A C K N O W L E D G E M E N T S

The work described in this Thesis was carried out under the guidance of Professor K.S.W. Sing, to whom the author wishes to express deep gratitude for his patience, understanding and constant encouragement throughout the past four years.

Appreciation is extended to Dr. S.J. Gregg for many helpful discussions during the course of writing this Thesis, and in which the author was introduced to the subject of "Dangling Participles".

Life for a research worker is made that much easier by good technical assistance: the author has been especially fortunate to encounter the friendly help and cooperation of many members of the Technical Staff of Brunel University. These are too numerous to mention all by name, but particular thanks are due to Bill Wilkings (who turned my pennies into pounds), Alan Higdon, Dick Bird, and the 'boys in the back room!', Doug and Ted. The expertise of a Glass Blower is an invaluable assistance to the Surface Chemist and Brunel' is able to boast one of the best; the photographs included in this Thesis are testimony to the glassworking skill of Tony Williams, to whom the author extends sincere thanks for his considerable help (and unfailing provision of 'Page 3' in the Surface Chemistry 'Rest Room').

During the course of this work the author was a member of the staff of Glaxo Research Ltd., to whom sincere thanks are extended for the company's generous financial support given throughout the author's university career. Acknowledgement is also due to the

Science Research Council for the Industrial S.R.C. Award to the author.

I am particularly grateful to my very good friends Peter and Jean Warren for their generous hospitality and understanding, which helped me through some difficult periods during the course of this work. Appreciation is extended to Mr. Denzil Plomer for the excellent photography of the adsorption apparatus described in this Thesis.

Last but not least, the author wishes to recognise an irremunerable debt of gratitude owed to Mrs Doreen Wray, who worked so hard and conscientiously late into many nights to type this Thesis. Without "Dodo's" help, perseverance and skill (and her understanding husband "Charlie" who took over all domestic chores), this Thesis may not have made typed form.

A B S T R A C T

The adsorption of nitrogen, argon and water vapour was studied on various well-characterised chromium oxides and silicas outgassed at selected temperatures between 25° and 1000°C. Standard data derived on non-porous oxides provided a basis for the analysis of the isotherms by the  $\alpha_s$ -method, which has been found especially useful for the identification of the various physisorption processes, e.g. micropore filling and capillary condensation. The Frenkel-Halsey-Hill (FHH) method has also been used to analyse the multilayer region of the isotherms.

Chromia gels precipitated at about pH 6 were found to be microporous. These gels, when outgassed at 25°C, exhibited molecular sieve properties; the sorption capacity for water was high, whereas the pore volume available to nitrogen and argon was small. It is suggested that cavities were formed in the gel in the vicinity of the  $\text{Cr}^{3+}$  ions through the removal of water ligands under conditions where the hydroxide structure was slow to develop. The molecular sieve character was considerably reduced in the case of gels precipitated at high pH (about 10.5), presumably because of the more efficient replacement of water ligands by hydroxyl ions.

Chromia gels outgassed at high temperature retained a strong affinity for water vapour, and gave argon and water vapour

isotherms which exhibited some slight stepwise character.

On the other hand, silicas outgassed at 1000°C were found to be strongly hydrophobic.

Mercury vapour adsorption was found to take place very readily on some outgassed chromium oxides. This presents a problem in both volumetric and gravimetric adsorption measurements unless special precautions are taken to exclude mercury vapour from the system. Pressure-sensitive transducers have been used to overcome this problem in the case of the water vapour adsorption studies.

## CHAPTER 1

### INTRODUCTION

Chromium oxides and hydrous chromium oxides are widely employed for diverse applications and have consequently been the subject of considerable investigation for over a century. Much of the interest in recent decades has been stimulated by the use of oxides in ceramics and semiconductors, but perhaps the most important role of the chromium oxide system is in the field of catalysis. With the exception of alumina, silica and group VIII metals, chromium oxide has probably received more attention than any other catalyst. Nevertheless, although a number of surface chemical studies have been made of chromium oxide gels, two particular problems merit further attention: (1) the difficulty of controlling the complex textural and surface chemical changes, which involve both surface hydration and oxidation state, and (2) the identification of catalytically active sites for particular reactions. For convenience, reference is usually made to 'chromia' to denote a hydrated chromium oxide of unspecified degree of hydration, but it must also be borne in mind that chromium may be present in different oxidation states.

The present work was undertaken in an attempt to gain an increased understanding of the bulk and surface chemistry of the  $\text{Cr}-\text{O}-\text{H}_2\text{O}$  system. In particular, attention has been given to the origin of porosity in chromia gels in relation to conditions of preparation, dehydration and calcination. For this purpose gas adsorption has provided the main experimental method of investigation, but the techniques of differential thermal analysis (DTA), differential scanning calorimetry (DSC), heat of

immersion, electron microscopy and x-ray diffraction have also been used to assist in the characterisation of the gels and the products of thermal decomposition. In addition, the adsorption properties of certain standard silicas have been studied: hydroxylated and dehydroxylated silicas may be expected to provide useful reference surfaces in the analysis of the adsorption data.

Nitrogen adsorption measurements are generally employed for the determination of surface area and pore size distribution. It is now recognised, however, that nitrogen undergoes a specific physisorption interaction with some surfaces. The degree of specificity of water vapour adsorption is very great, but on the other hand, the adsorption of argon involves only nonspecific interactions. A comparative study of the adsorption of these three adsorptive molecules is therefore likely to provide useful information concerning the chemistry of the chromia surface. A direct study of the second major problem associated with chromia (i.e. characterisation of the catalytically active sites) was, unfortunately, beyond the scope of the present work.

### 1.1 The influence of texture on the catalytic properties of chromia

The ability of chromia to act as a catalyst was recognised as early as 1852, when Wohler<sup>1</sup> reported that chromia catalysed the oxidation of sulphur dioxide to the trioxide. The classical work of Sabatier<sup>2,3</sup> some sixty years later established the usefulness of certain metal oxides as dehydrogenation catalysts, amongst which chromia was listed as a catalyst of "mediocre activity". However, the later work of Lazier and Vaughan<sup>4</sup> revealed that chromia is, in fact, a hydrogenation catalyst possessing a high activity. Early workers frequently failed to recognise the importance of pre-treatment conditions or, for example, the poisoning action of water

vapour in many catalytic reactions.<sup>5-7</sup> Similarly, there are many references to gas adsorption studies on chromia catalysts with "clean surfaces", although it appears that insufficient precautions have been taken to avoid the possible contamination of the surface by grease or oil vapour; indeed, under certain outgassing conditions employed,<sup>8</sup> the undetected chemisorption of mercury vapour would almost certainly have occurred.

The versatility of chromia as a catalyst is demonstrated by its use in a wide variety of reactions, many of industrial importance; e.g. hydrogenation,<sup>9</sup> dehydrogenation,<sup>10</sup> dehydration,<sup>11</sup> dehydrocyclisation,<sup>12</sup> hydrodealkylation,<sup>13</sup> dealkylation,<sup>14</sup> dehydrocracking,<sup>15</sup> aromatisation,<sup>16</sup> oxidation,<sup>17</sup> dehalogenation<sup>18</sup> and fluorination.<sup>19</sup> Other industrial uses include the removal of sulphur-containing gases from automobile exhaust systems,<sup>20</sup> as pigments in colour printing<sup>21</sup> and for the detection and removal of oxygen from olefin streams without polymerisation of the olefin.<sup>22</sup> There is now a strong tendency towards the industrial use of supported chromia catalysts, e.g. chromia dispersed on alumina or silica. Chromia - alumina is a particularly important catalyst in the manufacture of butadiene from butane for the synthetic rubber industry. Chromia supported on silica - alumina, is an active catalyst for the polymerisation of ethylene to give crystalline, orientated polymers.<sup>23</sup> Chromia-based catalysts will probably continue to play a major role in the heavy chemicals industry and in the reduction of atmospheric pollution.

The major function of the support of a dispersed chromia catalyst is generally to prevent loss in surface area that occurs when chromia is heated at temperatures above about 400°C.<sup>24</sup> Supported chromia catalysts exhibit certain properties which can be predicted from a consideration of the parent oxides. However, although supported chromia catalysts may, at least to a first approximation, be regarded as dual-function catalysts,<sup>25</sup> they also

possess properties which are attributed to a synergistic interaction of the two phases.<sup>26</sup>

Chromia is unusual in the respect that it displays both n and p-type semiconductivity.<sup>27</sup> The nature of the conductivity is dependent upon a number of factors, e.g. mode of preparation, pretreatment, temperature and reaction atmosphere. Chapman<sup>28</sup> has found that chromia behaves as a p-type semiconductor in oxygen and a n-type semiconductor in hydrogen. Weller and Voltz<sup>6,29</sup> have confirmed the findings of earlier workers<sup>30,31</sup> that chromium (III) oxide contains excess oxygen after oxidation and adsorbed hydrogen after reduction. Extensive studies by Dereń and Haber<sup>32,33</sup> suggest that the conduction mechanism is essentially the same in both the amorphous and crystalline oxide, at least for the annealing (in air) temperature range of 200 - 700°C.

Chromia annealed in air below 200°C is a poor conductor:<sup>32</sup> the conductivity increases on raising the annealing temperature, reaching a maximum at about 400°C and thereafter declining with higher annealing temperatures. Several workers<sup>34,35</sup> have noted that the degree of oxidation of the gel increases with the temperature of annealing in air. Dereń and Haber<sup>32</sup> have postulated that this will result in an increase of the concentration of Cr<sup>6+</sup> acceptor centres and consequently in the increase of conductivity. Crystallisation of Cr<sub>2</sub>O<sub>3</sub> at about 400°C probably results in a crystal lattice that is highly disordered and therefore exhibits high conductivity: on increasing the annealing temperature above 400°C the lattice becomes progressively more ordered, the concentration of Cr<sup>6+</sup> ions decreases and so does the conductivity. Several workers<sup>36,37</sup> have suggested that above 400°C, chromium (III) oxide changes from a predominantly p-type semiconductor to predominantly n-type. It is interesting to note that

although it has been proposed that conductivity in polycrystalline oxides is a function of the surface conductivity of the grains,<sup>38</sup> Dereń and Haber<sup>32</sup> found similar conductivities for chromias of widely different surface areas. However, there are insufficient data in the reported work to indicate whether the external surface areas of the gels were also dissimilar.

Many studies<sup>39-41</sup> have indicated that chromium ions may exist in chromia systems in oxidation states from +2 to +6. In addition, Shelef<sup>42</sup> has reported electron paramagnetic resonance (epr) evidence of the univalent state in a reduced chromia-alumina catalyst. The relative amounts of the various states present on the chromia surface may strongly influence its catalytic properties. The surface layer of an 'oxidised' chromia catalyst will contain predominantly the higher oxidation states, i.e.  $\text{Cr}^{6+}$ ,  $\text{Cr}^{5+}$  and  $\text{Cr}^{4+}$ , and apparently promotes reactions such as hydrogen peroxide decomposition and ethylene polymerisation etc. A 'reduced' chromia, containing  $\text{Cr}^{3+}$  (and possibly  $\text{Cr}^{2+}$ ) in the surface layers, apparently favours reactions such as hydrogen - deuterium exchange and olefin hydrogenation etc.

In many cases, chromia may simultaneously catalyse more than one reaction, e.g. both the dehydration and dehydrogenation of alcohols. In such cases, the selectivity of the catalyst is a particularly salient feature. Garner<sup>43</sup> has suggested that cation vacancies favour dehydration whilst anion vacancies favour dehydrogenation. There are different opinions as to the origin of p-type semiconductivity in  $\text{Cr}_2\text{O}_3$ , but Voltz and Weller<sup>6,29,44,45</sup> have postulated that at least in the surface layers, the conductivity is due to cation deficiency. It was shown by Dowden et al<sup>46</sup> that in the case of propan-2-ol, dehydration was favoured by p-type semiconductors and dehydrogenation by n-type. Kuriacose and co-workers<sup>47-52</sup> have observed a similar relationship in a series of studies of propan-2-ol on chromia and chromia - alumina catalysts; a puzzling feature of a few of their papers is,

however, the fact that they have also stated the reverse to be the case,<sup>50,52</sup>

In any assessment of the catalytic activity of chromia it is inherently difficult to distinguish clearly between surface chemical and textural contributions. The analysis is further confused by the extreme sensitivity of the adsorptive and catalytic properties of chromia to the conditions of preparation, storage and heat-treatment of the gel. Nevertheless, the texture of the chromia surface may also play an important part in determining the dehydration/dehydrogenation selectivity of the catalyst. Kuriacose et al<sup>51</sup> have shown that the activity of chromia, in respect of alcohol dehydration, is closely related to the pore structure of the catalyst. The dehydration activity is completely destroyed when the catalyst is sintered: pore size distribution analysis revealed that the micropore structure of the catalyst was considerably reduced after sintering. Conversely, Schwab et al<sup>53</sup> have found that dehydrogenation is facilitated by non-porous catalysts: a reduction (by sintering) or increase (by powdering) of the external surface area of the catalyst, decreases<sup>54</sup> or enhances,<sup>51</sup> respectively, the dehydrogenation activity. Several workers<sup>51,55</sup> have observed that there is a correlation between the loss of dehydration activity and the progressive removal of water from the surface of a chromia catalyst. Dowden<sup>55</sup> suggested that the active centres for dehydration are protons originating from water located at cation vacancies in the oxide lattice. Sintering of the catalyst results in the predominantly irreversible loss of surface hydroxyl groups: in the absence of pores, a rehydroxylated chromia surface imparts only a fraction of the original dehydration activity.<sup>51</sup> However, Topchieva<sup>56</sup> has shown that in the case of yttrium oxide, the original dehydration/dehydrogenation selectivity is restored if the dehydration process can be carried out reversibly; a reduced surface hydroxyl concentration enhances dehydrogenation at the expense of dehydration.

Burwell<sup>9,57</sup> and Zecchina<sup>58</sup> have applied the concept of "surface coordinative unsaturation" to the active sites formed on the surface of chromia by dehydration. Loss of water by condensation involving surface hydroxyl groups will, in general, generate coordinatively unsaturated sites (cus) of  $\text{Cr}^{3+}, \text{O}^{2-}$  and possibly  $\text{OH}^-$  species. In the case of  $\alpha\text{-Cr}_2\text{O}_3$ , water loss can generate sites of different geometries and degrees of coordinative unsaturation, and either one or two exposed  $\text{Cr}^{3+}$ : one cannot be so specific for the case of amorphous chromia, but it is suggested<sup>24</sup> that similar considerations will apply.

Burwell and his co-workers<sup>59</sup> have suggested that the microporous structure found in many amorphous chromias may impart special catalytic activity. For example, the ratio of isomerisation to hydrogenation of hex-1-ene was very low in the presence of a microporous chromia gel; when however, the gel was suitably treated to give a mesoporous texture, the ratio was high. Cross and Leach<sup>60</sup> have observed a similar relationship for the isomerisation of but-1-ene to cis and trans but-2-ene respectively. Gurevich et al<sup>61</sup> observed that the diffusion (and subsequent desorption) of polyethylene macromolecules formed on the surface of a chromia catalyst, was hindered in the presence of a predominantly microporous structure and subsequent catalytic activity was lost: a macroporous structure represented an insufficient surface area, but a pore diameter range of 50 - 150 Å was found to be the optimum. Thus, the surface area available, and its nature, frequently play an important role in the type of catalytic activity displayed by chromia.

## 1.2 Preparation of Chromia

Generally speaking, supported chromia catalysts are made using either co-precipitation or impregnation techniques, whilst unsupported catalysts are obtained by the requisite activation of amorphous chromia gels.

Lazier and Vaughen<sup>4</sup> studied the catalytic properties (in respect of ethylene hydrogenation) of some twenty chromia gels, prepared from a number of chromium salts and basic precipitating agents. They, and later Köhlschutter,<sup>62</sup> concluded that the precipitation of chromia gel from chromium nitrate and ammonium hydroxide was the most reliable and convenient method for preparing an active chromia catalyst. Various other early preparations of chromia gel have been summarised by Turkevich et al.<sup>63</sup> These include the addition of ammonium hydroxide to chromium (III) acetate and the reduction of aqueous solutions of chromic acid by sucrose, oxalic acid or ethanol.<sup>64</sup> The production of chromium oxyhydroxide by the carbohydrate reduction of sodium dichromate is now an important process for the manufacture of  $\alpha$ -Cr<sub>2</sub>O<sub>3</sub> pigment.<sup>65</sup> Perhaps one of the most widely used and currently popular methods of preparing chromia gels is that developed by Burwell and his co-workers:<sup>11,66</sup> this relies upon the uniform generation of ammonia in a refluxed aqueous solution of urea and chromium nitrate. The Burwell preparation invariably results in a highly microporous gel of small particle size, but a gel of more open texture may be obtained by autoclaving the product in water or pentane.<sup>67</sup>

More recently, techniques have been developed for the production of chromium oxides with 'tailor-made' characteristics: Peri<sup>68</sup> has prepared a "self-sustaining"  $\alpha$ -Cr<sub>2</sub>O<sub>3</sub> aerogel film of unusually high surface area; Teichner<sup>69</sup> has similarly patented a process aimed at producing high surface area oxides (including chromium oxide), where hydrated metal salts are reacted with anhydrous bases in organic media, under conditions which ensure that the minimum amount of water is present; similarly, Lohmann<sup>70</sup> has prepared metal hydroxides by reacting metal sulphates with sodium hydroxide in such a manner that the water is effectively removed from the reaction sphere as the decahydrate of sodium sulphate. Such methods recognise the

important role played by water during the formation, and propagation, of the chromia gel polymer and on its subsequent textural properties.

Matijević<sup>71,72</sup> has extensively investigated the properties of chromium hydroxide hydrosols. Similar sols have been employed<sup>73,74</sup> in "sol-gel processes" to produce gels of controlled particle size and high surface area. These systems are likely to be the subject of much future work.

