-16.83 - \frac{10992}{T}\right) \quad (9)$$

365

366 where $C = 0.95$ wt.% and $C_o = 1$ wt.%. The model used calculates $\sqrt{(D_{H_2O_t})}$ and provides an
367 approximate distance that the diffusion dehydration front will propagate into the sample over time
368 (Fig. 3), where T is temperature. It is found that diffusional degassing is unlikely to have
369 significantly affected measured growth rates in most of the experiments, where diffusion fronts
370 only propagate ~ 5 μm into the edge of wafers (Fig. 3). Due to the long duration of the lowest
371 temperature (575-725°C) experiments, diffusive H₂O loss likely affected the distribution of water
372 in these samples. Our model suggests that diffusional fronts propagated up to 30 μm into the
373 sample in these low temperature experiments. In all experiments, including those that attained high
374 final vesicularity, the sample surface displayed a continuous “skin” of dense, unvesiculated melt
375 \sim microns in thickness, as observed outgassing experiments on rhyolitic obsidian (von Aulock et
376 al., 2017). This reflects how such diffusive degassing at the wafer surface can stifle bubble
377 nucleation (Saubin et al. 2016) and create an impermeable barrier that can prevent foam collapse

378 (von Aulock et al., 2017). Most of the tracked bubbles grew near the interior of the sample at >>
379 5 μm from the upper sample surface.

380

381 **3. RESULTS**

382

383 **3.1 Nucleation, growth and evolution of vesicles**

384

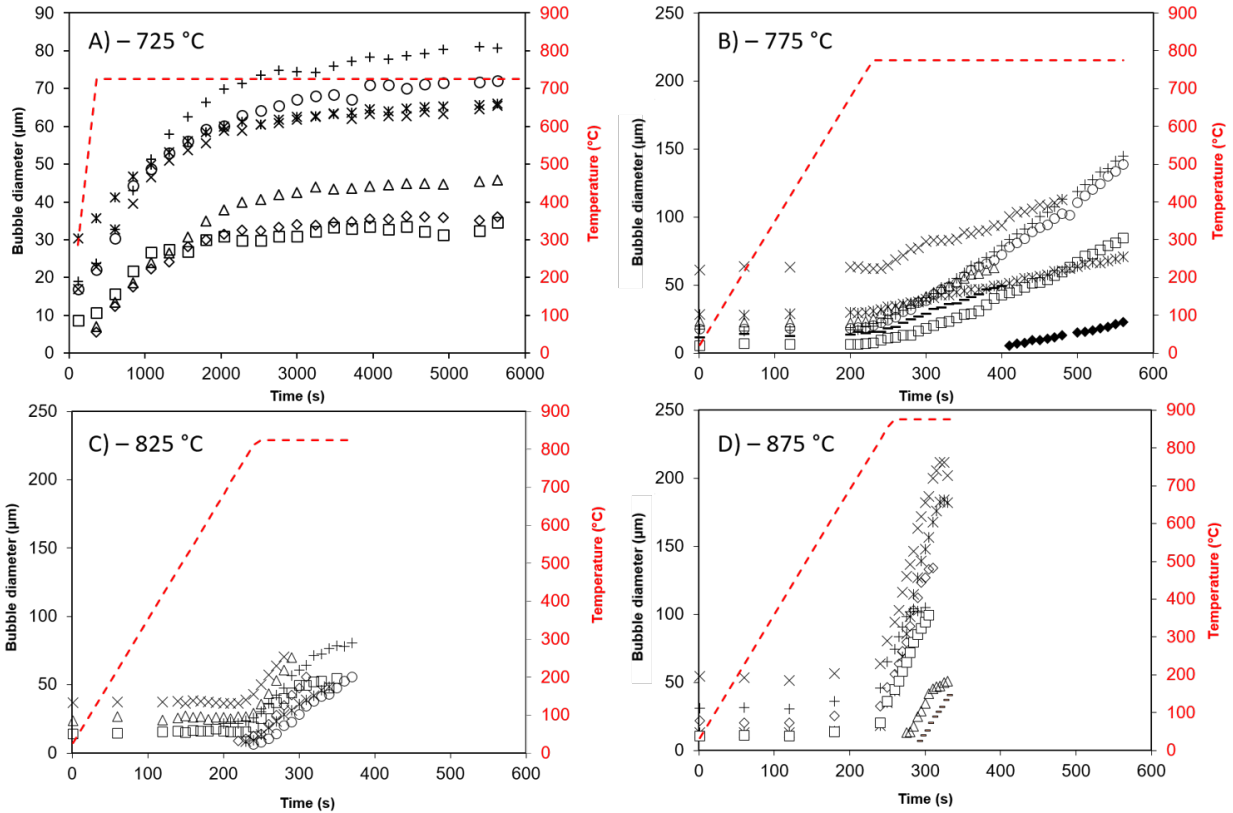

385 All starting glass wafers, which were prepared from the same centimetric obsidian clast, initially
386 contained between ~ 1 and ~ 10 % of vesicles ranging in size from 8–55 μm , estimated from
387 manually picked pixel percentages in optical images. Those vesicles were randomly distributed,
388 except for clearly-defined banded zones of greater vesicle abundance in some wafers
389 (Supplementary data). Pre-existing vesicles were predominantly elongate with maximum aspect
390 ratios of 2:1, where the *b*-axes were commonly near-parallel to flow banding as defined by bands
391 of enhanced bubble and microlite content. Short inter-bubble wall distances within bubble-rich
392 bands permitted only a brief period of uninhibited growth during heating experiments, prior to
393 bubble-bubble interactions (Fig. 4). The interactions can be, at least, partly discerned from the
394 curves of growth with time, where the two highest temperature tests display sigmoidal curves,
395 indicating an initial period of slow growth rate, followed by an acceleration and near-linear growth
396 rate (as used to calculate the averaged growth rates used in the later analysis) and a final reduction
397 in growth rate after the isotherm was reached (Fig. 5). At the lowest temperature test we note a
398 decaying growth rate long after the isotherm was reached. In the highest temperature (875°C)
399 experiments we note five stages of bubble evolution (Fig. 5):

400 1) Relaxation of pre-existing bubbles;

- 401 2) Free growth and nucleation;
- 402 3) Nearest neighbour interaction;
- 403 4) Coalescence and
- 404 5) Foam formation.

