GUIDED DESCENT TO MARS. VISION-BASED LOCALIZATION SYSTEM FOR A MARS PROBE.

S. Luque Ribas[1], D. Hernandez[2] and E. Zenou[1], [1]ISAE (10 Avenue Édouard Belin, 31400 Toulouse, France, Luque.Sergi@gmail.com), [2]Devil-Hop (11 Route des Bardis 31320 Rebigue, France), [3]ISAE.

Introduction: The Vision-based Navigation System designed aims to provide a better navigation feedback to the control systems and increase the landing precision of the probes. The frame mission is the Mars Minor project of ISAE TAS-ASTRO Master, a low cost and low weight lander mission to Mars.

This navigation system will start operating at around 15 km altitude, once the speed is reduced after the re-entry phase. A small hole is opened to allow the camera to start taking images of the surface.

System Design: The algorithm which obtains the position and velocity of the probe has been structured in two separate processes: *absolute localization* and *motion estimation*.

Feature points database. Prior to the launch of the probe, the database of images [2] is preprocessed in order to obtain characteristic points [3]. These points are described and then stored on the memory of the probe. By doing this, the size of the database is reduced drastically, as well as the onboard processing time, compared to a raw image.

Absolute localization algorithm. A first position estimation is provided by the Inertial Measurements Unit (IMU) onboard the probe and gross position estimation provided by the Earth control center. It is used to filter the database according to the position of each characteristic point. In addition, the points are also filtered according to local solar time, to increase the similarities between the surface images taken by the probe and the database images. The selected part of the database is then matched with the points obtained from the surface image coming from the probe's camera, providing the latitude, longitude and altitude of the probe.

Motion estimation algorithm. A first initial position, coming either from the IMU or the absolute localization algorithm is required. This algorithm compares the feature points extracted from two successive images. It estimates the relative movement of the points along the second image and, together with the first initial position and the elapsed time, it is able to estimate the new position and velocity.

Simulation: The system, comprised by the absolute localization and motion estimation algorithm, has been implemented in Matlab.

The *simulation visualization* has been designed in order to be easy to use no matter the computer used. A web-based interface has been designed (freely available at **www.marslanding.tk**), which is able to run in most browsers and operative systems (Figure 1). The page is based in HTML language combined with CSS to structure and organize its elements. JavaScript is used to provide dynamism to the page and to communicate with the Google Earth API [4] and the Flot libraries [5]. These last two are responsible to show, respectively, the 3D visualization of the descent and the data plots coming from the trajectory generation and estimation of the system.

Conclusions: The algorithm is capable of reaching a mean error of 13.4 px, compared to the database resolution, which is translated to around 75 meters over the ground. The computing performance is able to execute the algorithm in a reasonable time, around 0.62 seconds for the absolute localization algorithm. The combination with the motion estimation algorithm, which is 10 times faster, allows reducing the total computing time, making possible an embedded system on a real probe.

Versatility. The localization system can be used as long as there is an image database and the surface does not change much in time, as on the Moon or other rocky moons of Mars. The web-based simulation makes it very easy to manage any localization data, being able to be used for other missions. It is also possible to change from one celestial body to another, as long as the planet is represented by the Google Earth API.