### 1.3 Structure of Chromia Gels

Weiser and Milligan<sup>75</sup> supported the early view of van Bemmelen<sup>76</sup> that a hydrous oxide gel consists essentially of agglomerates of minute crystals of oxide, hydrate or hydroxide, rather than of polymerised species of condensation products. However, many other workers, notably Willstätter et al<sup>77</sup> and Morley et al,<sup>78</sup> held the latter view, and that the freshly precipitated hydrous oxide is subject to an ageing process to yield polyhydroxides of increasing complexity. This is basically the opinion that is now widely accepted.<sup>9,79</sup>

It is generally regarded by many investigators that chromia gel has a "brush heap" structure, made up of a complex network of fibre-like particles.<sup>80</sup> The exact structure of the chromia fibres is unknown, although Selwood<sup>79</sup> has presented one picture of the gel as a chain polymer extending along the hexagonal axis, but the properties of the gel are consistent with those of large polymers:<sup>81,82</sup> for example, extremely low solubility and the resolubilisation of freshly precipitated gel by the addition of a small amount of chromium nitrate. In general, freshly precipitated chromia gels are amorphous, but Ratnasamy and Léonard<sup>83</sup> have recently claimed the identification of crystalline  $\text{Cr}(\text{OH})_3$  in a gel prepared according to the high pH method of the present author.<sup>84</sup>

Burwell<sup>9,24</sup> has proposed that chromia gel fibres are condensation polymers of  $\text{Cr}(\text{H}_2\text{O})_3(\text{OH})_3$ ,

formed by the neutralisation of the hexaquo-ion,  $[\text{Cr}(\text{H}_2\text{O})_6]^{3+}$ , upon the addition of a base, e.g. ammonia. The hexaquo ion forms at least the dimer and trimer,<sup>85-87</sup> but the polymerisation reaction is thought to involve species such as  $[\text{Cr}(\text{H}_2\text{O})_5(\text{OH})]^{2+}$  etc., which undergo condensation much more rapidly than  $[\text{Cr}(\text{H}_2\text{O})_6]^{3+}$ . When air-dried at  $25^\circ\text{C}$ , nearly all chromia gels, and particularly those prepared using the Burwell method,<sup>11,66</sup> retain appreciable quantities of physisorbed water of composition approximating to the formula,  $\text{Cr}_2\text{O}_3 \cdot 7\text{H}_2\text{O}$ . However, Selwood<sup>79</sup> and Berg<sup>88</sup> have reported gels, dried under similar conditions, that analyse very closely to  $\text{Cr}_2\text{O}_3 \cdot 5\text{H}_2\text{O}$ , i.e. the empirical formula of the hypothetical polymer shown above.

#### 1.4 Thermal Decomposition of Chromia Gels

Many authors<sup>34-37,88-95</sup> have noted that the thermal decomposition of chromia gels is a complex process. Dereñ and Haber<sup>33</sup> have proposed that at least three different simultaneous processes are involved: (a) dehydration, leading to the formation of chromium (III) oxide hydrates (and oxy-hydroxide) which subsequently decompose at higher temperatures; (b) redox processes involving chromium ions in different oxidation states, and (c) formation of crystalline  $\alpha\text{-Cr}_2\text{O}_3$  as the stable end product. Generally, for temperatures  $< 250^\circ\text{C}$ , the thermal effects observed by DTA are a result of gel-hydration

changes, and are independent of the surrounding atmosphere; for temperatures  $> 250^{\circ}\text{C}$ , the thermal effects are associated with redox processes and, as such, are dependent upon the nature of the surrounding atmosphere, i.e. inert, oxidising or reducing.

The dehydration process, (a), will effectively vary the coordination state of  $\text{O}^{2-}$ . For example, in the hypothetical polymer the coordination number (n) of  $\text{Cr}^{3+}$  with respect to  $\text{O}^{2-}$  is 6, whilst that of  $\text{O}^{2-}$  with respect to  $\text{Cr}^{3+}$  is 1.5. During progressive heating, the polymer loses water which may result in the bridging of chains and, at the extreme, to an average coordination of  $n = 2$  for  $\text{O}^{2-}$ ; further loss of water by condensation from bridging OH groups will lead to a coordination of 3, i.e. that found in chromium oxy-hydroxide,  $\text{CrOOH}$ .<sup>96a</sup> Finally, total elimination of water results in an  $\text{O}^{2-}$  coordination of 4, i.e. that found in  $\alpha\text{-Cr}_2\text{O}_3$ .<sup>96d</sup> In an amorphous gel the average coordination of  $\text{O}^{2-}$  appears<sup>24</sup> to be always  $< 4$ .

During the redox process, (b),  $\text{CrOOH}$  (orthorhombic<sup>97</sup>),  $\text{CrO}_2$  (rutile structure<sup>96b</sup>),  $\text{CrO}_3$  (chain structure of linked  $\text{CrO}_4$  tetrahedra<sup>96c</sup>) and  $\alpha\text{-Cr}_2\text{O}_3$  (corundum structure<sup>96d</sup>) may, at least in the surface layers, co-exist. Recent work by Ratnasamy and Léonard,<sup>83</sup> using x-ray scattering techniques, has identified the presence of  $\text{CrOOH}$ ,  $\text{CrO}_3$  and  $\alpha\text{-Cr}_2\text{O}_3$ ; Fenerty,<sup>95</sup> using magnetic susceptibility measurements, has confirmed the presence of ferromagnetic  $\text{CrO}_2$  in amorphous chromia gels. The subsequent 'glow' of the gel, a phenomenon first described by Berzelius<sup>98</sup> in 1818, results in the formation of macro-crystalline  $\alpha\text{-Cr}_2\text{O}_3$ .<sup>99</sup>

DTA, in addition to thermogravimetric analysis (TG), has been widely employed to investigate the decomposition of chromia gels. Bhattacharyya et al<sup>37,93,94</sup> have attributed the endotherms at  $160^{\circ}$  and  $250^{\circ}\text{C}$  to the expulsion of 'loosely bound' and 'rigidly bound' water respectively. Narasimha Rao and Kesavulu<sup>100</sup> correlated DTA observations with parallel oxygen

adsorption/evolution studies (indicated below in parentheses) and reached a similar conclusion; the evolution of water from the gel pores is responsible for the first endotherm (no oxygen adsorbed or evolved), whilst the second dehydration endotherm (oxygen adsorbed by exposed surface chromium ions) is associated with the oxide structure, i.e. condensation of hydroxyl groups. Dereń and Haber<sup>32</sup> assigned the two endotherms to the loss of water to form  $\text{Cr}_2\text{O}_3 \cdot 3\text{H}_2\text{O}$  (trihydrate) and  $\text{Cr}_2\text{O}_3 \cdot \text{H}_2\text{O}$  (monohydrate) respectively, a view that is widely accepted. However, Sing and his co-workers<sup>34,35</sup> have found for certain gels, that the DTA may also exhibit an exotherm at about  $230^\circ\text{C}$  as a result of the formation of crystalline orthorhombic  $\text{CrOOH}$ . Fenerty<sup>95</sup> has confirmed the presence of micro-crystalline orthorhombic  $\text{CrOOH}$  in certain calcined gels. Apparently, the crystalline monohydrate is only formed if the gel contains sufficient water trapped in the pores of large granules. The mechanism for the formation of the oxy-hydroxide structure is probably very similar to the hydrothermal process involved in the formation of boehmite ( $\gamma\text{-AlOOH}$ ), which has been characterised by Tertian and Papée<sup>101</sup> and by de Boer et al.<sup>102</sup> The crystalline orthorhombic  $\text{CrOOH}$  is probably the principal source of  $\text{CrO}_2$  in an amorphous gel: the interconversion of orthorhombic  $\text{CrOOH}$  and tetragonal  $\text{CrO}_2$  is known to proceed via a topotactic reaction.<sup>103-105</sup> Subsequent decomposition of  $\text{CrO}_2$  to  $\alpha\text{-Cr}_2\text{O}_3$  may also proceed via a topotactic reaction.<sup>106</sup>

The exact mechanism of the glow phenomenon is still largely a matter for conjecture. The temperature at which the strongly exothermic transformation of amorphous  $\text{Cr}_2\text{O}_3$  into macro-crystalline  $\alpha\text{-Cr}_2\text{O}_3$  occurs is dependent on the mode of gel preparation,<sup>107</sup> thermal history of the gel<sup>34,95</sup> and on the nature of the surrounding atmosphere:<sup>35</sup> the glow phenomenon occurs at about  $400^\circ\text{C}$  in an oxidising atmosphere, at about  $500^\circ\text{C}$  in hydrogen and up to  $600^\circ\text{C}$  in an inert atmosphere, e.g. nitrogen or vacuum; the crystallisation

temperature under vacuum is a function of pressure.<sup>88,92,108</sup> The actual temperature of the sample may rise to at least 800°C during the glow phenomenon,<sup>95</sup> which is slightly more in line with the temperature of > 1000°C required for large scale crystallisation of  $\gamma$ -alumina to the corundum structure.<sup>109</sup>

Chromium (VI) assists the crystallisation process by lowering the energy barrier to nucleation, but in itself, is not a prerequisite for the glow phenomenon.<sup>95</sup> Alternative sites for nucleation<sup>110</sup> may be provided by the micro-crystalline  $\alpha$ -Cr<sub>2</sub>O<sub>3</sub> which is present in amorphous gels.<sup>83,95</sup> In such cases, the situation is analogous to that of Fe(OH)<sub>3</sub>, where Weiser<sup>111</sup> has shown that the form of Fe<sub>2</sub>O<sub>3</sub> is  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> before and after the glow. Sorrentino et al<sup>112</sup> have correlated the incidence of the glow phenomenon with the particle size of the hydrous oxide: they postulate that the glow is a visible manifestation of the coalescence of primary particles into larger masses, with the consequent release of surface energy. Supporting evidence for this view is, in part, derived from their confirmation of the earlier findings of Milligan et al<sup>113,114</sup> that only single oxide systems exhibit the glow phenomenon. When mixed with another hydrous oxide the glow is quelled, a fact attributed to the adsorption of one oxide on the surface of the other; the effect is independent of whether or not the second hydrous oxide itself exhibits the glow phenomenon, e.g. Fe(OH)<sub>3</sub> and Al(OH)<sub>3</sub> respectively.

Perhaps the one certain feature related to the glow phenomenon is that the abrupt crystallisation of  $\alpha$ -Cr<sub>2</sub>O<sub>3</sub> invariably causes a large reduction in surface area and catalytic activity.<sup>4</sup> However, it does not, as some authors have stated,<sup>100</sup> render the oxide completely inactive as a catalyst.

### THEORETICAL ASPECTS OF PHYSICAL ADSORPTION

The theory of gas adsorption by solids has been extensively developed and discussed in recent years.<sup>1-5</sup> This chapter is, therefore, concerned only with certain theoretical aspects of physisorption which are relevant to the present work. Emphasis is placed on the utilisation and interpretation of gas adsorption data, in both the monolayer and multilayer regions of the adsorption isotherm.

#### 2.1 Introduction

Physisorption occurs whenever a gas, or vapour, (the adsorptive) is brought into contact with an outgassed solid (the adsorbent). The phenomenon, often termed van der Waals adsorption, is dependent on molecular interaction forces similar in type to those responsible for the condensation of a vapour to a liquid (or solid). Since physisorption is related to this process, it occurs to an appreciable extent only at pressures and temperatures close to those required for liquefaction. In physisorption, as distinct from chemisorption, there is no electron exchange between the adsorbed species (the adsorbate) and the adsorbent.

In principle, the amount,  $x$ , of gas adsorbed per unit mass of the adsorbent may be expressed as a function of the equilibrium pressure,  $P$ , the temperature,  $T$ , and the nature of the adsorptive and adsorbent:

$$x = f (P, T, \text{gas, solid}) \quad (2.1)$$

The adsorption data are generally recorded in the form of an adsorption isotherm, i.e. the adsorption measured at various equilibrium pressures, all other variables being held constant. If, as is usually the case in practice, the gas is below its critical temperature then the amount adsorbed is conveniently expressed as a function of the relative pressure,  $P/P_0$ , where  $P_0$  is the saturated vapour pressure of the adsorptive:

$$x = f \left( \frac{P}{P_0} \right)_{T, \text{ gas, solid}} \quad (2.2)$$

The majority of published isotherms may be assigned to one of the five types originally proposed by Brunauer, Deming, Deming and Teller,<sup>6</sup> but now more frequently referred to as the Brunauer Classification.<sup>1</sup> This classification is illustrated in Fig. 2.1. In practice, many isotherms show an upward deviation (represented by dotted lines in Fig. 2.1) as the saturated vapour pressure is approached. Hysteresis loops (the desorption branch of an isotherm) are frequently encountered with the various types of isotherms, notably in the case of a Type IV isotherm. de Boer<sup>7</sup> developed a useful classification of hysteresis loops; this will be referred to in succeeding chapters concerned with the discussion of the adsorption isotherms.

As with most classifications, there are borderline cases which possess the characteristics of one or more types, and are therefore difficult to assign to a particular group. In addition, there are many isotherms, notably stepwise isotherms, which are difficult to fit into the Brunauer classification at all.

The underlying reasons and the significance and interpretation of the various isotherm types have been discussed in detail by Brunauer<sup>1</sup> and Gregg and Sing.<sup>4</sup> Briefly, the type I isotherm is usually associated with micropore filling. Types II and III with monolayer-multilayer adsorption and Types IV and V with capillary condensation. Only those types particularly

relevant to the present work, namely Type I and Type II, will be discussed in any further detail (Section 2.3). Some discussion on step-wise isotherms is included in Chapter 6.

Most adsorbents of high surface area are porous, possessing both internal and external surface area.<sup>8</sup> The pore systems are of many different kinds, the pores varying greatly both in size and shape for any given adsorbent. To discuss the interpretation of adsorption isotherms, it is helpful to classify pores according to their effective width. The classification is necessarily arbitrary and is still the subject of much discussion. However, for the purpose of the present work, the recent IUPAC classification<sup>9</sup> (similar to an earlier classification by Dubinin<sup>10</sup>) has been adopted: namely, the narrowest pores of width not exceeding about 20 Å (2.0 nm) are called "MICROPORES"; pores of width exceeding about 500 Å (50 nm) are called "MACROPORES". The pores of intermediate width, which have previously been termed intermediate or transitional pores,<sup>11</sup> are referred to as "MESOPORES".

Adsorption in the relative pressure region of  $P/P_0 \sim 0.05$  to  $\sim 0.5$  may depend on three different mechanisms:<sup>12</sup> (a) monolayer-multilayer coverage, (b) micropore filling, and (c) capillary condensation. Dubinin<sup>10</sup> proposed that the whole of the accessible micropore volume may be pictured as adsorption space, since in pores of these dimensions the adsorption potentials of opposite walls overlap. The micropore volume is thus filled at low relative pressure and no well-defined monolayer is formed. Mechanisms (a) and (b) may therefore be considered as primary processes of adsorption. On the other hand, capillary condensation in mesopores (involving the formation of a liquid-like meniscus) is preceded by the formation of an adsorbed layer on the pore walls, and is, therefore, a secondary process.

In practice, it is difficult to resolve the different processes occurring in micropores and mesopores. Frequently, the above processes, (a), (b) and (c), may all contribute to the measured adsorption. Sing<sup>13</sup> has pointed out that in any real system, there are two main problems: first, the adsorption properties of the solid are determined by its texture and by the adsorbent-adsorbate and adsorbate-adsorbate interactions, which occur in a unique way in each adsorption system; secondly, as already mentioned, the pores in a real solid are generally distributed over a wide range of size and shape. The interpretation of isotherms, in terms of monolayer-multilayer adsorption and micropore filling, is therefore frequently very difficult.

## 2.2 Physical Interaction Energies

The detailed studies of Kiselev<sup>14,15</sup> and Barrer<sup>16</sup> have revealed that, in addition to non-specific interactions, physisorption is frequently associated with specific adsorbent-adsorbate interactions. The adsorption potential,  $\phi$ , (i.e. interaction energy) for a polar adsorbate molecule on a heteropolar or ionic surface may be expressed<sup>16</sup> as the sum of the number of energy contributions:

$$\phi = \phi_D + \phi_P + \phi_{F\mu} + \phi_{FQ} + \phi_R \quad (2.3)$$

The dispersion energy,  $\phi_D$ , and the short range repulsion energy,  $\phi_R$ , may be regarded as originating from non-specific interactions; the polarisation,  $\phi_P$ , the field-dipole,  $\phi_{F\mu}$ , and the field gradient-quadrupole,  $\phi_{FQ}$ , terms represent the specific interaction energy contributions. The contribution of  $\phi_P$  is usually small, but that of  $\phi_F$  or  $\phi_{FQ}$  may be very important in the case of adsorbate molecules possessing permanent dipole or quadrupole moments.

In general, the specific interactions are the result of the concentration of charge density on the periphery of the adsorbate molecule.

Oxide surfaces are generally energetically heterogeneous; they are hydrated (or hydroxylated) unless they have been outgassed at a high temperature, i.e. at about 1000°C. The degree of surface hydroxylation may have pronounced effect on the adsorbent-adsorbate interactions, notably the specific contributions. Kiselev and his co-workers<sup>14,15,17,18</sup> have studied the effect of the surface dehydroxylation of silica on the physisorption of a number of polar and non-polar vapours. Their investigations revealed that the differential heats of adsorption for adsorptives with  $\pi$ -bonds (e.g. benzene, nitrogen) or lone pairs of electrons (e.g. pyridine, diethyl ether) were considerably reduced by a decrease in the number of hydroxyl groups per unit surface area of silica. Conversely, the differential heats of adsorption for comparable non-polar adsorptives (e.g. n-hexane, argon) were not significantly affected. Thus, the  $\phi_D$ ,  $\phi_P$  and  $\phi_R$  contributions are insensitive to the degree of surface hydroxylation, but the  $\phi_{F\mu}$  and  $\phi_{FQ}$  terms are dependent on the concentration of the surface hydroxyl groups.

In view of the differences in the differential heats of adsorption for certain adsorptives on hydroxylated and dehydroxylated oxide surfaces,<sup>19</sup> it is not surprising that the shape of the isotherms may also be significantly affected. For example, the similarity of their molecular size and polarisability would suggest that argon and nitrogen should be alike in their physisorption behaviour. In fact, dehydroxylation of a silica surface has very little effect on argon adsorption,<sup>20</sup> but for nitrogen adsorption the specific nitrogen quadrupole interaction,  $\phi_{FQ}$ , is considerably reduced. The statistical monolayer for nitrogen adsorption on a hydroxylated silica surface is usually a well-defined point on the isotherm; dehydroxylation of

the surface has been shown<sup>20,21</sup> to result in a nitrogen isotherm that is very similar in shape to that for argon, where point B (section 2.3) is frequently poorly defined (for hydroxylated and dehydroxylated silica surfaces).

### 2.3 The BET Method for the Determination of Surface Area

The Langmuir theory<sup>22,23</sup> established the classical model of localised monolayer adsorption on a uniform surface, and may be represented by the equation:

$$\frac{V}{V_m} = \frac{bP}{1 + bP} \quad (2.4)$$

where  $V$  is the amount of gas adsorbed (mass, volume or mole) at an equilibrium pressure  $P$ ;  $V_m$  is the monolayer capacity (i.e. the amount of gas adsorbed in a completed monolayer), and the constant  $b$  is a function of the heat and the entropy of adsorption.<sup>24</sup> The model was designed for application to adsorption on an open surface freely exposed to the gas phase, the plateau of the Langmuir isotherm<sup>24</sup> (Type I in Fig. 2.1) representing a completed monolayer. It is now generally agreed, however, that if a Type I isotherm is obtained, then the adsorbent must be predominantly microporous in nature; furthermore, the plateau does not necessarily represent a completed monolayer and therefore the specific surface of the adsorbent.<sup>25</sup>

Brunauer, Emmett and Teller developed Langmuir's suggestion<sup>23</sup> that the dynamic condensation-evaporation mechanism might apply to second, and subsequent, adsorbate layers. Since its inception in 1938, the BET theory<sup>26</sup> has occupied a central position in the use of gas adsorption studies for surface area determination.