405 The initial stage of bubble growth involved the relaxation of elongate vesicles into spheres. Initial
406 growth rate of the *a*-axis was therefore often faster than the corresponding rate for the measured
407 *b*-axis (Fig. 5). Initial bubble growth occurred during the heating phase (i.e. under non-isothermal
408 conditions) in those tests where the sample was held at temperatures greater than ~ 750 °C (Fig. 4),
409 however the vast proportion of bubble diameter change during this phase was related to bubble
410 relaxation. Once bubbles had relaxed into spheres with aspect ratios of ~ 1 , we then note a period
411 of free bubble growth as opposed to re-rounding. We also note the first appearance of new bubbles
412 in stage 2 during isothermal conditions, indicating bubble nucleation.

413

414

415 *Figure 4. Bubble diameter against time for various maximum hold temperatures, A) 725 °C, B)*
 416 *775 °C, C) 825 °C and D) 875 °C. Note that the bubble diameter axes and time are different from*
 417 *the other plots in section A. This is because the duration of the experiments was one order of*
 418 *magnitude longer than the others. The different symbols represent the measurement of individual*
 419 *bubbles. The dashed red line indicates the temperature. For clarity, not all of the measured*
 420 *bubbles are shown.*

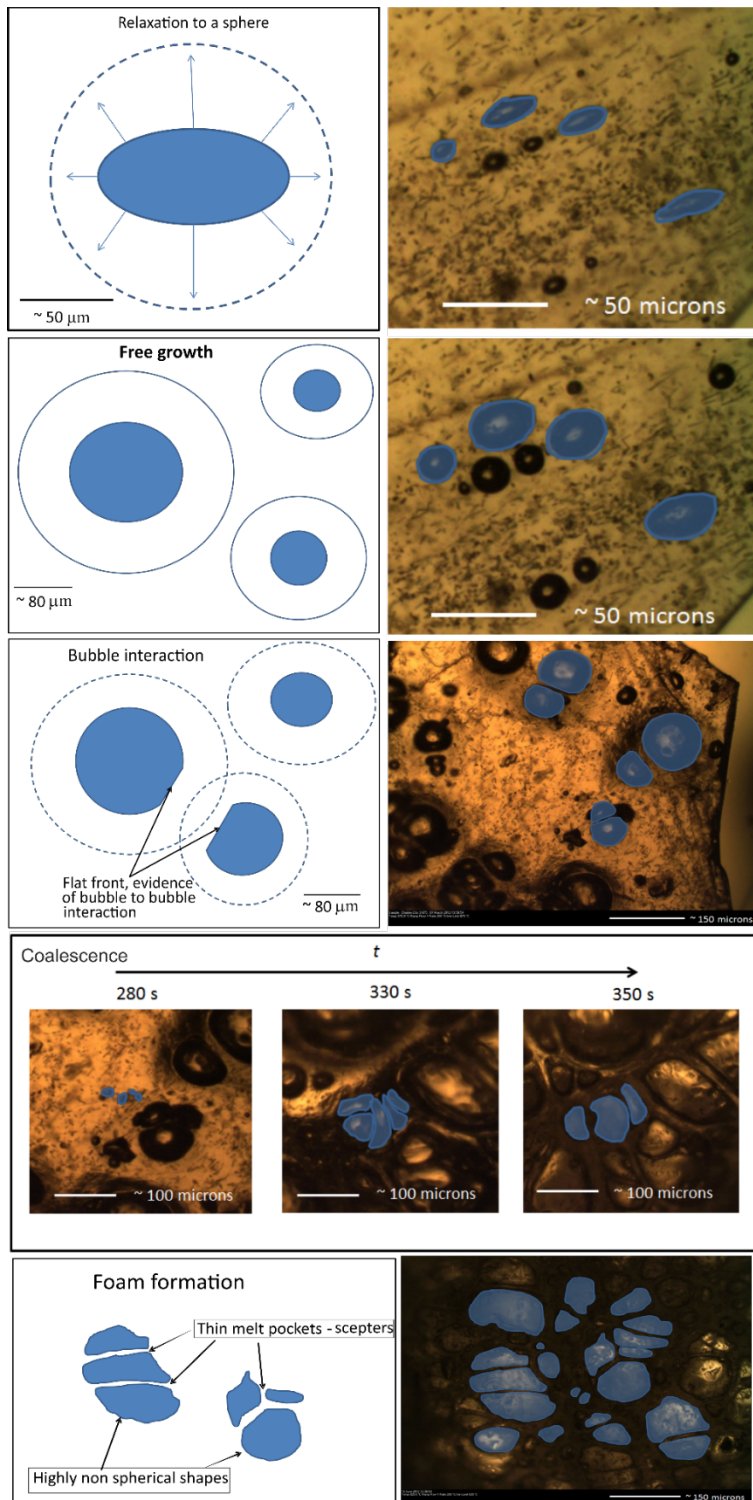

421

422 As bubbles continued to grow they began to interact with their neighbours, resulting in flattening
 423 of adjacent bubble walls, with the flattened surfaces normal to a line joining the two bubble centres.
 424 From the onset of bubble wall flattening, growth parallel to this bubble centre-centre line slowed
 425 significantly, sometimes resulting in a decreased bubble diameter in this orientation. However, in
 426 these cases, enhanced growth was instead observed along an axis normal to the centre-centre-line
 427 and parallel to the flattened surfaces, providing growth was not impinged by nearby bubbles in