The BET equation is usually applied in the form:

$$\frac{P}{V(P_0 - P)} = \frac{1}{V_m C} + \frac{(C - 1)}{V_m C} \cdot \frac{P}{P_0} \quad (2.5)$$

where  $V$ ,  $V_m$  and  $P$  are the quantities defined for equation (2.4) and  $P_0$  is the saturated vapour pressure of the adsorptive. According to the simplified theory,  $C$  is a constant related to the net heat of adsorption, but in fact it is a free energy term which is dependent on both the enthalpy and entropy of adsorption.<sup>27</sup> It is clear from equation (2.5) that there should be a linear relationship between  $P/V (P_0 - P)$  and  $P/P_0$ . In practice, however, the linearity of the BET plot rarely extends beyond the relative pressure range of 0.05 - 0.3, even with non-porous adsorbents. Indeed, the range of linearity is often much more restricted,<sup>28</sup> and with uniform surfaces, notably graphitised carbon,<sup>29</sup> may not extend beyond  $P/P_0 = 0.1$ .

From the linear region of the BET plot, the slope,  $S$ , and intercept,  $I$ , may be derived. The BET parameters,  $V_m$  and  $C$ , may then be readily calculated by application of the equations:

$$V_m = \frac{1}{S + I} \quad (2.6)$$

$$C = \frac{S}{I} + 1 \quad (2.7)$$

The main criticisms levelled at the BET model may be summarised as follows:

(1) It assumes that all adsorption sites are exactly equivalent. In fact, the variation of the heat of adsorption with coverage for many adsorbents implies that the surface is energetically heterogeneous;<sup>30</sup> in many cases, the range of linearity of the BET plot is better for heterogeneous surfaces than for uniform surfaces.<sup>31</sup>

(2) Lateral interactions of adsorbate molecules are neglected; only those interactions normal to the adsorbent surface are considered. As the degree of coverage increases the inter-adsorbate distance decreases, and therefore the lateral interactions must become significant. Further, the neglect of the lateral adsorbate interactions is in conflict with the most basic assumption of the BET theory - that the evaporation-condensation properties of the second and subsequent adsorbate layers are the same as those of the surface of the bulk liquid.<sup>32</sup>

(3) Adsorbate molecules in second and subsequent layers are treated as completely equivalent. It would be expected that the adsorption potential would diminish as a function of the distance from the adsorbent surface.<sup>33</sup>

(4) The model assumes that the number of adsorbate layers is infinite at the saturated vapour pressure of the adsorptive. In fact, there are many cases where the number of adsorbate layers is finite in the presence of the saturated vapour.<sup>34</sup>

Nevertheless, in spite of the limitations of the BET theory, it has provided a remarkably successful method for the analysis of adsorption isotherms. Many refined theories have been presented over recent years, but very few retain the essence of the BET theory - its practical utility.

Brunauer and his co-workers<sup>35</sup> have recently modified the BET equation in an attempt to improve the agreement with experimental isotherm data over a wider range of relative pressure. A third parameter,  $k$ , was introduced to allow for the finite number of adsorbate layers on a non-porous adsorbent as  $P \rightarrow P_0$ :

$$\frac{kP}{V(P_0 - kP)} = \frac{1}{V_m C} + \frac{(C - 1)}{V_m C} \cdot \frac{kP}{P_0} \quad (2.8)$$

As an empirical relationship, equation (2.8) was found to give a considerably better fit for nitrogen adsorption on several non-porous oxides.<sup>35</sup> The deviation of  $k$  from unity is an approximate measure of the inadequacy of the basic BET assumption - that the second and subsequent adsorbate layers possess the properties of the bulk liquid.

On empirical grounds, Emmett and Brunauer<sup>36</sup> suggested that the completion of the monolayer is indicated by point B on the isotherm, i.e. the point corresponding to the beginning of the almost linear region exhibited by many Type II isotherms (Figs. 2.1 and 2.2). Halsey<sup>37</sup> supported this view by suggesting that this point is located where the affinity of the surface for the adsorptive is changing most rapidly, and it is reasonable to identify this change in adsorptive power with the completion of the first layer. However, it is now clear that reasonable agreement between point B and the BET monolayer capacity,  $V_m$ , is only found if point B lies within the linear region of the BET plot.<sup>38</sup>

The characteristic 'knee' of a Type II isotherm is dependent on the numerical value of  $C$ ; as the value of  $C$  increases (i.e. as the value of the net heat of adsorption increases) so the shape of the knee becomes progressively sharper (Fig. 2.2). Many workers<sup>3,4,32,37,39</sup> have suggested that the BET method for the evaluation of monolayer capacity, should only be used if the isotherm exhibits a clear point B, i.e. in general, the value of  $C$  exceeds about 50.

The specific surface area,  $S_{BET}$  (expressed in  $m^2g^{-1}$ ), of an adsorbent may be calculated from the monolayer capacity,  $V_m$  (expressed in  $cm^3g^{-1}$ ), by application of the equation:

$$S_{BET} = \frac{V_m \cdot N \cdot A_m \times 10^{-20}}{22414} \quad (2.9)$$

where  $N$  is Avogadro's constant ( $6.023 \times 10^{23}$  molecules mole<sup>-1</sup>) and  $A_m$  (expressed in Å<sup>2</sup>) is the assumed average area occupied by the adsorbate molecule in the completed monolayer.

The main difficulty associated with the calculation of  $S_{BET}$  from  $V_m$ , is the lack of independent evidence on the correct value of  $A_m$ . Most workers have followed the example of Emmett and Brunauer,<sup>36</sup> in assuming that the close-packing of the adsorbate molecules in the monolayer is very similar to that in the bulk liquid state. For the case of nitrogen as the adsorbate, such an assumption leads to a molecular cross-sectional area (i.e.  $A_m$ ) of 16.2 Å<sup>2</sup> at 77 K: McClellan and Harnsberger,<sup>40</sup> in a recent comprehensive survey of the literature on assumed cross-sectional areas of adsorbed molecules, concluded that this is the most reliable recommended value. On a priori grounds, however, one might expect some degree of localisation of the adsorbate molecules in the monolayer and a variation in the area occupied per molecule from one surface to another. Indeed, recent investigations<sup>21,41-43</sup> have indicated that the nitrogen monolayer may be slightly more open than in the liquid state and consequently, the value of  $A_m$  may be as high as about 20 Å<sup>2</sup>.

For many other adsorbates, there is a greater degree of uncertainty attached to the assumed value of the cross-sectional area of the adsorbate molecule.<sup>40</sup> Extensive studies have indicated that the value of  $A_m$  to be adopted is dependent on the value of the BET  $C$  constant,<sup>44</sup> and therefore, the net heat of adsorption. Since the net heat of adsorption is a function of the degree of adsorbent-adsorbate interaction, a particular adsorbate may yield different values of  $C$  (and therefore,  $A_m$ ) on different adsorbents.<sup>45</sup> This is particularly the case for water adsorption, where the degree of adsorbent-adsorbate interaction will be dependent on the extent of the hydrophobicity of the adsorbent surface;<sup>46</sup> water adsorption on a hydrophilic

surface is highly specific.<sup>43</sup> The assumed value of  $A_m$  for water is, therefore, particularly sensitive to changes on the adsorbent surface; for the purposes of the present work, the value<sup>47</sup> of  $10.6 \text{ \AA}^2$  (representing close-packing of the adsorbate molecules) has been adopted.

In the case of argon adsorption, there is a two-fold problem: first, a similar question of the cross-sectional area for an adsorbate molecule where BET C values are frequently below 50; secondly, whether one assumes the adsorbate is in a solid or liquid-like state at temperatures below the bulk triple point of argon. These problems are discussed in Sections 4.1 and 6.5.

#### 2.4 Empirical Methods of Isotherm Analysis

In recent years, the t-method of Lippens and de Boer<sup>48</sup> has attracted considerable attention<sup>49-53</sup> as a simple and direct means of interpreting nitrogen isotherm data. The amount,  $V$ , of nitrogen adsorbed on the test adsorbent is plotted against  $t$ , the statistical thickness<sup>54</sup> of the adsorbed layer of nitrogen at corresponding relative pressures ( $t$  is obtained from the standard isotherm on a non-porous reference adsorbent, and is given by  $t = (V/V_m) \sigma$ , where  $\sigma$  is the statistical thickness of the monolayer). A deviation in shape from the standard isotherm may be interpreted in terms of the porosity of the test adsorbent, and is detected as a departure of the t-plot from linearity; furthermore, the slope of a linear t-plot is directly proportional to the surface area of the test adsorbent. Much of the early work<sup>41,54-56</sup> was directed at obtaining a common or "universal" multilayer thickness (t-curve) for nitrogen on different adsorbents, but with the growing awareness of specific interactions with nitrogen adsorption (cf. Section 2.2), it is now recognised<sup>12,27,39,57,58</sup> that this is not possible. Instead, it may be possible<sup>39</sup> to establish a set of t-tables for

the adsorption of nitrogen (and other adsorptives) on different adsorbents. Brunauer and his co-workers<sup>27,49,50,53</sup> have suggested that the correct t-curve should be based on a reference adsorbent that gives a similar value of the BET C constant as the adsorbent under analysis; furthermore, there should be a close agreement between the surface area obtained from the slope of the t-plot and the BET area.

Other limitations of the t-plot are: (1) it is necessarily dependent on the evaluation of the BET monolayer capacity, since t is itself calculated from  $V/V_m$  (i.e. for nitrogen,  $t = 3.54 \cdot V/V_m$ ), and (2) it cannot be readily applied where adsorption isotherms have low C-values. To avoid these difficulties, the t-method was modified by Sing<sup>12,59</sup> and the empirical  $\alpha_s$ -method introduced.

#### The $\alpha_s$ -Method

$\alpha_s$  is defined<sup>12,13</sup> as  $V/V_s$ , where  $V_s$  is the amount of vapour adsorbed at a selected relative pressure,  $(P/P_o)_s$ . The values of  $\alpha_s$  are calculated from the reduced standard isotherm for an appropriate non-porous reference adsorbent. For the isotherm under analysis, the  $\alpha_s$ -plot is constructed as the amount adsorbed, V, against the  $\alpha_s$  value obtained at the corresponding relative pressure,  $(P/P_o)_s$ .

In principle, the value of  $\alpha_s$  may be placed equal to unity at any convenient point on the standard isotherm. In practice, however, it is usually convenient to place  $\alpha_s = 1$  at  $(P/P_o)_s = 0.4$ ; with nitrogen adsorption at 77 K, both monolayer coverage and micropore filling occur at  $P/P_o < 0.4$ , whereas any hysteresis loop (associated with capillary condensation) is generally located at  $P/P_o > 0.4$ . Furthermore, greater precision is achieved<sup>59</sup> by placing  $\alpha_s = 1$  in the middle range of the isotherm, especially in the case of a Type III (or near Type III) isotherm.

Deviation of the  $\alpha_s$ -plot from linearity provides a convenient diagnostic test for both micropore filling and capillary condensation. Examples of hypothetical  $\alpha_s$ -plots, curves (d), (e) and (f), are shown in Fig. 2.3, together with the corresponding isotherms, curves (a), (b) and (c), respectively, from which they could possibly be derived. The linear plot in (d) is the result of unrestricted monolayer - multilayer adsorption on a non-porous or macroporous adsorbent. The upward deviation of curve (e) from linearity indicates that capillary condensation is taking place within mesopores of an adsorbent; a similar downward deviation from linearity may indicate the occurrence of inter-particle condensation. The restricted adsorption in the case of curve (f) is typical of a microporous adsorbent, with pronounced micropore filling followed by multilayer adsorption (the upper linear branch) on a small external surface.

The  $\alpha_s$ -method may also be used for the assessment of surface area<sup>12</sup> (internal and external) and micropore volume.<sup>60,61</sup> The surface area,  $S_s$ , is readily calculated from the slope,  $m$ , of the linear region of the  $\alpha_s$ -plot by the use of a proportionality (or normalising) factor; the factor,  $f$ , is obtained from the standard isotherm on the non-porous reference adsorbent of known BET surface area:

$$f = \frac{(S_{\text{BET}})_{\text{ref}}}{(V_{0.4})_{\text{ref}}} \quad (2.10)$$

where  $(S_{\text{BET}})_{\text{ref}}$  is the BET surface area of the non-porous reference standard, and  $(V_{0.4})_{\text{ref}}$  is the amount adsorbed on the reference standard at a relative pressure of 0.4 (assuming  $\alpha_s$  is placed equal to unity at  $P/P_0 = 0.4$ ). The surface area  $S_s$ , is then given by:

$$S_s = f \cdot m \quad (2.11)$$

In the cases where the linear region of the  $\alpha_s$ -plot passes through the origin (i.e. curve (d), and the lower linear region of curve (e), in Fig. 2.3), equation (2.11) may be rewritten in the form:

$$S_s = f \cdot \frac{V}{\alpha_s} \quad (2.12)$$

where V is the amount on the test adsorbent at a particular value of  $\alpha_s$ . Clearly, in cases such as curves (e) and (f) in Fig. 2.3, the slope, m, of the upper linear region is given by:

$$m = \frac{\Delta V}{\Delta \alpha_s} \quad (2.13)$$

and therefore, the external surface area,  $S_{ext}$ , is given by:

$$S_{ext} = f \cdot \frac{\Delta V}{\Delta \alpha_s} \quad (2.14)$$

The pore volume,  $V_p$ , or micropore volume,  $V_{mic}$ , may be assessed by the back-extrapolation of the upper linear region of the respective  $\alpha_s$ -plots (curves (e) and (f) in Fig. 2.3) to the intercept at  $\alpha_s = 0$ . If the uptake at the intercept is  $V_y$ , and assuming liquid close-packing of the adsorbate molecules, then for nitrogen adsorption<sup>60</sup>  $V_p$  (or  $V_{mic}$ ) is given by:

$$V_p = 0.00156 \cdot V_y \quad (2.15)$$

Occasionally, a compensating effect (between micropore filling and reversible capillary condensation<sup>62</sup>) may occur with certain isotherms, giving rise to an almost linear  $\alpha_s$ -plot over a very wide range of relative pressure. Such a compensating effect can be detected by means of a systematic study employing adsorptives of different size and polarisability, in order to check the constancy of  $S_s$  and the linearity of the different  $\alpha_s$ -plots on the same adsorbent.<sup>12</sup>

A particular advantage of the  $\alpha_s$ -method is that it may be employed for Type III isotherms, or Type II isotherms with a small or indistinct knee, where the calculation of the BET surface area is unreliable; e.g. adsorption of carbon tetrachloride on silica.<sup>12</sup> In such cases, the surface area,  $S_s$ , of the adsorbent (with respect to a particular adsorptive) may be obtained from the  $\alpha_s$ -plot on a comparative basis, usually with respect to a standard nitrogen surface area. Equation (2.10) is rewritten in the form:

$$f = \frac{(S_{\text{BET}}^{\text{N}})_{\text{ref}}}{(V_{0.4})_{\text{ref}}} \quad (2.16)$$

where  $(S_{\text{BET}}^{\text{N}})_{\text{ref}}$  is the BET nitrogen surface area of the non-porous reference standard, and  $(V_{0.4})_{\text{ref}}$  is the amount of the adsorptive in question adsorbed on the reference standard at a relative pressure of 0.4. The surface area,  $S_s$ , (with respect to the test adsorptive) is then calculated in the usual manner, by application of either equation (2.12) or (2.14).

In principle, the  $\alpha_s$ -method can be made entirely independent of the BET procedure; however, no absolute method of surface area determination has yet been developed that incorporates the necessary degree of accuracy and reliability.

#### The Frenkel - Halsey - Hill Method

Frenkel,<sup>63</sup> Halsey<sup>32</sup> and Hill<sup>64,65</sup> independently suggested that at high relative pressures, where an adsorbed film is several molecular layers in thickness and its properties approach those of the bulk liquid, the adsorption isotherm may be described by an equation of the form:

$$2.303 \log \left( \frac{P_0}{P} \right) = \frac{k}{\theta^r} \quad (2.17)$$

where  $k$  is a constant related to the energy of adsorption in the first layer,  $r$  is an exponent based on the decay of surface forces with distance, and  $\theta$  is the surface coverage (i.e.  $\theta = V/V_m$ ). Equation (2.17) may readily be transformed to give:

$$\log V = \frac{1}{r} (\log k - \log 2.303) + \log V_m - \frac{1}{r} \left[ \log \left\{ \log \left( \frac{P_0}{P} \right) \right\} \right] \quad (2.18)$$

Either equation (2.17) or (2.18) may be used to analyse adsorption data by plotting,  $\log \log (P_0/P)$  either against  $\log \theta$  or against  $\log V$ . From the slope of the plot the value of  $r$  may be readily determined.

The Frenkel - Halsey - Hill (FHH) treatment assumes that in the multilayer region of an adsorption isotherm, the periodicity due to the structure of the adsorbent may be regarded as effectively smoothed out and that the adsorbed film may be treated as a uniform slab of liquid similar to the bulk liquid. According to the 'slab model',<sup>65,66</sup> at an appreciable distance from the surface the adsorbent-adsorbate interaction energy decays with the third power of distance and  $r = 3$ . The slab theory is strictly only applicable to adsorbates having spherically symmetrical molecules, but even for these adsorbates wide variations from the value of  $r = 3$  are found.<sup>32,46,67,68</sup>

Halsey<sup>32</sup> has suggested that the magnitude of  $r$  characterises the type of interaction between a vapour and the adsorbent surface: specific adsorbent-adsorbate interactions are indicated by a high value of  $r$ . In addition, Pierce and Ewing<sup>69</sup> have shown that if a log-log plot of  $\log (P_0/P)$  against  $V$  does not give a straight line of approximately normal slope for a particular adsorptive, then it may be concluded that there is

not unrestricted free surface adsorption. An upward deviation of the plot from linearity may be interpreted<sup>67,69,70</sup> in terms of capillary condensation, whilst a generally curved plot (or a linear plot of too low a slope) may indicate<sup>69</sup> the occurrence of micropore filling.

Zettlemoyer and his co-workers<sup>46,71,72</sup> have extended the earlier work of Pierce<sup>67,69,70</sup> and studied the applicability of the FHH plot to nitrogen and water adsorption isotherms on a range of non-porous adsorbents. In the case of nitrogen adsorption, it was noted that oxides and other high energy (polar) surfaces gave  $r$  values in the range 2.5 - 2.75, whereas low energy polymer surfaces gave  $r = 2.12$ . Zettlemoyer<sup>46</sup> has endorsed the opinion of Pierce<sup>41,67</sup> that the "ideal nitrogen isotherm" on a polar surface is represented by a linear FHH plot for which the value of  $r = 2.75$ ; for a non-polar surface, Zettlemoyer has proposed that the ideal value of  $r$  is 2.12. In the case of water adsorption on hydrophilic surfaces (e.g. hydroxylated  $\text{Fe}_2\text{O}_3$ ,  $\text{SiO}_2$ ,  $\text{TiO}_2$ ), the FHH plots gave  $r$  values around 2.5; water adsorption on hydrophobic surfaces (e.g. dehydroxylated  $\text{SiO}_2$  etc.) gave much lower  $r$  values in the range 1.3 - 1.9.

### EXPERIMENTAL

In the present chapter the materials studied and the methods used in their general characterisation and study, will be described.