428 that direction (Fig. 6). Through this process, bubbles became highly elongate and non-spherical.
429 Bubble wall flattening was noted even when adjacent bubble walls were not in direct contact, often
430 with a melt gap of $\leq 30 \mu\text{m}$ separating neighbouring bubbles. Unlike previous coalescence
431 experiments on hydrous rhyolitic melts (Castro et al. 2012), no dimpling of bubble walls was
432 observed – a phenomenon attributed to inter-bubble pressure differentials. Therefore in our
433 experiments the vapour pressure in adjacent bubbles appears to have been similar. The final two
434 stages of foam formation and bubble coalescence were only noted in the highest temperature
435 experiments (Supplementary data). We define a foam here to simply mean a state when a majority
436 of the bubbles were interconnected, with bubble to melt ratios $\geq 3:2$. We note that this is slightly
437 different to the definition of Proussevitch et al., (1993a) who define a foam as $>74\%$ vesicularity.
438 This is simply because at bubble to melt ratios of 3:2 it was not possible to accurately constrain
439 vesicularities as the samples changed shape substantially, influencing the range of focus, as
440 previously discussed. Bubble coalescence occurred in some experiments (Fig. 5), as inferred
441 predominantly from bubble number densities rather than direct observations. During foam
442 formation and multiple bubble-bubble interactions promoted highly-deformed, non-spherical
443 bubble shapes. Two bubble size populations are observed qualitatively during the foaming process,
444 with small bubbles ($<8 \mu\text{m}$) continuing to nucleate and grow within thin melt pockets separating
445 larger bubbles. It was not possible to discern, with confidence, the mechanism of nucleation,
446 whether on crystal surfaces or not although we speculate the nucleation was heterogeneous due to
447 the presence of microlites within the melt. Further analysis of the kinetics of bubble nucleation
448 were limited by resolution and imaging technique which only permits imaging of features $>1 \mu\text{m}$
449 in dimension. Several samples included microlite-rich bands that commonly contained an initial
450 higher bubble number density, as well as being slightly more H_2O -rich, suggesting that

451 heterogeneous nucleation had occurred during disequilibrium degassing prior to quenching during
452 explosive ejection. During stages 4 and 5, small newly-formed bubbles commonly coalesced with
453 older and larger bubbles, apparently via stretching and thinning of inter-bubble melt walls. Smaller
454 bubbles generally grew slower than the larger bubbles in whose walls they were growing. Foam
455 formation was observed at isothermal temperatures of ≥ 775 °C, whereas below this temperature
456 insufficient bubble growth and coalescence occurred to create foam textures.

457

458

459 *Figure 5. Five stages of bubble growth 1) Relaxation of pre-existing bubbles, 2) free growth*
 460 *and nucleation, 3) nearest neighbour interaction, 4) coalescence and 5) foam formation.*

461

462 3.2 Temperature-dependent bubble growth rate

463

464 The growth of individual bubbles was tracked during the heating phase and over a range of
465 isothermal temperatures during a hold phase. In Figure 4, we show the growth of individual
466 bubbles over four of the temperatures investigated. The early stages of heating show no bubble
467 growth below approximately 725 °C in all tests. Above this temperature all bubbles exhibit a
468 period of near-constant growth rate, during both heating (non-isothermal) and isothermal
469 conditions. Whilst full modelling of the growth trajectories would be possible we have chosen to
470 derive the average growth rates for each temperature considering this period of free growth as the
471 growth with time is linear in this portion. We found that in the highest temperature tests (at 875
472 °C) where ΔT (between initial bubble growth temperature and hold temperature) was
473 approximately 150 °C, bubble growth rates ranged from between $\sim 0.32 \mu\text{m s}^{-1}$, as the sample
474 reached 725 °C, and up to $\sim 1.27 \mu\text{m s}^{-1}$, as the sample reached the desired hold temperature of 875
475 °C. This large difference of growth rates reflected the range of temperatures through which the
476 sample experienced on the way to attaining the desired hold temperature. As such for later
477 comparison we deal only with the averaged growth rates obtained during both the period of free
478 growth but at isothermal conditions, when the hold temperature was attained. It is important to
479 note that the growth rates obtained under non-isothermal conditions do correspond well with the
480 averaged growth rates obtained during each hold phase in the lower temperature tests. In these
481 lower temperature tests bubble growth is only observed when the hold temperature is reached, and
482 this is why for comparison between tests we deal only with growth during these maximum hold
483 temperatures. To clarify, all growth rates discussed from here on relate to bubble growth during
484 the isothermal phase of our tests, where bubble growth was near constant. Near-constant growth