#### A. THE MATERIALS

##### 3.1 Chromium Oxide Gels

The chromium oxide gels were prepared from aqueous chromium(III) nitrate in three ways: (a) by the slow addition of chromium nitrate to vigorously stirred ammonia solution (A series); (b) by the method of Burwell<sup>1,2</sup> utilising the slow hydrolysis of urea (B series); and (c) by the simultaneous addition of solutions of chromium nitrate and ammonia under conditions of controlled pH and concentration (S series).

The single electrode pH meter employed for the gel preparations was carefully calibrated over the operational pH range of the respective gel preparations. The pH values quoted in the present work have been corrected, where necessary, by reference to the appropriate calibration plot. However, no account has been taken of a possible 'suspension effect', i.e. the difference between the pH of a suspension and that of its isolated mother liquor.<sup>3</sup> For example, in the case of gel S2 the precipitation pH of 8.6 is very close to the point of zero charge (pzc) for freshly precipitated chromia gel<sup>4,5</sup> (about pH 8.5), and the suspension effect may, therefore, be assumed to be absent.<sup>4</sup> However, in the case of gel A1, precipitated at a mean pH value of 10.5, the pH of the suspension may be approximately 0.2 pH units lower than that of the mother liquor,<sup>4</sup>

i.o. the precipitation process is actually taking place at a slightly different pH value than that observed. When compared, however, with the overall wide range of precipitation pH (notably for the A series preparations), the effect is of little significance.

With the exception of chromium nitrate, all materials employed in the preparation of the chromia gels were of Analytical Reagent (AR) grade. Analytical grade chromic nitrate was not commercially available and it was therefore necessary to use the BDH Laboratory Reagent (LR) grade material; in the case of chromic nitrate, i.e.  $\text{Cr}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$ , the purity of the LR grade material is at least 98% w/w, with less than 0.05% w/w Fe content.

The freshly prepared gels were washed with aliquots of distilled water (redistilled under nitrogen immediately prior to use) until tests<sup>6</sup> for  $\text{NH}_4^+$  and  $\text{NO}_3^-$  gave negative responses. The gel was then treated according to the individual methods described below. In the cases where the gels were washed with acetone and ether, a total volume of approximately 7 dm<sup>3</sup> of each solvent per mole of chromic nitrate employed in the gel preparation, was used in the washing process. Each gel was dried at room temperature in a cylindrical drying chamber (35 cm x 8 cm), through which dry air was continuously passed at a flow rate of about 300 cm<sup>3</sup> min<sup>-1</sup>. The gel was placed in a 'boat' (28 cm x 6 cm) and, unless otherwise stated, the 'boat' was periodically removed from the chamber in order to redisperse the wet gel, thereby allowing the gel to dry fairly uniformly.

The conditions for each preparation are summarised in Table 3.1.

### A Series

The A series gels were prepared under a dynamic atmosphere of nitrogen in a 5 dm<sup>3</sup> reaction vessel equipped with a mechanical stirrer. The pH of

the reaction medium was constantly monitored during the slow addition of the chromium nitrate solution to the ammonia solution. The addition was made below the surface of the ammonia solution (accompanied by vigorous stirring) in order to minimise localisation of the precipitation process. The initial pH of the ammonia solution was generally 11.2; upon commencement of the addition of the chromium nitrate solution, the pH rapidly fell to a value close to the mean pH value quoted in table 3.1 for the respective preparations. Thus, gels of this series were not prepared under conditions of constant pH and concentration; preliminary experiments revealed, however, that an S series-type preparation was difficult to control when the required pH was greater than about 10.

#### Gel A1

The gel was prepared by the addition of 0.1M chromium nitrate to 0.25M ammonia. The pH range for approximately 90% of the precipitation was 10.3 to 10.7, and the mean pH of the preparation therefore assumed to be 10.5. The gel was harvested by vacuum filtration and successively washed with aliquots of water, acetone and diethyl ether, using a slurry technique for each wash. The gel was dried to constant weight over a period of 16 hours.

#### Gel A2

The gel was prepared in a very similar manner to that of gel A1, but the ratio of 0.25M ammonia solution to 0.1M chromium nitrate solution was decreased in order to lower the minimum pH value of the preparation. Approximately 85% of the precipitation occurred in the pH range of 9.0 to 9.2, and the mean pH of the preparation was therefore assumed to be 9.1. The time taken for the harvesting and washing of the gel was considerably reduced (four-fold) with the aid of a large-capacity centrifuge. Using a

45° angle head, it was possible to centrifuge 3 dm<sup>3</sup> of the gel suspension (or wash) at 4,500 r.p.m., and thereby reduce the total harvesting and washing time to about 1.5 hours.

### Gel A3

In order to maintain the pH of the precipitation medium as high as possible, the concentration of the ammonia solution was increased to 1M for this preparation. In addition, 1M ammonia solution was simultaneously added with the chromium nitrate solution, to the ammonia solution already present in the reaction vessel. Thus, the overall mole ratio of ammonia to chromium nitrate was increased approximately six-fold (compared to gel A1) for gel A3. In this manner, approximately 95% of the gel precipitation was confined to the pH range of 10.4 to 10.6, i.e. a mean pH of 10.5. The gel was harvested by centrifugation, thoroughly washed with water, and dried to constant weight over a period of 7 days.

Thus, gels A1 and A3 were each prepared at about pH 10.5, but contrast in the respect that gel A3 was prepared using a much higher concentration of ammonia and only water was used to wash the gel.

### Gel A4

With the exception of gel A3, the mother liquors of all the gel preparations (A, B and S series) were colourless; for gel A3, the mother liquor was a light-violet in colour. Such a colour is typical of a hexaquo chromium (III) compound, e.g.  $[\text{Cr}(\text{H}_2\text{O})_6](\text{OH})_3$ , (cf. Chapter 6). The clear mother liquor was placed in a dark cupboard in order to investigate the reason for the colour in this instance. However, after a period of three days, a precipitate resulted leaving a colourless mother liquor. The precipitate was isolated, washed and dried as per gel A3, and the blue-grey powder designated gel A4.

## B Series

Gels B6 - B9 were prepared from a single Burwell-type preparation, as follows:

A vigorously stirred solution, containing 0.15 mole of chromium (III) nitrate and 1.0 mole of urea in 4 dm<sup>3</sup> of water, was refluxed at 100°C over a period of 4 hours. Gelation commenced after refluxing for about 1.5 hours. The resulting suspension was cooled to room temperature over a period of 1 hour and the precipitate isolated by centrifugation. The wet gel was split into two equal portions (by weight): gel B6 was isolated from the first portion, whilst gels B7 - B9 were isolated from the second portion.

### Gel B6

The wet gel was successively washed with aliquots of water, acetone and diethyl ether, and dried to constant weight over a period of 16 hours.

### Gels B7 - B9

The wet gel was thoroughly washed with water and dried to constant weight over a period of 8 days. However, instead of periodically redispersing the wet gel in the drying boat, the gel was left undisturbed during the drying process (apart from periodic removal of the boat to check the weight of the gel). During the drying of all the previous gels, a gradient in the rate at which the gels dried (particularly those washed with organic solvents) was observed to exist along the length of the drying chamber. Naturally, such a gradient was to be expected and therefore the gel was periodically redispersed. However, it was surprising to find that the rate at which the gel dried increased with distance from the dry air inlet, i.e. the rate apparently increased with increasing humidity through the drying chamber.

In order to investigate whether the phenomenon affected the subsequent surface properties of the gel, the vitreous dark green solid was split into three portions (ratio by weight of about 1 : 3 : 1) upon removal from the drying chamber. The portions were designated as follows:

Gel B7 - the portion furthest away from the air inlet.

Gel B8 - the major portion, removed from the centre of the drying chamber.

Gel B9 - the portion nearest to the air inlet.

### S Series

#### Gel S2

The mixing apparatus employed for the preparation of gel S2 was based on an earlier design of Harris and Sing.<sup>7</sup> The modified apparatus incorporated a number of new features which enabled a relatively large scale preparation to be carried out, with sensitive control on the flow rates of the reactants and constant monitoring of the pH of the reaction medium. The reaction medium was vigorously stirred magnetically, and was maintained under a dynamic atmosphere of nitrogen.

The gel was prepared at pH 8.6 ( $\pm 0.05$ ) by the simultaneous addition of 0.1M chromium (III) nitrate and 1M ammonia to the reaction vessel. The desired fraction (pH 8.6) of the gel was isolated by vacuum filtration, successively washed with aliquots of water, acetone and diethyl ether, and dried to constant weight over a period of 16 hours.

TABLE 3.1

Conditions for the Preparation of the Chromia Gels

| GEL | PREPN.<br>NO.     | MEAN<br>pH | CHROMIUM NITRATE |              | AMMONIA     |              | YIELD<br>(g) |

| S2  | FSB/G1            | 8.6        | 0.1              | 0.07         | 1           | 0.5          | 8.7          |

Footnotes:

- (a) Gel A4 was obtained from the preparation of gel A3.
- (b) The gel precipitation pH of a Burwell-type preparation is thought<sup>8</sup> to be about 6. When the precipitation of the gel is complete, the pH of the medium rises to about 8.5 when the above concentrations are employed.
- (c) The figures in the 'ammonia' column for gels B6 - B9 refer to urea: each mole of urea, upon hydrolysis, generates two moles of ammonia.
- (d) Gels B7 - B9 were obtained from the preparation of gel B6.

### 3.2 Chromium Oxy-hydroxide and Chromium Dioxide Samples

Pure samples of orthorhombic oxy-hydroxide ( $\text{CrOOH}$ ) and chromium dioxide ( $\text{CrO}_2$ ) were supplied by Dr. E.F. Hockings of the RCA Laboratories, Princeton, USA. No impurities could be detected by x-ray powder diffraction.

### 3.3 Silica Samples

The silica samples were obtained from commercial sources.

Fransil, a non-porous hydroxylated silica produced by a plasma process, was supplied by Fransol S.A. of France. The surface area determined by transmission electron microscopy ( $36 \text{ m}^2\text{g}^{-1}$ ) was in fairly good agreement with the BET nitrogen surface area ( $38.7 \text{ m}^2\text{g}^{-1}$ ).<sup>9</sup> This material was used as a reference standard for the calibration of the volumetric apparatuses.

Silica Gels E and J, prepared by a gelation process, were supplied by the Unilever Chemical Development Centre, England. The two gels were specially selected to provide a microporous reference adsorbent (gel E) and a mesoporous reference adsorbent (gel J), respectively.

TK 800, a non-porous hydroxylated silica produced by a plasma process, was supplied by Degussa Forschung Chemie, Rheinfelden, West Germany. This product has been found<sup>9</sup> to consist of discrete spherical particles, the degree of aggregation being lower than in the commercial grades of Aerosil (Degussa products), e.g. Aerosil 200. Two samples of TK 800, namely TK 800 - II and TK 800 - III respectively, have been employed in the present work. The latter sample, TK 800 - III, has been widely distributed by the National Physical Laboratory, England, to laboratories participating in the Surface Area Standards Scheme<sup>10</sup> (sample reference No. NPL 6A/32/31).

## B. METHODS OF CHARACTERISATION

### 3.4 Differential Thermal Analysis (DTA)

The DTA experiments on the chromia gels were performed on a Standata Model 6.25 instrument (Stanton Instruments, London), under a static atmosphere of air. The experiments on the samples of CrOOH and CrO<sub>2</sub> were carried out under a static atmosphere of air, and also, dynamic atmospheres of pure hydrogen, nitrogen and oxygen (flow rates of 200 cm<sup>3</sup> min<sup>-1</sup> at STP). The differential temperature,  $\Delta T$ , and the reference temperature, T (of the sample), were recorded by a twin-pen potentiometric recorder. Freshly calcined  $\alpha$ -Al<sub>2</sub>O<sub>3</sub> was used as the reference solid and the rate of heating was standardised at 10°C min<sup>-1</sup>. Previous work<sup>11</sup> on chromia gels has shown that a variation in the rate of heating, within the range 2.5°C min<sup>-1</sup> to 10°C min<sup>-1</sup>, has very little effect on the DTA curve.

In each DTA run, 100 mg of sample and of reference solid were placed in the respective dimpled platinum crucibles which were mounted on the two Pt - Pt/Rh thermocouples inside the vertical cylindrical furnace. The chromia gel samples were ground, prior to examination, using an agate mortar and pestle.

### 3.5 Differential Scanning Calorimetry (DSC)

A Perkin Elmer differential scanning calorimeter, Model DSC-1B, was employed for the DSC study of the chromia gels. The instrument was fitted with a thermal conductivity gas detector for the analysis of the sample effluent.

This instrument, unlike the DTA apparatus, maintains a sample isothermal with a reference material (or the furnace block) by supplying heat to the sample or reference material according to demand. The energy required to maintain an isothermal condition is recorded as a function of temperature (or time). The temperature of a transition was assumed to be the temperature at which the first evidence of the change appeared, i.e. a departure of the

recorder pen from the baseline calibration. A twin-pen potentiometric recorder, fitted with a fiducial marker, was used to simultaneously record the calorimetric, thermal conductivity and temperature output signals, respectively. The thermal conductivity trace provided information which related an exothermic or endothermic change to gas evolution at a particular temperature.

The use of the thermal conductivity gas detector requires the presence of a carrier gas; the chromia gel samples were therefore examined under a dynamic atmosphere of nitrogen (flow rate of  $30 \text{ cm}^3 \text{ min}^{-1}$  at STP).

### 3.6 X-Ray Diffraction

The Debye - Scherrer x-ray powder diffraction technique<sup>12</sup> was employed for the examination of the chromium oxide samples. The samples were finely ground, using an agate mortar and pestle, and packed into Lindemann silica glass tubes of 0.03 cm internal diameter. Each specimen was mounted in a powder camera of 11.48 cm diameter, so that its longitudinal axis was concentric with a cylinder of 35 mm photographic film on which the diffraction pattern was recorded. The  $\text{Cu K}_\alpha$  radiation ( $\lambda = 1.541 \text{ \AA}$ ) was obtained using a Philips 11704 x-ray unit, and was filtered by a nickel foil. The exposure time was varied between 4 and 12 hours.

### 3.7 Electron Microscopy

#### Transmission

Electron micrographs of the chromium oxide samples were obtained using a JEM-7 electron microscope (manufactured by Japan Electron Optics Laboratory, Japan). The finely ground samples were ultrasonically dispersed in absolute alcohol and the specimen prepared by placing a drop of the resulting suspension on a carbon film supported by a copper grid. The specimen was dried at ambient temperature and pressure before insertion into the instrument.

### Scanning

The chromium oxide samples were sequentially scattered (in the dry state) on segments of double-sided sellotape affixed to an aluminium mounting stub. The samples were then vacuum coated with a layer of carbon, followed by a layer of gold/palladium alloy, to a total thickness of about 200 Å. The specimens were examined using a Stereoscan S4 scanning electron microscope (manufactured by Cambridge Scientific Instruments, England).

### 3.8 Mass Spectrometry

A Hitachi Perkin Elmer mass spectrometer, Model RMS-4, (coupled to an SE Laboratories oscillograph recorder, Model 3006) was employed to assess the purity of the chromia gels. The gels were examined by direct insertion of the sample into the ion source chamber of the instrument. In addition, the gases evolved from the gels, on outgassing at room temperature and 250°C respectively, were identified by using a sampling technique similar to that described by Murphy and his co-workers.<sup>13</sup> The effluent gas sample was inserted into the ion source chamber of the instrument and the gases identified by their respective fragmentation patterns.

### 3.9 Atomic Absorption

A Perkin Elmer double beam atomic absorption spectrophotometer, Model 303, was employed to determine the mercury content of a number of chromium oxides outgassed in the presence of mercury vapour. The absorption at  $\lambda = 2537 \text{ \AA}$  was measured, with a mercury detection limit of  $0.5 \mu \text{g cm}^{-3}$  (aqueous solution).

The weighed sample was extracted with a standard volume of 3.8M nitric acid by vigorous mechanical shaking over a period of 16 hours. The solid was isolated from the extract by centrifugation and carefully washed with aliquots of distilled water. The extract and washes were combined and the solution clarified by filtration through a quartz wool plug. The solution was diluted

with water to a standard volume, such that the estimated mercury content was within the optimum working range of 20 - 200  $\mu\text{g cm}^{-3}$  and the strength of the acid was 0.1M  $\text{HNO}_3$ .

The mercury contents of the respective solutions (and therefore the original chromium oxide samples) were determined by atomic absorption, with reference to a calibration plot of % absorption against mercury concentration.

### 3.10 Heat of Immersion

The heats of immersion of a number of chromium oxide and silica samples were determined in a simple diathermal calorimeter similar to the type designed by Zettlemyer and his co-workers.<sup>14</sup> It consisted of a glass Dewar vessel fitted with a lid of tufnol, which carried supports for an ampoule holder, a thermistor, a heater coil and a stirrer. The stirrer incorporated a device for breaking the glass ampoule. The thermistor was connected into a Wheatstone bridge circuit and the out-of-balance current was registered as the deflection of a sensitive galvanometer. The details of the apparatus and method of operation have been described by Gregg and his co-workers.<sup>15</sup>

The author is indebted to Dr. R.R. Mather and Mr. C. Phillips for carrying out the heats of immersion studies.

### C. LOW TEMPERATURE GAS ADSORPTION

The two volumetric apparatuses employed for the present study of argon and nitrogen adsorption were designed and built by the author. Although a number of refinements were made to the design and construction technique of each apparatus, the principle of operation was very similar to that described by Harris and Sing.<sup>16</sup>

### 3.11 Design and Construction of the Volumetric Apparatuses

Traditionally, gas adsorption apparatus has generally been constructed on the 'rod and clamp' principle. Although such apparatuses have been very successfully applied to gas adsorption studies, they are usually fragile and cannot be moved without substantial re-building (and frequently, re-calibration). During the course of the present work, the surface chemistry research laboratories at Brunel University were scheduled to be relocated from the site in Acton on to the new university campus. It was, therefore, an essential pre-requisite that the design and construction of the new apparatuses should allow the complete assembly to be moved with the minimum of difficulty and subsequent re-building.

The design requirements for the attainment of a high vacuum in a particular apparatus contrast sharply with the requirements for successful gas adsorption studies: the design of any gas adsorption system is, therefore, a compromise between pumping speed (and ultimate vacuum) on one hand, and 'dead space' volume on the other. Particular attention was given to this problem when drafting the design of the present apparatuses.

The general view of the front of the two volumetric apparatuses is shown in Fig. 3.1. The general arrangement of the left hand apparatus (L.H.A.) is shown in diagrammatic form in Fig. 3.4; the arrangement of the right hand apparatus (R.H.A.) was very similar. The significant difference between the two apparatuses was only one of convenience: the R.H.A. was designed to handle samples of surface area less than about  $150 \text{ m}^2\text{g}^{-1}$ , whilst the L.H.A. could more easily handle samples with surface areas in excess of  $150 \text{ m}^2\text{g}^{-1}$ . The lower limit of each apparatus was about  $1 \text{ m}^2\text{g}^{-1}$ . In addition, the L.H.A. was designed to allow high temperature outgassing of the sample (up to  $1100^\circ\text{C}$ ). The two apparatuses were carefully mounted on a common back-plate, but were otherwise totally independent of one another. The vapour diffusion pumps,

cold traps, argon and nitrogen reservoirs, together with a Townson and Mercer thermostatic bath (and ancillary water pumps) were located on the rear of the back-plate; the rotary pumps, together with the low vacuum reservoir, were located beneath the base of the assembly. The cathetometers were placed on a heavy, purpose built, table securely anchored to the base of the assembly and located immediately in front of the apparatuses.

Each diffusion pump was protected against accidental over-heating by incorporation of both an Edwards 'Flowtrol' (monitoring the flow of the cooling water) and an Edwards 'Thermal Snap Switch' (activated by an excessive pump-body temperature) in the power supply circuits of the pumps. Edwards MS Silicone Fluid 704 was employed as the diffusion pump fluid. The gas adsorption system was protected against backstreaming of the pump fluid by sorption traps (at  $-196^{\circ}\text{C}$ ) containing a mixed zeolite bed of Linde molecular sieves, type 5A (to adsorb water vapour) and type 13X (to adsorb silicone oil vapour) respectively.

The essential differences between the design of the present apparatuses and those previously described,<sup>11,17-20</sup> were: (a) with the exception of the two-way stopcocks in the low vacuum line, greaseless stopcocks (supplied by Springham and Co. Ltd.) were employed throughout; (b) pressure-sensitive transducers (supplied by the Electronics and Instruments Group of Bell and Howell Ltd.) were incorporated in the dead space sections, and (c) the flexibility of the gas burette of each apparatus was considerably increased by the inclusion of 12 calibrated bulbs to vary the volume of the dead space. The calibration of the left hand limb of the "adsorption" manometer (M1 in Fig. 3.4) permitted an even finer control of the frequency and number of isotherm points. The characteristics of these particular features are discussed in the following sections.

### 3.12 Calibration of the Gas Adsorption System

The total volume of the adsorption system was composed of (a) the volume of the gas burette bulbs; (b) the volume of the left hand limb of the adsorption manometer (M1 in Fig. 3.4) and, (c) the dead space volumes, designated as  $V_a$ ,  $V_b$  and  $V_c$  respectively, in Fig. 3.5.

The calibration of the three main sections will be discussed separately and, unless otherwise stated, the discussion equally applies to both apparatuses.

#### Gas Burette Bulbs

Each set of six bulbs, complete with the outer water jacket, was calibrated before being carefully welded into position on the apparatus. The volumes of the bulbs were determined gravimetrically by weighing the amount of triple-distilled mercury necessary to fill each bulb to its fiducial mark (see Fig. 3.5). The calibrations were carried out in triplicate, with the bulbs maintained at a temperature of  $25^\circ \pm 0.01^\circ\text{C}$ ; the magnitude of the variation of the individual calibrations was less than  $0.004 \text{ cm}^{-3}$ . The volumes of the respective bulbs for each apparatus are recorded in Table 3.2.

#### The "Adsorption" Manometer

The adsorption manometer was constructed from high precision bore glass tubing, supplied by Jencons Scientific Ltd. The internal diameter of the manometer for the L.H.A. was 1.0 cm, whilst that for the R.H.A. was 0.5cm; the bore tolerances were each  $\pm 0.001 \text{ cm}$ . The left hand limb of each manometer was machine-calibrated, and scaled in divisions of  $0.1 \text{ cm}^3$  for the L.H.A. and  $0.05 \text{ cm}^3$  for the R.H.A. the zero graduation was placed at the top of the limb and the numerical markings engraved in an inverted position, such that the gaseous volume reading could be directly observed through the telescope of the cathetometer (simultaneously

TABLE 3.2

L.H.A. = Left Hand Apparatus

R.H.A. = Right Hand Apparatus

with the height of the mercury column). The calculated machine error in the volume of the left hand limb of each manometer was  $\pm 0.2\%$  for the L.H.A. and  $\pm 0.4\%$  for the R.H.A. The manometer was carefully welded into position on the apparatus, such that the dead space volume immediately above the zero graduation of the left hand limb was as small as possible without damaging the calibrated section.

#### Dead Space Volumes, $V_a$ , $V_b$ and $V_c$

The assembled apparatuses were thoroughly outgassed (to a pressure of less than  $10^{-5}$  torr) over a period of several weeks, before in situ calibration measurements were made. Where possible, sections of the systems were 'baked' at about  $250^{\circ}\text{C}$  during the outgassing process by means of an Electrothermal heating tape wound around the glassware. However, the operational areas of the mercury manometers ( $M_1 - M_4$  in Fig. 3.4) were not raised above ambient temperature. The Viton A diaphragms for the greaseless stopcocks were outgassed at  $250^{\circ}\text{C}$  over a period of four days, prior to insertion into the barrels of the stopcocks on the assembled apparatuses: Viton A is the tradename of a fluorocarbon rubber. Triple-distilled mercury was placed in each of the mercury reservoirs upon termination of the outgassing period.

The argon and nitrogen reservoirs were outgassed to a pressure of about  $10^{-5}$  torr before being filled, to a pressure of one atmosphere, with pure argon (99.995% purity) and 'white spot' nitrogen (99.9% purity) respectively. The reservoir-filling system was designed to allow all lines (including the cold trap) leading to the regulator of the gas cylinder, to be outgassed to a pressure of about  $10^{-2}$  torr. The gas was slowly passed through a cold trap immersed in liquid nitrogen to remove residual impurities, e.g. carbon dioxide, water and oxygen. Before the

gas was actually collected in the appropriate reservoir, the system was flushed with gas (at a pressure of about 20 torr) over a period of about 30 minutes. The manometer,  $M_4$  in Fig. 3.4, monitored the residual pressure in the gas reservoirs during operation of the apparatus, as well as serving as a safety valve.

The component sections,  $V_a$ ,  $V_b$  and  $V_c$  respectively, of the dead space volume are shown in Fig. 3.5. The dead space volume,  $V_a$ , is bounded by stopcock 'A' (in the closed position), stopcock 'B' (in the closed position), the transducer 'F', the upper fiducial marks of the gas burette (i.e. Nos. 6 and 12 respectively) and the zero graduation of the adsorption manometer,  $M_1$ : this volume is shown enclosed by broken lines in Fig. 3.5. The dead space volume,  $V_b$ , is the volume enclosed by stopcock 'A' (in the open position) and the datum line 'L' on the sample bulb.  $V_c$  is the volume of the sample bulb below the datum line 'L', i.e. the volume of the sample bulb below the surface of the liquid nitrogen in the cryostat bath. The datum line on the sample bulb is assumed to be the arbitrary point at which there is a sharp transition between the temperature of the refrigerant and the ambient temperature. Such an assumption is necessary in order to apply a 'non-ideality' correction to the volume of gas contained below the level of the refrigerant. In practice, however, a temperature gradient will exist along this region of the sample bulb; by maintaining the refrigerant level at the datum line for both the calibration and the test runs, the error arising from this assumption is negligible.

It is important to note that the operation of the type of greaseless stopcock employed in the present apparatuses results in a volume change within the barrel of the stopcock. Normally, such an effect is of no significance, but for stopcocks 'A' and 'B' in the dead space region the

consequences of the volume change must be taken into account. The volume change occurs only within the barrel of the stopcock; where the raised centre of the diaphragm seats on the bore of the opposite limb of the stopcock, there is no measurable volume change with the limb during normal operation of the stopcock. For the stopcocks employed in the adsorption region of each apparatus (i.e. stopcocks 'A', 'B', 'C', 'D' and 'E' respectively, in Fig. 3.2), the volume change occurring between the extreme limits of movement of the diaphragm was about  $0.45 \text{ cm}^3$ . In practice, the diaphragm was always manipulated well within the extreme positions and the corresponding volume change was, therefore, much less.

It is obvious, therefore, that each greaseless stopcock may be positioned in one of two opposite directions. During the assembly of the apparatuses, the stopcocks were positioned such that the barrel-limb was joined to the part of the system where the undesirable features of the stopcock would have the least effect. In addition to the volume change, the barrel of the stopcock is also the side with the greatest potential leak risk. The limb joined to the bore of the stopcock was designated the 'safe-side' and is represented by a small arrow in the symbol for the stopcock in Fig. 3.5.

The manipulation of stopcock 'A' (the sample stopcock) was particularly critical in respect of the volume change within the barrel: the diaphragm was always moved through the same distance for successive operations in order to ensure that the dead space volume,  $V_b$ , remained constant.

The programme for the studies of argon and nitrogen adsorption on chromia and silica samples respectively, included the in situ outgassing of the sample at temperatures of up to  $1100^\circ\text{C}$ . The sample bulb, shown in Fig. 3.2, was therefore fabricated from silica glass, and included a

condenser-type jacket to cool the neck of the bulb (by water circulation) during the high temperature outgassing process. The empty silica glass bulb was necessarily subjected to the maximum temperature outgassing conditions ( $1100^{\circ}\text{C}$  for 16 hours on the L.H.A.) prior to calibration of the dead space volume. The pyrex glass bulb (without condenser), for use on the L.H.A. at outgassing temperatures of up to  $450^{\circ}\text{C}$ , was similarly treated prior to calibration.

The calibrations were carried out by admitting a charge of nitrogen to the adsorption region and then measuring the pressure as the gas was compressed by either (a) raising the mercury in the gas burette bulbs to successive fiducial marks, and checking by emptying the bulbs in succession, or (b) maintaining the mercury in the gas burette at the upper fiducial marks, and compressing the gas by progressively raising the mercury in the adsorption manometer. Both methods were adopted, using several charges of nitrogen, such that the full operational pressure range was covered in detail. The total dead space volume,  $V_t$  (i.e.  $V_a + V_b + V_c$ ), was determined with stopcock 'A' in the open position;  $V_c$  was also determined with stopcock 'A' open, but with the sample bulb immersed (to the datum line) in liquid nitrogen.  $V_a$  was determined with stopcock 'A' closed, whilst  $V_b$  was determined by difference.

Dead Space Volumes,  $V_a$  and  $V_t$ :

It has been shown<sup>21</sup> that under the conditions employed for the determination of  $V_a$  and  $V_t$ , nitrogen does not deviate to any significant extent from ideal behaviour; equation (3.1), based on Boyle's Law, was therefore applied to calculate the dead space volumes,  $V_a$  and  $V_t$ :

$$V_a \text{ (or } V_t) = \frac{T \cdot V_o \times 76}{P \cdot 273.16} - V_g \quad (3.1)$$

where  $V_a$  (or  $V_t$ ) = the dead space volume (in  $\text{cm}^3$ )

$T$  = the temperature of the measurement (in  $^{\circ}\text{K}$ )

$P$  = the measured pressure (in cm of mercury)

$V_o$  = the volume of the charge admitted, which is a constant for a series of compression readings

$V_g$  = the combined volume of the gas burette bulbs, and the left hand limb of the adsorption manometer, not filled with mercury.

From equation (3.1), it is clear that a plot of  $V_g$  against  $T/P$  should be a straight line with a negative intercept equal to the dead space volume,  $V_a$  or  $V_t$ . For each of the determinations, a satisfactory straight line plot was obtained; the least squares method was used to evaluate the intercept. The various determinations for each apparatus are summarised in Table 3.3

#### Dead Space Volume, $V_c$ :

In order to calculate the dead space volume,  $V_c$ , it was necessary to apply a non-ideality correction factor to the volume of nitrogen contained below the level of the refrigerant. Madeley<sup>18</sup> has shown that  $V_c$  may be expressed by an equation of the form:

$$V_c = \frac{[P_2 (V_t + V_{g2}) - P_1 (V_t + V_{g1})] 77.3}{T(P_1' - P_2') + 77.3 (P_2 - P_1)} \quad (3.2)$$

where  $P_1$  and  $P_2$  are the first and second pressure measurements respectively, of a pair of compression readings (in cm of mercury).

$P'_1$  and  $P'_2$  are the values of  $P_1$  and  $P_2$  respectively, corrected for non-ideality.

$V_{g1}$  and  $V_{g2}$  are the first and second gas burette volumes respectively, of a pair of compression readings (in  $\text{cm}^3$ ).

$V_t$  is the total dead space volume, as given by equation (3.1).

$T$  is the temperature of the measurement (in  $^{\circ}\text{K}$ ).

The non-ideality correction factor,  $\alpha$ , for nitrogen at  $77.3^{\circ}\text{K}$ , was applied in the form:

$$P' = P + \alpha P^2 \quad (3.3)$$

where, for a pressure measurement expressed in cm of mercury,  $\alpha = 6.58 \times 10^{-4}$ ; i.e. the value reported by Emmett and Brunauer,<sup>22</sup> and confirmed by Harris.<sup>17</sup>

The determinations of  $V_c$  for each apparatus are summarised in Table 3.3. From the respective mean values of  $V_a$ ,  $V_c$  and  $V_t$ , the value of  $V_b$  was obtained by difference.

The variable dead space volumes (i.e.  $V_a$  plus the volume of the gas burette bulbs not filled with mercury), for each apparatus are shown in Tables 3.4 and 3.5 respectively. For any combination of gas burette bulbs filled with mercury, the residual dead space volume may be obtained by reference to the appropriate table. The fiducial mark numbers in the left hand column of each table correspond to the first set of gas burette bulbs (i.e. Nos. 1 - 6), whilst those across the top of the table correspond to the second set of bulbs (i.e. Nos. 7 - 12). The fiducial marks, and the corresponding gas burette bulbs, are shown in Fig. 3.5.

Under experimental conditions,  $V_b$  was decreased by an amount equal to the volume ( $V_b^1$ ) of the glass wool plug inserted in the neck of the sample bulb; similarly,  $V_c$  was decreased by an amount equal to the volume ( $V_c^1$ ) of the sample under investigation. These decreases in the dead space volumes were taken into account during the derivation of the isotherm data. Values of  $V_b^1$  and  $V_c^1$  were estimated from the outgassed weight and density of the plug and sample respectively. Earlier workers have shown<sup>11,17,18,20</sup> that an error of less than 1% in the surface area is incurred by assuming a mean value for the density of the sample over a range of outgassing temperatures. Thus, since the majority of the present work was comparative, rather than absolute, in nature, it was not considered necessary to carry out an actual measurement of  $V_c^1$  (using helium) but to assume a constant value for the density of the sample: e.g. chromia,  $6.0 \text{ g cm}^{-3}$ ; silica (Fransil),  $2.5 \text{ g cm}^{-3}$ ; silica (TK 800),  $2.1 \text{ g cm}^{-3}$ .

#### Absolute Nature of the Calibrations

The validity of the calibrations for each apparatus was checked by determining both the nitrogen and argon isotherms on samples of Fransil and TK 800-II respectively. The values of the nitrogen and argon BET surface areas so obtained are shown in Table 3.6, together with the published<sup>9,23,24</sup> values for Fransil and TK 800. Following the recent recommendation of Sing,<sup>25</sup> the BET C-constant values are recorded alongside the corresponding BET surface area values. It is evident from Table 3.6, that the respective surface area values obtained using each apparatus are in good agreement for a particular adsorbent; furthermore, the absolute nature of the calibrations is confirmed by the agreement of the experimental data with those reported for Fransil and TK 800.

a see reference Nos. 9, 23 and 24.

b Surface area expressed in m<sup>2</sup>g<sup>-1</sup>; taking 16.2 Å<sup>2</sup> and 18.2 Å<sup>2</sup> as the apparent cross sectional areas of nitrogen and argon, respectively. The silica samples were outgassed at 140°C over a period of 16 hours.

Fig. 3.6. clearly demonstrates the excellent agreement between the experimental isotherm data obtained in the present work, and the isotherm data previously reported<sup>9</sup> for a particular standard adsorbent. The isotherm obtained using the L.H.A. for nitrogen adsorption on TK 800-II (outgassed at 140°C) has been taken as an example: the adsorption points are shown superimposed on the isotherm reported by Turk (determined using another volumetric apparatus), for a sample of TK 800-II taken from the same bulk batch. For the sake of clarity, desorption points have not been included in Fig. 3.6, but each isotherm was almost totally reversible and characteristic of a non-porous adsorbent. The complete isotherm data for Fig. 3.6 are recorded in Appendix 7.

### 3.13 The Pressure-Sensitive Transducers

A pressure-sensitive transducer converts fluid pressures experienced by the diaphragm of the instrument, to a controlled strain in the strain-gauge windings that form an integral part of an excited Wheatstone bridge in which all four arms are active. A rod welded to the centre of the force-summing diaphragm transmits its displacement to a spring element. The resulting flexure of the spring tilts the sapphire posts on which the strain gauge windings are mounted, increasing the strain and hence the resistance in the two windings at one end of the posts, and decreasing the strain and resistance in the windings at the other end. The thermal and mechanical symmetry of the unit ensure that the output is a linear function of the pressure applied to the diaphragm. A diagram of the pressure-sensing element is shown in Fig. 3.7.

Each volumetric apparatus was equipped with a Bell and Howell pressure-sensitive transducer (type 4-366) with an operation range of 0.1 - 776 torr (absolute). The resolution of this transducer is infinite,

but in practice, the ultimate sensitivity of the complete system is governed by the resolution of the potentiometric device that is employed to measure the output of the transducer. In the present work, an API Instruments Co., (Chesterland, Ohio, USA) Model 4304, digital voltmeter was used to measure the output voltage of the transducer (full range output of the transducer was about 40 mV). The resolution of the digital voltmeter (DVM) was  $\pm 0.005$  mV; in terms of absolute pressure, the sensitivity of the complete system was about  $\pm 0.1$  torr, i.e., an order of magnitude lower than a corresponding manometer measurement.

The excitation potential for the transducer ( $10 \text{ V} \pm 0.02\%$ ) was provided by a purpose built power supply, the circuit diagram of which is shown in Fig. 3.8. The zero and span of the transducer itself were set to within very fine tolerances at the time of manufacture; adjustments in the electrical zero were therefore made in an external circuit, i.e. by the potentiometer, P1, in Fig. 3.8. The zero and span of the DVM were adjustable by controls on the instrument; a high quality, low thermal e.m.f., multiway switch was incorporated into the circuit, such that the output signal of the transducer could be short-circuited in order to check the zero setting of the DVM. The multiway switch also served to share a single DVM between the two transducers.

It is worth noting that a negligible change in the dead space volume is incurred with movement of the transducer diaphragm in response to pressure changes within the system. For example, if the least-favourable case is considered, namely for that of the minimum dead space volume,  $V_a$ , the total variation in the volume resulting from movement of the diaphragm over the full operational range of the transducer (0.1 - 776 torr) was less than 0.009%.

### Calibration of the Transducers

Each unit of the complete pressure-measuring system was thoroughly tested for electrical stability, and reproducibility, prior to the calibration measurements. These tests were made over a period of several weeks, and showed that the respective stabilities of the power supply, transducer and DVM were entirely satisfactory. The output of the transducers employed in the present work was relative to absolute pressure and was, therefore, unaffected by variations in the ambient pressure.