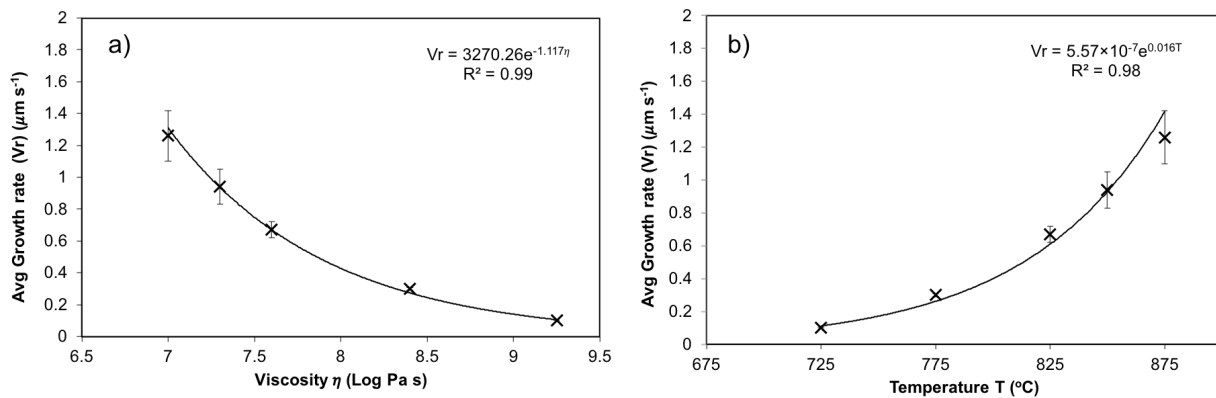

485 rate began when a bubble reached $\geq 5\%$ of its initial size regardless of whether growth occurred
486 isothermally or non-isothermally. The aspect ratio of bubbles is rarely constant, therefore for the
487 purpose of obtaining growth rates (i.e. measuring growth rather than relaxation), only
488 measurements obtained within measurement error of an aspect ratio of 1 were used. This growth
489 phase occurred only after the attainment of maximum temperature in all tests. The time interval of
490 constant growth, which ranges from ~ 30 seconds at $875\text{ }^\circ\text{C}$ to ~ 30 minutes at $725\text{ }^\circ\text{C}$ is dictated
491 largely by the initial bubble number density (BND) (Supplementary data), whereby higher BNDs
492 increase the likelihood of bubble-bubble interactions and reduce the time interval available for the
493 measurement of constant growth. For example, we performed repeat tests at $825\text{ }^\circ\text{C}$ as one of the
494 samples contained approximately $300\text{ bubbles mm}^{-3}$ and the other contained approximately 3000
495 bubbles mm^{-3} . This hence influenced the chance of bubble-bubble interactions but it did not
496 substantially change the average growth rates derived (Supporting information).

497
498 *Figure 6. Effect of bubble deformation on observed growth rate. Here the measured b-axis of a*
499 *bubble appears to grow faster but this effect is due to neighbouring bubbles preferentially*
500 *squeezing the measured bubble along the b-axis. The reverse situation is also observed, whereby*
501 *slower than expected growth is found on the b-axis.*

502

503 No bubble growth was observed in experiments at temperatures < 725 °C. At 725 °C, a
504 maximum of 9 μm of growth along the a -axis occurred over a period of ~ 30 minutes, indicating a
505 sluggish growth rate of $\sim 0.5 \times 10^{-3} \mu\text{m s}^{-1}$. No growth was observed after this time or at all along
506 the b -axis. The growth was minimal and characterized by relaxation of pre-existing vesicles
507 towards a more spherical form, with expansion of their a -axis only, and so is better defined as
508 shape relaxation rather than true growth. Far higher growth rates were determined for higher-
509 temperature experiments, reaching $1.27 \mu\text{m s}^{-1}$ at 875 °C, and the bubble growth rate as a function
510 of viscosity (Fig. 7a) and temperature (Fig. 7b) describes an exponential relationship where $V_r =$
511 $3270.26e^{-1.117\eta}$ and $V_r = 5.57 \times 10^{-7} e^{0.016T}$ respectively. The best fits were simply the most
512 appropriate empirical choice of simple functions to provide a relatively easy tool for later
513 interpretation and modelling. The duration of growth over which the bubble growth rates were
514 obtained account for only a small portion of the total test duration of our vesiculation experiments,
515 as shown in Figure 4. However, it was only in this period that we could be confident that the bubble
516 growth was not impacted by morphological interactions between bubbles.

517

518 *Figure 7. a) Exponential relationship between experimentally derived averaged bubble growth*
519 *rates and modelled melt viscosity (from Giordano et al., 2008) and b), averaged bubble growth*
520 *rates and temperature.*

521

522 **4. DISCUSSION**

523

524 Our isothermal bubble growth results are now considered in the context of an ejected cooling bomb
525 model. The aim is to investigate the maximum attainable bubble size in clasts of rhyolite ejected
526 during Vulcanian explosions. It must be reiterated that the experiments were conducted under
527 atmospheric conditions, without the application of external stress (Hajimirza et al., 2019) or
528 confinement and hence are most relevant to conditions occurring outside of the volcanic conduit
529 such as in ejected large volcanic bombs.

530

531 **4.1 Observing the physical processes of vesiculation**

532

533

534 The results presented here provide direct observations of bubble growth in a rhyolitic melt. Most
535 of our samples contained some pre-existing elongated vesicles, often aligned in bands. The
536 existence of non-spherical bubbles indicates that the timescale of natural pyroclast cooling was
537 faster than that of viscous bubble relaxation. The relaxation timescale can be estimated by $\tau_{rel} =$
538 $R\eta / \sigma$ (Navon et al., 1998), where σ is the surface tension of a bubble, estimated at $\sim 0.106 \text{ N m}^{-1}$
539 (Mourtada-Bonnefei and Laporte, 2004). Taking the estimated melt viscosity of $10^{7.1} \text{ Pa s}$ at 875
540 °C (from Giordano et al. 2008), an initially elongate $10 \mu\text{m}$ bubble should relax within 20 minutes.
541 This far exceeds the short relaxation timescales observed in our higher temperature experiments
542 ($\sim 5 \text{ s}$). Changing values of surface tension within an order of magnitude does not significantly
543 change the estimated relaxation time and it is unlikely that an order of magnitude difference in
544 surface tension would be experienced here. The disparity between the findings here and the

545 modelled outcome must instead be due to an overestimate of the viscosity, for example a change
546 in viscosity to 10^6 Pa s corresponds to a relaxation time of ~ 2 seconds, which is in far better
547 agreement with our observations. Such dramatic viscosity changes can be achieved by temperature
548 increase or the addition of H₂O (Giordano et al., 2008). In our strain-free experimental procedure
549 localised strong temperature increase is implausible, leaving locally high H₂O at bubble walls as
550 the only possible explanation. Strong H₂O enrichment around large (millimetric) bubbles in
551 rhyolitic pyroclastic obsidian has been identified (Watkins et al. 2012), and also found in
552 experimentally decompressed samples (McIntosh et al., 2014). Enrichment, attributed to either gas
553 pressure increase or H₂O resorption during cooling, occurs within 20-1000 microns of bubbles,
554 and can involve local H₂O increase of up to 2 wt % above the “far-field” concentration (McIntosh
555 et al., 2014). It is possible that similar enrichment occurs around pre-existing bubbles in Chaitén
556 obs 3 sample, but the small bubble size and large aperture associated with benchtop FTIR analysis
557 precluded quantification of any heterogeneities. The relaxation stage of growth is followed by a
558 free growth stage, whereby spherical bubbles continue to grow without visibly interacting with
559 neighbouring bubbles. The timescale of this growth phase is limited by initial bubble number
560 density where more bubbles decrease the space available for free growth.