The calibration curve was constructed as a plot of the transducer's open circuit output voltage as a function of pressure (measured by the mercury manometer, M1 in Fig. 3.4). Measurements were made for both increasing and decreasing pressure excursions over the full range output of the transducer. The calibration plots are shown in Figs. 3.9 and 3.10 respectively; for the sake of clarity, only a small proportion of the calibration points have been reproduced in the figures. Several different pressure excursions were made to confirm the reproducibility of the transducer's response. The slope of each plot, and hence the transducer calibration factor, was computed using the method of least mean squares to analyse about 120 calibration points for each transducer: the calibration factors, expressed as cm of mercury per mV, are recorded in Table. 3.7.

TABLE 3.7

TRANSDUCER CALIBRATION FACTORS

| L.H.A. TRANSDUCER |                    | R.H.A. TRANSDUCER |                    |
|-------------------|--------------------|-------------------|--------------------|
| Hg Temp<br>°C     | Factor<br>cm Hg/mV | Hg Temp<br>°C     | Factor<br>cm Hg/mV |
| 26.7              | 2.081              | 24.6              | 1.921              |
| 0                 | 2.071              | 0                 | 1.913              |

Each calibration factor was corrected for the density of mercury at the mean temperature of the calibration measurements, thereby allowing the factor to be expressed in terms of cm of mercury at 0°C. The "corrected" factor was used in the computer program written for the analysis of volumetric adsorption data derived from transducer-pressure measurements (Appendix 1). The "original" factor, expressed in terms of cm of mercury at the mean temperature of the calibration measurements, was used to formulate various conversion tables of relative pressure, manometric pressure and transducer pressure; manipulation of the volumetric apparatus was optimised during the determination of an isotherm by reference to the conversion tables. Examples of the conversion tables are recorded in Appendix 2.

It is evident from Figures 3.9 and 3.10 that hysteresis and non-linearity effects respectively, of each transducer are negligible. Furthermore, the calibration measurements were made using both nitrogen and argon respectively: no significant difference in the calibration factors for each gas was observed.

### Comparison of Manometric and Transducer Pressure Data

Isotherm data were always computed using manometric pressure measurements; the digital display of the transducer pressure provided a very useful means of assessing the moment at which the adsorption system had attained an "equilibrium pressure". However, by way of an example of the possible applications of a transducer in a volumetric apparatus, the isotherm data for nitrogen adsorption on a standard silica sample (TK 800 -III) were also computed on the basis of transducer pressure measurements: the comparison of the manometric and transducer pressure data respectively, is shown in Fig. 3.11. The transducer pressure data lead to a BET surface area value which is lower by less than 4% of the corresponding area derived from the manometric data.

It is worth noting that the application of a single wide-range transducer to an accumulative volumetric technique, is the least-favourable example of the use of a transducer in the present type of adsorption experiments. Nevertheless, the present work has shown that such a transducer may be usefully employed in a volumetric apparatus for the routine study of nitrogen adsorption, especially if the studies are required to be made in the absence of mercury vapour.

#### 3.14 The Oxygen Vapour Pressure Thermometer

The temperature of the liquid nitrogen in the cryostat bath surrounding the sample bulb, and therefore the saturated vapour pressure of the adsorbate ( $P_0$ ), was measured with a conventional oxygen vapour pressure thermometer. The thermometer bulb was located as closely as possible to the sample bulb, leaving just sufficient space to slide an outgassing furnace into position around the sample bulb. Two thermometers of different lengths were necessary for the L.H.A. (shown in Fig. 3.2), for use with the low and high temperature sample bulbs respectively. Each thermometer

contained 'grade X' oxygen (purity greater than 99.96%) at a pressure of about 700 torr, providing sufficient condensate at  $-196^{\circ}\text{C}$  to register a reliable vapour pressure. The outgassed thermometers were filled with oxygen using a procedure very similar to that described by Payne.<sup>20</sup>

Plots of the saturated vapour pressure (SVP) of liquid oxygen against the SVP of liquid nitrogen<sup>26</sup> and solid argon<sup>20</sup> respectively, were constructed: the plots were used to evaluate the SVP of the adsorbate from the readings of the appropriate oxygen vapour pressure thermometer, taken at frequent intervals during the course of an adsorption isotherm determination. Equivalent SVP data (taken from the SVP plots) for oxygen, argon and nitrogen respectively, are recorded in Table 3.8.

TABLE 3.8

Equivalent Values of Saturated Vapour Pressure Data

| SVP (Expressed in torr) |       |          |
|-------------------------|-------|----------|
| Oxygen                  | Argon | Nitrogen |
| 151.0                   | 191.0 | 740.8    |

| 163.0                   | 210.0 | 788.5    |
| 164.0                   | 211.6 | 792.4    |

### 3.15 Sample Outgassing Procedure

The chromium oxide samples were outgassed over a period of at least 15 hours at the desired temperature; the time of outgassing for the silica samples generally varied between 2 and 20 hours, according to the outgassing temperature. In all cases, samples were outgassed to a pressure of about  $2 \times 10^{-4}$  torr. The outgassing conditions for a particular sample are recorded in the notation for the sample specimen: for example, S2(25)20V was a sample of chromia gel S2 outgassed at  $25^{\circ}\text{C}$  over a period of 20 hours; similarly,  $\text{CrO}_2(100)17\text{V}$  was a sample of chromium dioxide outgassed at  $100^{\circ}\text{C}$  over a period of 17 hours. Unless otherwise stated, samples were outgassed in the presence of mercury vapour.

A typical arrangement for the outgassing of a sample is shown for the R.H.A. in Fig. 3.1. The temperature of the furnace was controlled (to better than  $\pm 1\%$  up to  $1100^{\circ}\text{C}$ ) by a Linear Variable Programmer, with a potentiometric chart recorder placed in parallel with the thermocouple, thereby providing a permanent record of the outgassing conditions. An industrial air blower was employed to maintain the greased joint of the sample bulb at ambient temperature. When outgassing at temperatures in excess of about  $400^{\circ}\text{C}$ , using the L.H.A. in Fig. 3.1, additional cooling for the neck of the sample bulb was provided by a flow of water through the condenser jacket of the silica sample bulb.

### 3.16 Isotherm Determination

In the following outline of the procedure for making adsorption measurements, the stopcocks specifically referred to are those shown in Fig. 3.2, or alternatively, those depicted in the diagram in Fig. 3.4.

After outgassing the sample at the desired temperature, stopcock 'A' was closed and, where appropriate, the sample allowed to cool to

ambient temperature; with the exception of the main pumping system, all other stopcocks were also closed. The mercury in the gas burette bulbs was lowered to the zero fiducial marks. A controlled charge of nitrogen (or argon) was admitted, via stopcocks 'C' and 'B' respectively, to the dead space section; the pressure of the charge (optimised by reference to the conversion tables discussed in Section 3.13) was measured using the adsorption manometer, M1, and also, the transducer 'F'. The temperature of the manometric measurement was noted from the mercury thermometer ( $\pm 0.1^{\circ}\text{C}$ ). The gas charge was then shared with the sample bulb section, by opening stopcock 'A', and the liquid nitrogen cryostat bath then raised into position around the sample bulb. This procedure differs from those previously described<sup>9,11,20</sup> for low temperature gas adsorption (where the cryostat bath was raised into position before admittance of the adsorptive charge), and was introduced to considerably reduce the risk of "gettering" effects by the reactive samples. After the system had attained a state of apparent equilibrium, the pressure and temperature of the adsorptive were again recorded (generally with stopcock 'A' open). Further points on the isotherm were obtained by progressively raising the mercury in the burette bulbs to successive fiducial marks, and, as necessary, admitting a further charge of the adsorptive.

Desorption points were obtained by either lowering the mercury in the gas burette bulbs, or, as necessary, removing a proportion of the adsorptive from the dead space section (stopcock 'A' closed) via stopcock 'B'.

Equilibration times generally varied between 15 minutes and 2 hours, depending on the nature of the adsorbent and the magnitude of the equilibrium pressure. The majority of the isotherms were determined in detail, necessitating the recording of the adsorption points over a period

of 16 hours on one day, whilst the desorption points were recorded over a similar period on the following day: the readings were held in abeyance for about 8 hours, with a constant level device monitoring, and maintaining, the level of liquid nitrogen in the cryostat bath.

The arrangement for the simple constant level device employed in the present work, based on a gas thermometer connected to a mercury cut-off, is shown in Fig. 3.3. The device was used both for the dead space calibrations and throughout the determination of the isotherms, and was capable of controlling the level of liquid nitrogen in the cryostat bath to within about  $\pm 1$  mm of the sample bulb datum line. A similar constant level device has been described in detail by Feld and Klein.<sup>27</sup>

The experimental adsorption data were processed using an Elliot 803 computer. The programs, for manometric and transducer pressure measurements respectively, were written in Autocode language and are recorded in Appendix 1. The following quantities were computed, using the outgassed sample weight:

- (a) the relative pressure,  $P/P_0$
- (b) The amount of vapour adsorbed at the equilibrium pressure,  $P$ , expressed in  $\text{cm}^3$  (STP)  $\text{g}^{-1}$ , and
- (c) the 'BET factor',  $P/V(P_0-P)$ .

The experimental data for nitrogen and argon adsorption on chromium oxides and silicas respectively, are recorded in Appendices 3,4,7 and 8.

#### D. WATER AND MERCURY VAPOUR ADSORPTION

Two gravimetric apparatuses were employed in the present work to study the adsorption of water and mercury vapour respectively, on chromium oxides, and of water vapour on silicas. A quartz-spring balance of the McBain-Bakr type<sup>28</sup> was designed and built by the author, and used for the majority of the gravimetric studies. A Gulbransen manual microbalance,<sup>29</sup>

built by Payne,<sup>20</sup> was employed for a number of the mercury vapour adsorption studies and for the study of water vapour adsorption on chromium oxy-hydroxide.

## THE SPRING BALANCE

### 3.17 Design and Technique

General views of the spring balance are shown in Fig. 3.12 (high temperature sample outgassing arrangement) and Fig. 3.13 (adsorption measurement arrangement) respectively: the general arrangement of the balance is depicted in diagrammatic form in Fig. 3.16. Essentially the spring balance comprised a tapered helical quartz spring (sensitivity about  $100 \text{ cm g}^{-1}$ , maximum load of 1g) suspended inside a water jacket maintained at a temperature of  $26.5^{\circ} \pm 0.05^{\circ}\text{C}$  by water pumped from a B.T.L. 'Circon' thermostatic bath. A silica glass bucket (weight about 0.2g), containing the sample, was attached to the spring by means of a thin silica glass sliver: silica wool was placed in the narrow neck of the bucket to prevent loss of the sample by "spurting" during the outgassing process. The sliver, bucket and sample are just discernible in Fig. 3.14. The sample bucket was enclosed in a separate water jacket maintained at  $25^{\circ} \pm 0.01^{\circ}\text{C}$  by water pumped from a Townson and Mercer thermostatic bath. The upper and lower joints on the balance "case" were each made by means of a clamped 'Rotulex' spherical greaseless joint, with a Viton A 'O'-ring employed as the seal. In order to permit high temperature outgassing of the sample (up to  $1100^{\circ}\text{C}$ ), the sample section of the balance case was fabricated from transparent 'Vitreosil' silica glass.

The total weight of the bucket, plug and sliver suspension was about 0.4g, thereby allowing sample weights of about 0.3 - 0.5g to be used, depending on the expected uptake of water (or mercury) vapour. Occasionally, for silica samples of low bulk-density, additional silica glass weights

were hung on the bucket suspension in order to restrict the overall movement of the bucket to the lower region of the sample jacket. By arranging that the bucket was always as near as possible to the base of the sample jacket at the SVP of water vapour, thermal transpiration effects<sup>30</sup> were reduced to a minimum.

The balance case was connected, via greaseless stopcocks, to (a) a vacuum pumping system which was protected against failure of the cooling water supply etc., in a manner similar to that described in Section 3.11, (b) a pressure-measurement system comprising a mercury manometer, a silicone oil manometer (Edwards MS 704 silicone fluid), and a pressure-sensitive transducer, and (c) a water storage reservoir, containing triple distilled water, which was outgassed for about 10 minutes prior to each experiment (using a freeze-thaw cyclic process).

The vacuum pumping system comprised both oil and mercury vapour diffusion pumps respectively, arranged in parallel with a common rotary pump such that each could be selected at will. A polyphenyl ether (Edwards 'Santovac 5') was employed as the fluid for the oil diffusion pump, in preference to a silicone fluid. The pressure-measurement system allowed a particular manometer, or the transducer, to be employed for an experiment whilst the remainder of the system was isolated from the balance case; each manometer was used in conjunction with the corresponding diffusion pump.

Silicone oil vapour is known<sup>31,32</sup> to reduce certain chromium oxide surfaces; furthermore, it may even result in the deposition of silica on an active oxide surface, e.g. chromia or titania.<sup>33</sup> In addition, the present work has revealed that certain chromium oxides have a high affinity for mercury vapour<sup>34,35</sup> (Chapter 5). Ideally, therefore, silicone oil (or mercury) should be excluded from manometric systems employed for the

study of chromium oxides. In practice, however, there are very few alternative low vapour pressure fluids, possessing a greater chemical inertness, which also satisfy the requirements of a manometric fluid: for example, the viscosity of 'Santovac 5' at 25°C is greater than 500 cSt, consequently resulting in intolerable "drainage times". The flexibility of the pressure-measurement system in the present apparatus permitted a study of mercury vapour adsorption to be made. The study of water vapour adsorption per se was made in the strict absence of either silicone oil vapour or mercury vapour: pressure measurements were made using the sensitive transducer.

### 3.18 Calibration of the Spring Balance

The quartz spring was calibrated, at a temperature of  $26.5^{\circ} \pm 0.05^{\circ}\text{C}$ , against precision milligramme weights (conforming to NPL 'grade A' specifications) with the balance case under high vacuum ( $10^{-5}$  torr). The calibration plot is shown in Fig. 3.18: the extension of the spring was both elastic, and linear, with load. All spring extension measurements were taken with a cathetometer ( $\pm 0.001$  cm) and were referred to a fixed point, in the form of very fine cross-wires, on the balance case.

The silicone oil manometer (M2 in Fig. 3.16) was calibrated against the precision wide-bore mercury manometer (M1 in Fig. 3.16): the calibration factor, expressed in terms of cm of mercury (at 0°C) per cm of silicone oil (at the temperature of the calibration), was written into the appropriate computer program for manometric pressure measurements.

A Bell and Howell pressure-sensitive transducer (type 4-353) with an operational range of 0.01 - 26 torr (absolute), was employed in the present apparatus. The principle of operation and calibration etc., of this transducer is very similar to that described for the type 4-366 transducer

(Section 3.13). However, in terms of absolute pressure, the sensitivity of the type 4-353 transducer system for water adsorption was about  $\pm 6.2 \times 10^{-3}$  torr, i.e. about 16 times greater than the sensitivity of the type 4-366 system for nitrogen adsorption. Thus, the transducer pressure measurements on the spring balance were more sensitive than mercury-manometric measurements and could therefore be confidently employed for isotherm determinations. The calibration plot for the transducer is shown in Fig. 3.19; the calibration factor, expressed in terms of cm of mercury (at  $0^{\circ}\text{C}$ ) per mV, was written into the computer program for transducer pressure measurements (Appendix 1). A conversion table of relative pressure, manometric pressure and transducer pressure respectively, was constructed to optimise the manipulation of the spring balance; the table is recorded in Appendix 2.

### 3.19 Sample Outgassing Procedure

A typical arrangement for the outgassing of a sample is shown in Fig. 3.12. The procedure was similar in many respects to that described for the volumetric apparatuses in Section 3.15. However, unless otherwise stated, samples were outgassed in the absence of either mercury or silicone oil vapour, generally to a pressure of about  $5 \times 10^{-5}$  torr. Helium ('grade X', purity greater than 99.9997%), at a pressure of about 2 torr, was generally admitted to the balance case during the cooling period following completion of the outgassing of chromium oxide samples; the sample was re-evacuated (at  $25.0^{\circ}\text{C}$ ) immediately prior to the isotherm determinations.

### 3.20 Isotherm Determination

The uptake of water vapour was simply followed by measuring the extension of the spring with progressive increase of pressure.

Equilibration times were very dependent upon the nature of the adsorbents, generally varying between about 1 and 6 hours: in some cases, equilibration times were much longer and the isotherm points so recorded did not necessarily represent a state of true equilibrium.

A correction for the buoyancy effect<sup>36</sup> was incorporated into the computer program (Algol language) written for the processing of the experimental data, by application of the equation:

$$\delta w = \frac{Mv}{RT} \cdot P \quad (3.4)$$

where  $\delta w$  = the upthrust on the load of the spring

$M$  = the molecular weight of water

$v$  = the volume of the load, i.e. the sum  
of the volumes of the bucket, plug,  
sample and adsorbate respectively

$R$  = the gas constant

$T$  = the temperature in  $^{\circ}\text{K}$

and  $P$  = the pressure of the water vapour.

The sorption of water vapour by the spring, bucket and plug respectively, was found to be negligible when determined in the absence of a sample.

The experimental data for water adsorption on chromium oxides and silicas, are recorded in Appendices 5 and 9 respectively: the experimental data for mercury vapour adsorption on chromium oxides are recorded in Appendix 6.

#### THE GULBRANSEN MICROBALANCE

Apart from a small number of the mercury vapour adsorption studies, the use of the Gulbransen microbalance was limited to a single experiment involving the study of water vapour adsorption on low-area chromium oxy-hydroxide. In the latter case, the advantage of the microbalance lay

in the fact that the sensitivity of the microbalance ( $\pm 1 \mu\text{g}$ ) was an order of magnitude greater than that of the spring balance.

The Gulbransen microbalance employed in the present work has been described in considerable detail by Payne<sup>20</sup> and will not, therefore, be discussed further here.

RESULTS AND DISCUSSION I

GAS ADSORPTION AND RELATED STUDIES ON THE SILICA SAMPLES

The present chapter deals with the analysis and interpretation of the argon, nitrogen and water vapour adsorption data determined on the silica samples, together with their heats of immersion in water. The experimental data are presented in tabular form in Appendices 7, 8 and 9 respectively. Conclusions are drawn concerning the texture and degree of hydroxylation of the silica samples.

4.1 The Adsorption Isotherms

The reversible Type II nitrogen and argon isotherms obtained for Fransil, in the present work, are shown in Fig. 4.1, together with the irreversible water isotherm: the nitrogen and argon isotherms are typical of a non-porous adsorbent. The nitrogen isotherm exhibits a well-defined point B (BET C value of about 138) whereas the argon isotherm gives a more gradual curvature in the region of the statistical monolayer (BET C value of about 32). The water isotherm exhibits hysteresis over the complete range of relative pressure, and indicates that, whilst the sample of Fransil is non-porous, the surface is not fully hydroxylated. The argon isotherm, plotted as a function of  $P/P_o(s)$  (where  $P_o(s)$  is the saturated vapour pressure of solid argon), cuts the ordinate  $P/P_o(s) = \text{unity}$  at a finite angle instead of approaching asymptotically. In studies of argon adsorption at  $-196^{\circ}\text{C}$  (i.e. below the bulk triple point of argon) it

has been customary to take the value of  $P_0$  as that of the supercooled liquid.<sup>1-3</sup> Recently, however, Sing and his co-workers<sup>4</sup> have suggested that although this may be justified in the case of certain porous solids,<sup>5</sup> there is no sound reason for making the same assumption with non-porous adsorbents.<sup>6</sup> Consequently, the value of  $P_0$  used throughout the present work is that of solid argon.