561
562 Bubble growth rate decreases exponentially with increasing viscosity. At the highest temperatures
563 (875 °C) diffusivity (Eq. 10) is estimated to be $\sim 2.3 \times 10^{-13}$ m²s⁻¹, and at the lowest temperature
564 (575 °C) $\sim 3.5 \times 10^{-15}$ m²s⁻¹. This relationship suggests that bubble growth rate varies linearly with
565 diffusivity, with diffusivity increasing exponentially with temperature (Supplementary
566 information).

567

568 Bubble interaction is an important influence on the growth rate in our experiments, and thus is the
569 defining feature of the third stage of bubble growth. This finding is in disagreement with that of
570 Lui and Zhang (2000), who found that bubbles do not significantly affect the growth rate of their
571 neighbours. In contrast, our measured growth rates are significantly impacted as bubbles interact
572 (see also Proussevitch et al., 1993b). As discussed, all of the measurements consider only a two-
573 dimensional field but it is possible that some of the growth or interaction is accommodated in the
574 third dimension, which we could not image accurately. However, whilst we cannot discount this
575 possibility, we expect the effects will be less since the samples are approximately 1000 times
576 longer than they are thick. Bubble interactions eventually lead to coalescence and foam formation
577 in the highest-temperature experiments, which is also marked by a decrease in growth rate. The
578 formation of dense bubble packing and foams in magma are significant in creating degassing
579 pathways through interconnected bubbles, and whilst this did not occur in our experiments, can be
580 followed by compaction and foam collapse (Stasiuk et al. 1996; Kennedy et al., 2016; Forte and
581 Castro, 2019), especially if diffusively degassed dense skins are removed (von Aulock et al., 2017).
582 During the foam formation stage it is expected that growth decreases or stops as volatiles have a
583 defined degassing path. At this stage the major limitation of volatile movement is the increasingly
584 high melt viscosity as volatiles escape, and a viscous quench of the melt may be experienced at
585 this point (Proussevitch et al., 1993b; Thomas et al., 1994). Our results broadly agree with those
586 of Thomas et al., (1994) who find that a viscous quench at viscosities $>10^9$ Pa s prohibits bubble
587 growth. In our lowest temperature experiments we estimate viscosities of $10^{9.5}$ Pa s with very
588 minimal growth rates ($0.02 \mu\text{m s}^{-1}$), which largely relates to bubble relaxation rather than real
589 growth. Although not proven with our FTIR data, localised H_2O enrichment at bubble walls could

590 have locally reduced melt viscosity to $\leq 10^9$ Pa s, thus facilitating the observed low-temperature
591 relaxation.

592

593 4.2 Relationship with natural bomb textures at Chaitén

594

595 Our experimental results provide a two-dimensional framework for estimating vesicle growth
596 timescales at atmospheric pressure in moderately water-rich rhyolitic bombs that do not experience
597 external stresses. With the rate of vesicle growth expressed as a function of melt viscosity, we can
598 also approximate vesicle growth rates in bombs over a range of water concentrations – assuming
599 that there is sufficient supersaturation for initial bubble nucleation. The presence of microlites in
600 Chaitén melts will lower the supersaturation threshold, and textural and water content analysis
601 indicates ~ 4 MPa is sufficient for vesicle nucleation in Chaitén bombs (Saubin et al. 2016). As the
602 H₂O solubility at 4 MPa is ~ 0.7 wt. % (at 825 °C and CO₂-free), sufficient supersaturation on
603 ejection to atmospheric pressure is therefore assured for bombs with ~ 0.7 wt. % H₂O and above as
604 determined from the model of (Newman and Lowenstern, 2002). Here we examine the
605 implications of temperature-dependent bubble growth rates for the extent of post-fragmentation
606 vesiculation in ejected bombs. We consider the conductive cooling of an initially-dense bomb of
607 1 m in diameter, which is instantaneously ejected from the vent at the initial eruptive temperature
608 of 825 °C. Conductive cooling of a spherical body (Carslaw and Jaeger, 1959) can be approximated
609 by:

610

$$611 \quad T = T_o - \left(\frac{2}{\pi}\right)\left(\frac{a}{r}\right)(T_1 - T_0) \sum_{n=1}^{n=\infty} \frac{(-1)^n}{n} \sin\left(\frac{n\pi r}{a}\right) \exp\left(\frac{-kn^2\pi^2 t}{a^2}\right) \quad (10),$$

612 where k and a are the thermal diffusivity and radius of the body respectively, T is the temperature
613 at a distance r from the centre of the body at a time t , T_i is the body's initial temperature and T_0 is
614 the fixed temperature at the surface of the sphere. This provides the temperature as a function of
615 position and time within the cooling bomb. In the model shown in Figure 9 we used a set value of
616 of $7 \times 10^{-7} \text{ m}^2 \text{ s}^{-1}$ for k with an initial temperature T_i of 825°C . We then consider the extent of
617 vesiculation within the bomb using the derived relationships for bubble growth rate. For melt with
618 an initial water concentration of 0.95 wt. %, as the sample analysed in this study, growth rate $V_r =$
619 $5.57 \times 10^{-7} e^{0.016T}$. However, more broadly, the growth can be approximated as a function of
620 viscosity where $V_r = 3270.26 e^{-1.117\eta}$. The latter equation, when combined with a model of melt
621 viscosity as a function of temperature and H_2O concentration, can be used to approximate vesicle
622 growth rates at a range of different water concentrations. We acknowledge that the residual water
623 concentration will decrease during vesicle growth, due to diffusive transfer of H_2O from melt to
624 vapour, as examined in variably-vesiculated Icelandic obsidian (Owen et al., 2013). However, at
625 the low confining pressure within an ejected bomb (1 atm), this decrease is negligible, even when
626 high vesicularity has been reached.