In Fig. 4.2, the nitrogen adsorption data are represented as  $\alpha_s$ -plots, the data previously reported for Fransil<sup>7,8</sup> being taken as standard. The  $\alpha_s$ -plot is both linear and passes through the origin; this provides useful confirmation of the accuracy of the present measurements (see also Section 3.12, page 60) and demonstrates that the surface properties of this particular sample of Fransil have not changed significantly over the past four or five years.

In confirmation of previous work,<sup>4,8,9</sup> reversible Type II nitrogen and argon isotherms were also obtained on TK 800 outgassed at both 25°C and 140°C; the corresponding water vapour isotherms exhibited hysteresis over the complete range of relative pressure. The hysteresis of the water isotherms was enhanced with increase in temperature of outgassing. In general terms, the picture for the nitrogen, argon and water vapour isotherms respectively, on TK 800 outgassed at either 25°C or 140°C was very similar to that described for Fransil (shown in Fig. 4.1). Replicate water vapour isotherms on the same sample of TK 800 revealed that the degree of hydroxylation of the silica surface was gradually increased with repetitive exposure to water vapour - i.e. water vapour adsorption was enhanced, whilst the degree of irreversibility of the isotherms was progressively reduced.

In order to obtain a fully reversible water isotherm on TK 800 a sample was "soaked" in water vapour, at a relative pressure of about 0.98 at 25°C, over a period of three days: the pressure of water vapour was then

progressively decreased and the "desorption isotherm" obtained. The soaked sample was outgassed at 25°C to constant weight and the complete nitrogen and water vapour isotherms respectively, determined. The isotherms (the uptake expressed in terms of  $\mu$  mole per unit nitrogen area) are shown in Figs. 4.3 and 4.4 respectively, together with the corresponding isotherms determined on the original, partially hydroxylated, material. It is clear from Fig. 4.3, that the soaking treatment has not significantly affected the subsequent adsorption of nitrogen at relative pressures below about  $P/P_0 = 0.5$ ; apart from a slightly more rounded knee of the isotherm, the BET nitrogen area remained virtually unchanged (Table 4.1). At higher relative pressures in the multilayer region, however, the nitrogen isotherm on the soaked material exhibits a small degree of irreversibility, characteristic of capillary condensation. The  $\alpha_s$ -plots of the nitrogen adsorption data for the original and soaked materials respectively, are shown in Fig. 4.5. The upward deviation from linearity of the plot for the soaked material is typical of capillary condensation, and is probably a result of a small degree of cementation of particles of TK 800 upon prolonged exposure to water vapour. The fact that the  $\alpha_s$ -plots in Fig. 4.5 all show a negative intercept with the ordinate at  $\alpha_s = 0$ , indicates that Fransil is not a strictly suitable standard adsorbent for comparison with TK 800 adsorption data.

The water vapour isotherms shown in Fig. 4.4 reveal that the soaking treatment of TK 800 resulted in the almost complete hydroxylation of the adsorbent surface. The adsorption of water vapour on the soaked material was considerably enhanced and, apart from a very small degree of hysteresis at high relative pressure (characteristic of capillary condensation), the isotherm was completely reversible below a relative pressure of about  $P/P_0 = 0.7$ . Furthermore, the "desorption isotherm" obtained (in the manner

referred to above) immediately after the soaking treatment at  $P/P_0 = 0.98$  was virtually coincident with the subsequent adsorption branch of the (almost) reversible isotherm on the soaked material; in addition, the isotherm on the soaked material was reproducible.

The effect on the nitrogen isotherms by outgassing a non-porous silica and two porous silicas at  $1000^{\circ}\text{C}$ , as compared with  $25^{\circ}\text{C}$ , is shown in Figs. 4.6 - 4.8. For ease of comparison the isotherms are plotted as adsorption per unit area (using  $S_{\text{BET}}^{\text{N}}$ ); it should be noted, however, that in the case of the microporous gel E the BET nitrogen area is an apparent area.

It is clear from Fig. 4.6, that on outgassing TK 800 at  $1000^{\circ}\text{C}$ , the general shape of the nitrogen isotherm (which was reversible) was changed very little; the reduction in the value of the BET C constant (Table 4.1), indicates that the adsorbent-adsorbate interactions have been reduced by dehydroxylation of the adsorbent surface at  $1000^{\circ}\text{C}$ . The  $\alpha_s$ -plot for the high temperature outgassed material, Curve 'C' in Fig. 4.5, is clearly linear over a wide range of relative pressure; although the high temperature treatment has resulted in some sintering of the adsorbent particles ( $S_{\text{BET}}^{\text{N}}$  in Table 4.1 is reduced by about 13% at  $1000^{\circ}\text{C}$ ), the texture of the TK 800 sample has remained unchanged after outgassing at  $1000^{\circ}\text{C}$ .

In contrast, however, when the microporous silica, gel E, was outgassed at  $1000^{\circ}\text{C}$ , a small amount of pore-widening occurred as was revealed by the subsequent nitrogen isotherm (Fig. 4.7). The nitrogen isotherm, although still predominantly Type I in character, exhibits an upward swing at relative pressures greater than about  $P/P_0 = 0.5$  in a manner similar to that of a Type III isotherm.<sup>10</sup> If the adsorption of nitrogen on the dehydroxylated gel E is indeed particle co-operative in nature, it suggests that the adsorbent-adsorbate interactions are reduced by the outgassing at

1000°C whilst the adsorbate-adsorbate interactions have increased.

This change is reflected by the drastic reduction in the value of the BET C constant (which is accompanied by a four-fold reduction in the apparent nitrogen area) for the nitrogen isotherm on the high temperature outgassed material (Table 4.1). Kiselev,<sup>11</sup> in studies of nitrogen, benzene and water vapour adsorption, has observed a very similar effect in the cases of hydroxylated and dehydroxylated silicas, and of ungraphitised and graphitised carbons respectively.

The behaviour of the mesoporous silica, gel J, on outgassing at 1000°C was very similar to that for the non-porous TK 800: the texture of the adsorbent remained virtually unchanged, whilst the proportionate loss of nitrogen area (about 12% from Table 4.1) by sintering was almost identical to that for TK 800. The slight enhancement of the hysteresis loop (Type A in the de Boer classification<sup>12,13</sup>) for the nitrogen isotherm on gel J outgassed at 1000°C may, in part, be associated with the slightly higher relative pressure obtained during the determination of this isotherm; otherwise, the Type IV nitrogen isotherms obtained after outgassing at 25°C and 1000°C respectively, are almost completely coincident (Fig. 4.8).

In general, therefore, the nitrogen isotherms determined on the various silicas, reveal that there was very little change in the texture of the adsorbents when outgassed at 1000°C, as compared with 25°C, particularly in the cases of the non-porous TK 800 and the mesoporous gel J. However, the water isotherms, shown in Figs. 4.4, 4.9 and 4.10 for silicas outgassed at 25°C and 1000°C respectively, clearly indicate a substantial change in the chemical nature of the adsorbent surface outgassed at 1000°C. It should be emphasised that the curves in Fig. 4.10 do not necessarily represent equilibrium isotherms for the physical adsorption of water vapour on dehydroxylated silicas; in addition to physical adsorption, irreversible

chemisorption of water vapour also occurred. The rate of chemisorption rapidly increased with increasing relative pressure, whilst the amount of chemisorbed water was dependent on the time of exposure of the adsorbent to water vapour. To minimise the amount of chemisorption, the complete isotherm on a dehydroxylated silica was determined during a continuous period of about 16 hours. Isotherm adsorption points were recorded when a plot of water uptake against time elapsed indicated that the (relative rapid) physical adsorption of water vapour was, for the present purposes, complete at the particular relative pressure; in contrast, during desorption apparent equilibrium was attained relatively quickly (5 - 15 minutes as compared to 20 - 80 minutes for adsorption, in the case of TK 800) and it appeared to represent a genuine state of equilibrium.

The water isotherm on gel E outgassed at 25°C, shown in Fig. 4.9, exhibits a considerable degree of Type IV character, especially in respect of the hysteresis loop; however, the corresponding nitrogen isotherm, shown in Fig. 4.7, demonstrates that gel E is microporous. The hysteresis loop in the water isotherm, Type E in the de Boer classification,<sup>12,13</sup> is characteristic of pores of the ink-bottle type<sup>14-17</sup> which probably comprise the micropores of the adsorbent; in this instance, the micropores may be visualised as having a neck, too narrow to permit the entry of nitrogen molecules, but sufficiently wide to allow the penetration of water molecules. The water vapour isotherm on gel E (Fig. 4.9) is almost identical with that reported in earlier work by Kiselev et al.<sup>18,19</sup> for water vapour adsorption on a microporous silica gel (with an apparent nitrogen area of 540 m<sup>2</sup>g<sup>-1</sup>); furthermore, Kiselev and his co-workers<sup>20</sup> have also commented on a molecular-sieve effect as between nitrogen and water on such a gel. It is interesting to note that the apparent close similarity of Kiselev's microporous silica gel with gel E studied in the present work, is further

demonstrated by the close similarity in total pore volumes (liquid water): i.e.  $0.25 \text{ cm}^3 \text{ g}^{-1}$  and  $0.26 \text{ cm}^3 \text{ g}^{-1}$  respectively.

When gel E was outgassed at  $1000^\circ\text{C}$  the subsequent water isotherm displayed none of the familiar characteristics of a microporous adsorbent; in fact, the adsorption branch was very similar to that of the water isotherm determined on the mesoporous gel J, similarly outgassed at  $1000^\circ\text{C}$  (Fig. 4.10).

Water adsorption on all three silicas was much reduced at relative pressures below about 0.35 by outgassing at  $1000^\circ\text{C}$ , presumably because the rate of chemisorption (and hence, rehydroxylation) at low relative pressures is practically negligible.<sup>21</sup> Moreover, the adsorption branches of the isotherms at low relative pressures are in very close proximity and may, therefore, be in approximate coincidence with reversible physical adsorption of water on a dehydroxylated silica. Apart from a barely discernible point of inflexion close to the origin (which may be attributed to a small amount of hydroxyl groups remaining on the dehydrated surface), the adsorption branches are essentially Type III in character thereby reflecting the hydrophobicity of the dehydroxylated silicas. Kiselev and his co-workers<sup>21</sup> have observed an identical effect for silicas outgassed at  $900^\circ\text{C}$ . The adsorption branch becomes progressively steeper, as the rate of surface rehydration is increased at higher relative pressures; the relative location of the adsorption branches of the isotherms above a pressure of about 0.35  $P_0$  is some measure of the ease of rehydration or, conversely, the degree of hydrophobicity of the respective silicas outgassed at  $1000^\circ\text{C}$ ; i.e. order of hydrophobicity is - TK 800 > gel J > gel E.

The difference between the desorption branch of the water isotherm on gel E outgassed at  $1000^\circ\text{C}$ , and those of the corresponding isotherms for gel J and TK 800 respectively, is noteworthy: in the latter cases, the pronounced hysteresis extending to zero pressure is characteristic of

surface rehydration, but for the microporous silica, gel E, the hysteresis is a result of both surface rehydration and pore-emptying. The steep section of the desorption branch, within a very narrow range of relative pressure at about 0.25 P<sub>o</sub>, is most probably associated with the sudden emptying of the ink-bottle type micropores, mentioned earlier; at relative pressures below about 0.25 P<sub>o</sub>, the hysteresis is solely associated with surface rehydration. Furthermore, the desorption branch of the water isotherm on gel E outgassed at 1000°C is remarkably similar, in location and shape, to that of the isotherm obtained after outgassing the gel at 25°C (Fig.4.9). Thus, as previously indicated by the general superposability of the corresponding nitrogen isotherms, shown in Fig. 4.7, the pore size distribution for gel E outgassed at 25° and 1000°C respectively, must be fairly similar.

In conclusion to the present discussion on the nitrogen and water vapour isotherms, it is noteworthy that the amount of water remaining after outgassing the respective high-temperature silicas to constant weight at 25°C (expressed as  $\mu$  mole per m<sup>2</sup> of apparent nitrogen area), is very similar in each case. In fact, it is obvious from Fig. 4.10 that the amount of residual water per unit area is identical for the micro and mesoporous silicas, gels E and J respectively, whilst that for the non-porous TK 800 is about 35% less. This result indicates that the chemical nature of the surfaces of the respective silicas is probably very similar, rehydration of TK 800 being slightly more difficult than for gels E and J respectively.

#### 4.2 Comparison of the Water Adsorption Data

The results of the experiments on nitrogen and on water vapour adsorption respectively, on silicas are summarised in Table 4.1. The values of the BET nitrogen area,  $S_{\text{BET}}^{\text{N}}$ , were calculated by taking 16.2 Å<sup>2</sup>

**TABLE 4.1**

**Nitrogen and Water Vapour Adsorption on the Silicas**

| SAMPLE                 | OUTGASSING TEMPERATURE (°C) | NITROGEN ADSORPTION |          |   | WATER ADSORPTION |  |   | N <sub>OH</sub> per 100 Å <sup>2</sup> | Q <sub>L</sub> (erg cm <sup>-2</sup> ) |     |

N, non-porous; Mic, microporous; Me, mesoporous.

<sup>a</sup> Fransil was outgassed at 140°C for the nitrogen isotherm, but at 25°C for the water isotherm.

<sup>b</sup> Fully hydroxylated TK 800, i.e. 'soaked'.

<sup>c</sup> Partially hydroxylated TK 800, i.e. as received.

<sup>d</sup> Dehydroxylated TK 800, i.e. outgassed at 1000°C.

as the cross-sectional area of the nitrogen molecule in the completed monolayer; the values of the corresponding BET water area,  $S_{\text{BET}}^{\text{W}}$ , were calculated by taking  $10.6 \text{ \AA}^2$  as the cross-sectional area of the water molecule. However, in view of the fact that the water isotherms did not give a well-defined point B (very low BET C constant in each case), the  $S_{\text{BET}}^{\text{W}}$  values recorded in Table 4.1 are of limited significance. In order to make a more meaningful comparison of the water adsorption data for the various silicas the water uptakes at 0.2 Po, reduced to a unit area basis (using  $S_{\text{BET}}^{\text{N}}$ ), are shown in column 9 of Table 4.1.

The amounts of water adsorption per unit area range widely, from 0.9 to  $11.6 \mu \text{ mole m}^{-2}$ . For comparison, an uptake of  $15.7 \mu \text{ mole m}^{-2}$  would correspond to a close-packed water monolayer (taking  $A_{\text{m}} = 10.6 \text{ \AA}^2$ ). In confirmation of previous findings,<sup>4,22</sup> all the silicas gave a lower uptake of water vapour at 0.2 Po than the amount required for the close-packed monolayer coverage. It is noteworthy that the microporous silica, gel E (outgassed at  $25^{\circ}\text{C}$ ), gave an appreciably higher level of water adsorption, even though the apparent hydroxyl group population was exceptionally low (Section 4.3), than did the other silicas. As discussed in Section 4.1, this was probably due to the penetration of water into pores (of width about  $4 \text{ \AA}$ ) too narrow to accept nitrogen molecules and therefore, the term 'sorption' may be usefully applied to describe such phenomena.<sup>23</sup> In confirmation of the work of Kiselev,<sup>19,21,24</sup> the adsorption of water on the dehydroxylated samples of TK 800 and gels E and J (outgassed at  $1000^{\circ}\text{C}$ ) was especially low; about  $1 \mu \text{ mole m}^{-2}$  in each case.

In Fig. 4.11, representative water vapour adsorption isotherms are plotted to 0.4 Po on a unit area basis (by taking the corresponding  $S_{\text{BET}}^{\text{N}}$  value from Table 4.1), along with the standard, reversible, water isotherm

on fully hydroxylated non-porous silica (Kiselev<sup>24</sup>) included as a comparison. Curves lying below the standard isotherm may be interpreted in terms of the chemistry of the adsorbent surface; e.g. increase in the degree of hydroxylation of TK 800 results in the progressive movement of the isotherm towards the standard curve. The fact that the curve for the soaked TK 800 (reversible water isotherm) is markedly displaced from the standard curve, probably indicates that there is a significant difference in the chemistry of the (apparently) fully hydroxylated TK 800 surface and that of the standard. The location of the curve for the microporous silica, gel E, appreciably above the standard curve clearly indicates on the other hand that the texture of the gel is now the over-ruling factor during the sorption of water vapour. The curve for the mesoporous silica, gel J, is located close to the standard curve, and indicates that the chemical nature of the respective surfaces is probably very similar.

#### 4.3 Surface Concentration of Hydroxyl Groups

The apparent number of surface hydroxyl groups per  $100 \text{ \AA}^2$ ,  $N_{\text{OH}}$ , shown in column 10 of Table 4.1, was assessed from the weight loss of each silica on outgassing at  $1000^\circ\text{C}$  for 2.5 hours. In the assessment of  $N_{\text{OH}}$  it was assumed that all the physisorbed water was removed<sup>25</sup> by prolonged outgassing of the sample (to constant weight) at  $25^\circ\text{C}$ ; and furthermore, that the hydroxyl groups remaining were confined to the surface available for nitrogen adsorption. Neither of these assumptions, particularly the latter, is strictly valid: Zhuravlev and Kiselev<sup>25,26</sup> have shown that a thermogravimetric method essentially determines the total content of the "structural water", i.e. that hydroxyl groups are liberated both from the surface and from the bulk of the silica. On the other hand, it is known<sup>24,27</sup> that some hydroxyl groups are retained by a

silica surface, even after outgassing at  $1100^{\circ}\text{C}$ . The fact that some water was physisorbed on the nominally dehydroxylated silicas in the present work (about  $1 \mu\text{ mole per m}^2$  at  $0.2 \text{ Po}$ ), clearly indicates the presence of residual hydroxyl groups even on the surfaces outgassed at  $1000^{\circ}\text{C}$ . It is to be expected that prolonged outgassing at high temperatures would increase the degree of dehydroxylation; however, under such conditions very fine micropores may develop with a diameter approximating to that of a water molecule.<sup>25,28</sup> In order to reduce the risk of the formation of these very fine pores, a relatively short outgassing period of 2.5 hours at  $1000^{\circ}\text{C}$  was adopted for the present thermogravimetric studies.