627

628

629 *Figure 8. a) Rhyolitic breadcrust bomb from May 2008 Chaitén pyroclastic deposits, at*
 630 *42°49'38.62" S, 72°39'32.51" W, photographed in January 2014. The 1 m-diameter bomb*
 631 *comprises a highly expanded, pumiceous centre (white) enveloped by a dense black obsidian*
 632 *margin that is 3-5 cm thick. The apparently thicker margin top right is of similar true thickness.*
 633 *b) Detail of bottom right-hand portion, where a 3 cm-thick dense outer margin grades into a 2 cm-*
 634 *thick partially-vesicular transitional zone. Patchy vesiculation reflects derivation of the bomb from*
 635 *a welded breccia with variable H₂O concentrations (Saubin et al. 2016), with subtle spatial*
 636 *variations in H₂O concentration persisting. c) Typical textures in the expanded interior, with >60*
 637 *% highly coalesced bubbles 100-500 μm in diameter. d) Textures in the moderately vesicular*
 638 *transition zone 3-5 cm from the bomb margin, with ~30 % largely isolated bubbles up to 150 μm*
 639 *in diameter. d) The dense quenched marginal material contains a low proportion (<1 %) of*
 640 *spherical bubbles <15 μm in diameter.*

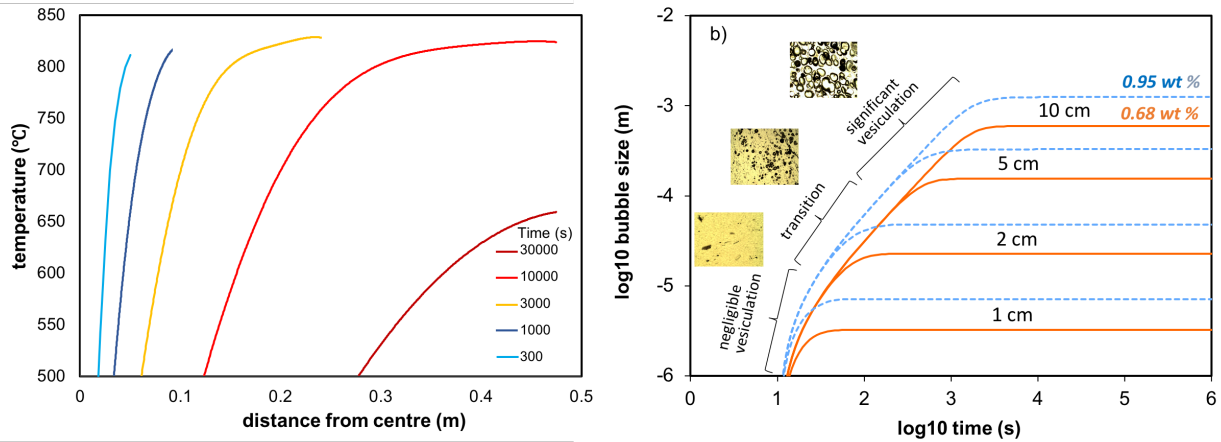

641

642 We thus consider the post-fragmentation vesiculation of BOMB-1, a 1 m-diameter partially-
643 vesiculated, near-spherical bomb with a prominent dense margin (Fig. 8). Infra-red spectroscopic
644 results indicate a water concentration of 0.68 wt. % in the 3 cm-thick dense margin, with a standard
645 deviation of 0.01 wt. % and extreme values of 0.64 and 0.72 wt. % (see Supplementary data). The
646 dense margin contains <1 % vesicles <15 μm in diameter (Figure 9e), in great contrast with the
647 highly-inflated bomb centre (Fig. 8c; porosity \sim 72 %, determined using a bead displacement
648 method on a 2 x 2 cm sample; Halliwell, 2014). The transitional zone \sim 3-5 cm from the bomb
649 margin displays an intermediate vesicularity (\sim 30 %) with bubbles attaining 150 μm in diameter.
650 We have used a numerical approach to solve for the evolving radii of vesicles at a range of
651 distances from the outer surface of the bomb, accounting for both conductive cooling (Eq. 10) and
652 viscosity-dependent growth rates. Figure 9 shows the modelled evolution of bubble size as a
653 function of distance from the bomb margin. It indicates that insignificant bubble growth will occur
654 in the outer \sim 2 cm of the bomb with 0.68 wt. % H_2O , with bubble radii only attaining \sim 10 microns,
655 similar to the measured bubble sizes (Fig. 8e). However, there is scope for significant bubble
656 expansion $>$ 5 cm from the bomb surface, with bubbles sizes approaching hundreds of microns,
657 sufficient for bubble-bubble interaction and the formation of foam textures with a high final
658 vesicularity. The thickness of a dense rind on a 1 m-diameter bomb with this water concentration
659 would therefore be expected to lie between 2-5 cm. This estimate agrees well with the measured
660 dense rind thickness on BOMB-1 (Figure 8), and the highly-vesicular core (Fig. 8c) displays
661 considerable bubble coalescence as well as bubbles reaching 500 μm in diameter.

662 There is therefore a good fit between the data and model for BOMB-1, despite the model
663 using growth rates extrapolated from melt with 0.95 wt. % H_2O to considerably less H_2O -rich melt
664 (0.68 wt. % H_2O). However, caution should be applied when extrapolating bubble growth rate-

665 melt viscosity relationships across wide ranges of water concentration to account for different
666 bombs, especially when the degree of supersaturation varies greatly and spatially variable microlite
667 concentrations could introduce variably heterogeneous bubble nucleation. A future study will
668 investigate the influence of H₂O concentration on growth rate at a single temperature across a wide
669 range of H₂O concentrations.

670 Additionally, heterogeneity of H₂O concentrations over spatial scales of tens of microns to
671 centimetres within individual bombs, introduced by formation and healing of diverse fragmented
672 magma in the shallow conduit (Castro et al., 2012b; Saubin et al. 2016), can lead to spatially
673 heterogeneous vesiculation within dense melt. This phenomenon is demonstrated by the ~3 cm-
674 thick transitional zone between the dense margin and inflated core of BOMB-1, which corresponds
675 to the modelled “transition” zone (Fig. 8d; 9), in which intermediate vesicularity between core and
676 margin is expected. In fact, the ~3 cm thick zone is highly texturally heterogeneous, displaying
677 pale lens-shaped patches <1 to >6 cm across of similarly high vesicularity to the core, embedded
678 within dense glass more texturally similar to the margin. These textures likely correspond to clastic
679 textures in what is now a densely-welded breccia, with bubble-rich lenses representing large,
680 subtly more water-rich clasts within a fine-grained, more degassed matrix, a transient textural
681 phase recorded within another Chaitén bomb (Saubin et al. 2016). This phase of highly patchy
682 post-fragmentation vesiculation, with strong spatial variation in bubble growth rate, can become
683 largely overprinted in bomb centres by vesicle growth and coalescence, obscuring an important
684 intermediate phase of vesiculation. In a similar manner, potentially abundant healed clastic
685 textures in highly inflated pumices may remain largely unrecognised, even though there is
686 increasing evidence for the pyroclastic origin of dense obsidian (Castro et al., 2014; Gardner et al.,
687 2017).

688

689 *Figure 9. (a) Temperature at different times as a function of distance from bomb edge, (b) modelled*
 690 *bubble sizes over time at between 1 cm and 10 cm from the bomb margin using two different water*
 691 *contents. Negligible bubble growth is expected within approximately 2 cm of the bomb margin.*

692

693 **5. CONCLUSIONS**

694

695 The experiments conducted have allowed the two-dimensional observation of in-situ bubble
 696 growth in rhyolite. Our study has shown that rate of bubble growth is strongly related to
 697 temperature and melt viscosity, where $V_r = 5.57 \times 10^{-7} e^{0.016T}$ and $V_r = 3270.26 e^{-1.117\eta}$. This simple,
 698 empirically-derived relationship facilitates modelling of evolving vesicularity within rhyolitic
 699 bombs, in the absence of applied shear stresses. We find that post fragmentation bubble growth
 700 can occur fast enough to promote the formation of dense bubble packing associated with foam
 701 textures in bombs and pyroclasts from Vulcanian type events. The efficiency of bubble growth at
 702 comparatively low pressure changes is important to consider in models of conduit fragmentation
 703 and degassing which often neglect the role of post-fragmentation bubble growth in cooling
 704 pyroclasts. The vesiculation of bombs is not always complete upon fragmentation in the shallow
 705 conduit or after a dome collapse event (Giachetti et al., 2010; Saubin et al., 2016). Instead, post-

706 fragmentation vesiculation may occur (e.g., Castro et al., 2012b) dependent on heat retention and
707 H₂O concentration and presence of melt, creating textural diversity in pyroclasts with contrasting
708 post-fragmentation thermal histories. It is important that future interpretive studies of rhyolitic
709 pumice consider the potential for post-fragmentation vesiculation to ensure that the pre-
710 fragmentation bubble population is not misrepresented (Giachetti et al., 2010; Saubin et al., 2016).
711 Our quantification of vesicle growth rates for a rhyolitic bomb with approximately 1 wt.% water
712 indicate relatively rapid growth at eruptive temperatures, with foaming over a timescale of
713 approximately 60 seconds.

714

715 **ACKNOWLEDGEMENTS**

716 We thank the editor and three anonymous reviewers for insightful comments that helped improved
717 the manuscript. We also thank Heidy Mader, Thomas Giachetti and Heather Wright for helpful
718 comments on an earlier version of the manuscript. JB acknowledges a Masters scholarship from
719 Lancaster University, Fondecyt project 11190143 and FONDAP project 15090013. HT and JO
720 were respectively supported by a Royal Society University Research Fellowship and an AXA
721 Postdoctoral Research Fellowship. JMC was supported by the VAMOS research centre. We thank
722 Debbie Hurst for assistance with FTIR analysis.

922 **SUPPLEMENTARY DATA:**

923 *Supplement 1. Composition of Chaiten obs 3 rhyolite glass sample*

924

Oxide	(wt.%)
SiO ₂	76.10
TiO ₂	0.13
Al ₂ O ₃	12.00
FeO(T)	1.27
MnO	0.06
MgO	0.28
CaO	1.41
Na ₂ O	4.00
K ₂ O	2.98
P ₂ O ₅	0.04
H ₂ O	0.95
F ₂ O-1	0.00
Total	99.84

925

926 *Supplement 2. Summary of results, bubble number density increase is shown for each sample.*

927 *Nucleation rates and growth rates are calculated using the methods previously discussed.*

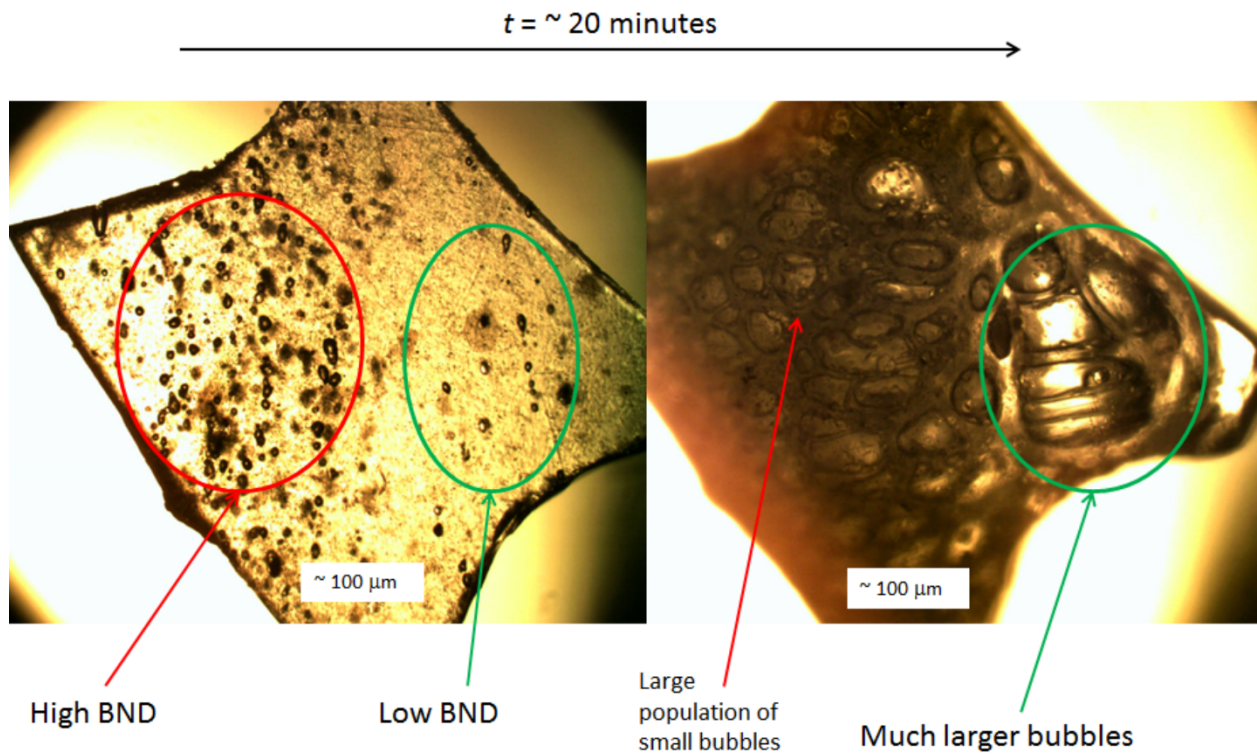

928

Sample no.	Initial BND mm⁻³ (<i>n_i</i>)	Final BND mm⁻³ (<i>n_f</i>)	% increase	Maximum Diameter (mm) (<i>d_{max}</i>)	Avg Growth rate (mm s⁻¹) (<i>V_r</i>)	Maximum Nucleation Rate (mm⁻³ s⁻¹) (<i>I_{max}</i>)	Avg Nucleation Rate (mm⁻³ s⁻¹) (<i>I</i>)
875	560	1360	143	101	1.27	24	15
875_R	467	1167	150	119	1.72	14	10
850	1120	1800	61	152	0.94	12	4
825	300	767	156	207	0.67	15	7
825_R	3040	3380	11	101	0.57	4	2
775	1000	1217	22	102	0.37	1	1

775_R	1816	1994	10	139	0.24	6	5
725	311	311	0	80	0.02		
625	367	367	0	52	None		
575	800	800	0	65	None		

929

930

931

932 *Supplement 3. Chaiten rhyolite imaged at x10 magnification over a period of ~20 minutes. A*
 933 *contrast exists between areas of high and low initial vesicularity and the final bubble size of*
 934 *populations in these two areas. In an area of high BND, growth of vesicles has been prohibited*
 935 *causing a population of many small bubbles. In contrast the bubbles in an area of low BND have*
 936 *been able to grow and deform significantly more.*

937

938

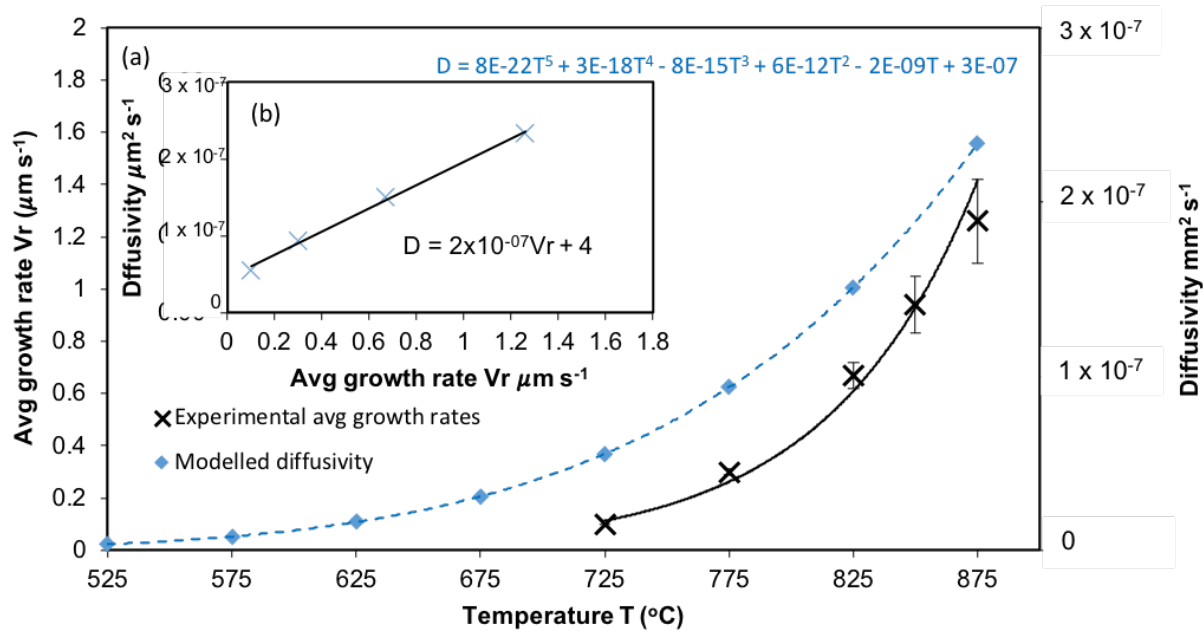

939

940

941 *Supplement 4. FTIR data showing the H_2O_m and OH_T contents of BOMB-1.*

942

943

944 *Supplement 5. Relationship between diffusivity and temperature is similar to that of growth rate*
 945 *and temperature (a), showing an exponential relationship where diffusivity = exp (0.0119T) and*
 946 *$V_r = exp (0.0169T)$. As such the relationship between modelled diffusivity (D) and growth rate*
 947 *(V_r) is linear (b).*