The values of the surface concentrations of hydroxyl groups,  $N_{\text{OH}}$ , obtained for the silicas in the present work, range from 1.8 for the microporous gel E to 4.3 for the non-porous Fransil. In general, the values of  $N_{\text{OH}}$  are lower than the range reported<sup>25,26</sup> for fully hydroxylated amorphous silica, as determined by a deuterium exchange method,<sup>29</sup> namely 4.2 - 5.7 OH groups per  $100 \text{ \AA}^2$  (i.e. 7 - 9.5  $\mu\text{ mole OH per m}^2$ ); this range corresponds to approximately one hydroxyl group per surface silicon atom. Water isotherms on the porous silicas, gels E and J (outgassed at  $25^{\circ}\text{C}$ ), were reversible below a relative pressure of about 0.3 Po indicating that these gels were probably almost fully hydroxylated: nevertheless, the values of  $N_{\text{OH}}$  (1.8 and 3.4 respectively) were lower than those reported<sup>22</sup> for a number of microporous and mesoporous silicas ( $N_{\text{OH}}$  ranging from 5.8 to 11.5), which were determined by a thermogravimetric method. Of course, it is not unexpected that the value of  $N_{\text{OH}}$  for the microporous gel E is abnormally low, since the apparent nitrogen area ( $572 \text{ m}^2\text{g}^{-1}$ , Table 4.1) was employed to express the surface concentration of hydroxyl groups on a unit area basis. However, it is difficult to

account for other apparently low values of  $N_{OH}$  for the hydroxylated silicas, e.g. gel J. The present value of  $N_{OH}$  should accordingly be interpreted on a semi-quantitative basis only.

Although a plot of weight loss against time elapsed indicated that, in each case, a constant sample weight was achieved, the time of outgassing, 2.5 hours at  $1000^{\circ}C$ , may be too short. Nevertheless, assuming a consistent error from this cause, it is apparent from Table 4.1 that the soaking treatment of TK 800 did result in an increase in the value of  $N_{OH}$ , which closely approached the range reported<sup>25,26</sup> for a fully hydroxylated silica. Although the value of  $N_{OH} = 4.3$  for the Fransil sample does lie within the reported range of 4.2 - 5.7 OH groups per  $100 \text{ \AA}^2$ , the water isotherm exhibited hysteresis over the complete range of relative pressure (Fig. 4.1), indicating that the surface was not fully hydroxylated. With the exception of the porous silicas (gels E and J), it is noteworthy that an increase in the apparent surface concentration of hydroxyl groups was accompanied by an increase in the sorption of water vapour at 0.2 Po for a particular adsorbent.

#### 4.4 Heats of Immersion in Water

The values of  $Q_i$ , the heat of immersion of silica in water expressed as erg per  $cm^2$ , are given column 11 of Table 4.1 for the various silicas. Each value was calculated from the heat of immersion per gram of outgassed sample (at the temperature indicated in column 2 of Table 4.1), using the corresponding value of  $S_{BET}^N$ ; it was assumed that the surface area available to adsorbed nitrogen (at the gas-solid interface) and water (at the liquid-solid interface) was the same. For reasons already discussed it is evident that, in a number of cases, this assumption is not fully justified and therefore the values of  $Q_i$  determined in the present work do not

always represent the true heats of immersion per unit area.

For Fransil, the value of  $Q_i$  determined in the present work ( $160 \text{ erg cm}^{-2}$ ) is in excellent agreement with the value of  $160 \pm 3 \text{ erg cm}^{-2}$  reported by Taylor and Hockey,<sup>30</sup> for the heat of immersion in water of a fully hydroxylated amorphous silica. These workers observed that the value of  $Q_i$  was independent of the surface area over the range of 8 - 147  $\text{m}^2\text{g}^{-1}$  (from Table 4.1,  $S_{\text{BET}}^{\text{N}} = 38.6 \text{ m}^2\text{g}^{-1}$  for Fransil). All other values of  $Q_i$  recorded in Table 4.1 are appreciably higher than  $160 \text{ erg cm}^{-2}$ . With the exception of TK 800, the value of  $Q_i$  decreases with surface dehydroxylation of a particular silica; this result is in accord with the findings of Kiselev and his co-workers.<sup>19,21</sup> It is clear, therefore, that two particular features must be taken into account with the present results: differences in (a) the porosity, and (b) the degree of surface hydroxylation of the silicas. Unfortunately, the two effects cannot be separated, presumably because of the complex nature of the wetting process and the fact that the heat of immersion is directly related to the integral enthalpy of adsorption. These results serve to emphasise the importance of differential enthalpy determination.<sup>31</sup>

#### 4.5 The Frenkel-Halsey-Hill Plots

Representative Frenkel-Halsey-Hill (FHH) plots are shown in Fig. 4.12 - 4.16. The ranges of linearity of the various FHH plots for nitrogen and water vapour respectively, are recorded in Table 4.2, together with the values of  $r$  (in the equation  $\ln (P_0/P) = k/\theta^r$ ) determined from the slopes of the plots (Section 2.4). Values of  $r$  for "ideal" FHH plots<sup>32-34</sup> are also included in the Table for the sake of comparison.

The non-porous texture of both TK 800 and Fransil was confirmed by the fact that the FHH plots (i.e. Curve 'A' in Fig. 4.13 and Fig. 4.15

respectively) for nitrogen adsorption on these samples were linear over a wide range of relative pressure, rarely less than 0.25 to 0.9. It is noteworthy that, for nitrogen adsorption on these adsorbents outgassed at 140°C,  $r = 2.73$  for TK 800 (i.e. the mean of the two values in Table 4.2) whilst for Fransil,  $r = 2.95$ . According to Halsey,<sup>35</sup> the magnitude of  $r$  characterises the type of interaction between a vapour and the adsorbent surface; in the present instance, the respective values of  $r$  indicate the the specific adsorbent-adsorbate interactions of nitrogen with Fransil was greater than that with nitrogen on TK 800. It is interesting to note, by way of comparison, that Halsey<sup>35</sup> (utilising the data of Jura and Harkins<sup>36</sup>) found for nitrogen on a non-porous sample of anatase ( $\text{TiO}_2$ ), a value of  $r = 2.67$ . In terms of the FHH Slab Theory<sup>37,38</sup> this would indicate that the surface of the TK 800 and that of anatase are energetically similar, and that both differ significantly from that of Fransil. Furthermore, Pierce<sup>32,33</sup> and Zettlemoyer<sup>34</sup> have suggested that the "ideal" isotherm for nitrogen on a polar surface is represented by a FHH plot for which  $r = 2.75$ , i.e. very close to the present value of 2.73 for nitrogen on TK 800.

For water adsorption on Fransil and TK 800 respectively, the contrast between the values of  $r$  is even greater. For example, one may take the case when each adsorbent was outgassed at 25°C, i.e. Curve 'B' in Fig. 4.15 and Curve 'A' in Fig. 4.16 respectively: for Fransil,  $r = 2.03$  whilst for TK 800,  $r = 1.32$  (Table 4.2). Clearly, therefore, the difference between the respective magnitudes of the specific adsorbent-adsorbate interactions with Fransil and TK 800 is greater for water than for nitrogen; this is presumably because of the very much greater specificity of water vapour adsorption. In contrast to nitrogen adsorption however, there is a considerable difference between the present values of  $r$  for water adsorption

on Fransil ( $r = 2.03$ ) and on TK 800 ( $r = 1.32$ ), on the one hand and published data for FHH plots of water vapour isotherms on the other hand: for example, Halsey<sup>35</sup> found  $r = 2.50$  for anatase and similarly, Zettlemyer<sup>34</sup> found  $r = 2.49$  for a hydroxylated silica, in excellent agreement. Pierce and Ewing<sup>39</sup> have proposed that if an "abnormal" value of  $r$  is obtained from a linear FHH plot for a particular adsorbate, then it may be concluded that there was not unrestricted free surface adsorption on the adsorbent. However, in view of the fact that the  $r$  values in Table 4.2 are consistently low for water vapour adsorption, and are also located in a relatively narrow range (for TK 800), the question arises as to whether one can accept the limited published data as being representative of water vapour adsorption on a hydroxylated silica. Certainly, the present findings, and the scarcity of published FHH plots for water vapour isotherms, serve to show that a great deal more work is necessary to resolve this anomaly.

It is interesting to note from Table 4.2 that apparently either hydroxylation or dehydroxylation of a partially hydroxylated silica surface results in a reduction in the value of  $r$  for the FHH plots for both nitrogen and water vapour isotherms. For example, consider the case of nitrogen adsorption on TK 800 - II, for which the partially hydroxylated surface is represented by the sample outgassed at  $25^{\circ}\text{C}$  ( $r = 2.73$ ): on soaking the sample in water vapour the degree of hydroxylation was increased (Section 4.3), and it resulted in a value of  $r = 2.39$  (Curve 'A' in Fig. 4.12); on the other hand, when the sample was outgassed at  $1000^{\circ}\text{C}$  the degree of hydroxylation was reduced to almost zero, and a value of  $r = 2.63$  resulted (Curve 'B' in Fig. 4.13). A similar phenomenon was found for water vapour adsorption on TK 800 - II (see Fig. 4.16), although outgassing of the sample

at 1000°C resulted in a greater reduction in the range of linearity of the FHH plot, than that for the corresponding nitrogen FHH plot. The soaking treatment resulted in an increased range of linearity of the FHH plots for the nitrogen and water vapour isotherms respectively, especially in the case of the latter.

The value of  $r$ , determined from a FHH plot, is primarily related to the diminution of forces emanating from an adsorbent surface with successive layers in the adsorbed film; i.e. the value of  $r$  is established in the multilayer region after the specific effects of the surface are dissipated.<sup>34,35</sup> The downward deviation from linearity of FHH plots below a relative pressure of about 0.15  $P_0$  corresponds to the monolayer region and is therefore of little significance. However, as already stated, Halsey<sup>35</sup> has proposed that a high value of  $r$  is indicative of specific adsorbent-adsorbate interactions, since the specific effects of the adsorbent surface decay rapidly with distance from the surface. Conversely, a low value of  $r$  may indicate that the specific effects of a surface have been reduced by a particular treatment of the adsorbent, so that dispersion forces now predominate. Thus, the above results for partially hydroxylated TK 800 indicate that, for both nitrogen and water vapour adsorption, the specific interactions are reduced by either an enhanced degree of hydroxylation (soaking TK 800 in water vapour) or by drastic dehydroxylation of the surface (outgassing TK 800 at 1000°C). A similar conclusion may be tentatively drawn from a study of the values of the BET C constants, recorded in column 6 of Table 4.1, for nitrogen adsorption on TK 800; the C constants for water adsorption on TK 800 (column 8 of Table 4.1) also show a similar trend.

The FHH plots for nitrogen adsorption on the mesoporous silica,

gel J, are shown in Fig. 4.14 for outgassing of the gel at 25°C (Curve 'A') and 1000°C (Curve 'B') respectively. The upward deviation and restricted range of linearity, (Table 4.2) of each plot is clear evidence of capillary condensation. The magnitude of  $r$  for each plot was less for gel J than for TK 800 (suggesting that the surface of the mesoporous gel was energetically dissimilar to that of TK 800) but in other respects, gel J appeared to behave in a similar manner to TK 800 when outgassed at 1000°C.

Finally, in the case of argon adsorption on the silicas, the FHH plots were curved over almost the whole of the multilayer region, with a very restricted range of linearity. For example, the FHH plot for argon adsorption on TK 800-II outgassed at 140°C is shown as Curve 'B' in Fig. 4.12: the linearity is restricted to a relative pressure range of 0.35 to 0.65, for which the value of  $r = 2.39$ . It is interesting to note that this is identical with the value of  $r$  for nitrogen adsorption on fully hydroxylated TK 800 (Table 4.2). Payne<sup>40</sup> has found similar curves for argon adsorption on  $\gamma\text{-Al}_2\text{O}_3$ . The downward deviation from linearity of the FHH plot for argon above a relative pressure of about 0.65  $P_0$  (Curve 'B' in Fig. 4.12), is most probably explained by the particular choice<sup>4</sup> of the solid rather than the liquid as the reference state for the SVP of the adsorptive.

TABLE 4.2

Nitrogen and Water FHH Plots

| SAMPLE                   | OUTGASSING TEMPERATURE (°C) | NITROGEN ADSORPTION           |      | WATER ADSORPTION              |         |
|--------------------------|-----------------------------|-------------------------------|------|-------------------------------|---------|
|                          |                             | LINEARITY (P/P <sub>0</sub> ) | r    | LINEARITY (P/P <sub>0</sub> ) | r       |
| "Ideal"<br>(Refs. 32-34) | -                           | Polar                         | 2.75 | Hydrophilic                   | 2.50    |
|                          |                             | Non-polar                     | 2.12 | Hydrophobic                   | 1.3-1.9 |
| <sup>a</sup> Fransil     | 25                          | 0.20-0.85                     | 2.87 | 0.25-0.75                     | 1.64    |

### RESULTS AND DISCUSSION II

#### MERCURY VAPOUR ADSORPTION ON CHROMIUM OXIDES

In the present chapter, the adsorption of mercury vapour on certain chromium oxide surfaces is discussed. An explanation as to why mercury vapour is irreversibly adsorbed is presented. The gravimetric techniques utilised in this study were described in Chapter 3, whilst the relevant mercury adsorption data are tabulated in Appendix 6.

#### 5.1 Mercury Vapour Adsorption on Chromium Oxide Gels

During the prolonged outgassing of certain calcined chromia gels at 25°C, it was observed<sup>1</sup> that the weight of the sample decreased to a minimum (after 2-3 hours) and then underwent a slow but uniform rate of increase. The weight change was arrested by the introduction of a small pressure of a permanent gas (e.g. nitrogen), but the same rate of increase was restored on continuation of the outgassing. When similar experiments were performed using a Gulbransen microbalance (in place of the spring balance) and a mercury-free adsorption system, no increase in weight could be observed. It seemed likely that the weight increase was due to the adsorption of mercury vapour, which originated from various exposed mercury surfaces in the system, e.g. the manometer. To test this hypothesis, a systematic study was undertaken in which mercury vapour was introduced at will into the adsorption system.

A sample of chromia gel A1 was heated in air at 225°C for 16 hours to give gel A1(225)16. In Fig. 5.1, the influence of mercury vapour on the weight of the calcined sample, during outgassing at 25°C, is shown as a function of time. For the sake of convenience, the variable time scale is interrupted between 59 and 75 hours.

The curve lying between points 'A' and 'B' in Fig. 5.1, represents the weight loss of A1(225)16 on outgassing (to about  $10^{-4}$  torr) in the absence of mercury vapour; after a period of about 55 hours, a maximum weight loss was achieved. At point 'B', the sample was exposed to mercury vapour (mercury source at 22°C) and immediately, a steady increase in the weight of the sample was observed: between points 'B' and 'C', the rate of increase was about  $2.2 \text{ mg g}^{-1} \text{ h}^{-1}$ . At point 'C', the mercury source was isolated, the weight of the sample then remaining constant over a period of several hours until mercury vapour was re-introduced into the system at point 'D'. To test whether the weight increase of the sample was a function of the pressure of mercury vapour, the temperature of the mercury source was raised to 65°C: between points 'D' and 'E', the rate of increase was now about  $3.2 \text{ mg g}^{-1} \text{ h}^{-1}$ . At point 'E', both the mercury source and the pumping system were isolated, and pure oxygen at a pressure of 1 torr introduced to the sample. The small weight increase between points 'E' and 'F' was probably due to the chemisorption of oxygen by A1(225)16: in a similar experiment where pure nitrogen or helium was introduced (in place of oxygen), the sample weight remained constant. At point 'F', the sample was re-exposed to high vacuum, and mercury vapour (from a source at 35°C) re-introduced into the system: between points 'F' and 'G', the rate of increase was about  $2.5 \text{ mg g}^{-1} \text{ h}^{-1}$ . Finally, at point 'G', the mercury source was isolated from the system and the sample outgassed (at 25°C and about  $10^{-5}$  torr pressure) over a period of several weeks: no significant weight loss of the sample was observed.

Put in a more succinct manner, these results show that mercury vapour was adsorbed, apparently irreversibly, by gel A1(225)16 and furthermore, that the rate of adsorption was a function of the mercury vapour pressure.

A number of other experiments showed<sup>2</sup> that mercury vapour adsorption was not exhibited by orthorhombic chromium oxy-hydroxide, nor by chromia gels calcined (or outgassed) at temperatures lower than about 150°C, or at temperatures above that of the glow phenomenon.<sup>3</sup> Positive identification of mercury adsorbed on the activated gels after exposure to the vapour, was obtained from the atomic absorption studies described in Section 3.9.

## 5.2 Mercury Vapour Adsorption on Chromium Dioxide

When a sample of pure chromium dioxide was outgassed, in the presence of mercury vapour, the weight of the sample was observed to increase. The rate of increase was particularly high at pressures less than about  $10^{-3}$  torr. The mercury vapour was irreversibly adsorbed, outgassing at a temperature of 250°C failing to result in a significant weight loss of the sample. To study the effect of mercury vapour adsorption by chromium dioxide, on the subsequent sorptive properties of this oxide, a series of experiments were constructed as follows:

- (1) A sample of chromium dioxide was outgassed at 25°C in the complete absence of mercury vapour, and the water vapour adsorption/desorption isotherm determined (shown as Fig. 5.3).
- (2) On completion of the first water vapour isotherm, the sample was re-outgassed at 25°C in the presence of mercury vapour until a maximum weight gain was achieved (represented by Curve A in Fig. 5.2): the mercury source was then isolated, the sample further outgassed

at 25°C in order to remove residual mercury vapour from the system, and a second water vapour adsorption/desorption isotherm determined (shown as Fig. 5.4).

- (3) On completion of the second isotherm, the sample was again re-outgassed in the presence of mercury vapour until a maximum weight gain was achieved (represented by Curve B in Fig. 5.2): a third water vapour adsorption/desorption isotherm was then determined, but this time in the presence of mercury vapour (shown as Fig. 5.5).

Throughout this series of experiments, the temperature of the mercury vapour source was maintained at 25.0°C, whilst equilibrium pressure measurements were made (to  $\pm 6 \times 10^{-3}$  torr) using a pressure-sensitive transducer (cf. Sections 3.13 and 3.18).

Curves A and B in Fig. 5.2 represent the uptakes of mercury vapour by the sample of chromium dioxide, on outgassing at 25°C in the interval between the first and second, and between the second and third water vapour isotherms respectively. Limiting values for the uptakes, of about 13.5 mg g<sup>-1</sup> and 8 mg g<sup>-1</sup> respectively, were observed after outgassing for about 25 hours. This result, and those of subsequent experiments, showed that after apparent saturation of the chromium dioxide surface with mercury, the surface was re-activated to further mercury vapour adsorption by exposure to water vapour. This effect could be repeated many times; on each subsequent occasion a smaller quantity of mercury vapour was adsorbed. Furthermore, in general, satisfactory agreement was obtained between the values of the mercury vapour uptakes as estimated by the gravimetric studies on the one hand, and the atomic absorption technique on the other: for example, 20.6 mg g<sup>-1</sup> (gravimetric) and 18.5 mg g<sup>-1</sup> (atomic absorption).

The water vapour isotherm, determined on the pure chromium dioxide in the complete absence of mercury vapour (Fig. 5.3), exhibited hysteresis over the full range of relative pressure, with some permanent retention of water. Although the adsorption isotherm exhibited some broad stepwise character (where the initial step was located near the monolayer capacity), a nearly linear BET plot was obtained in the relative pressure range of 0.07 to 0.3 Po. From the plot a value of  $6.5 \text{ m}^2\text{g}^{-1}$  was obtained for the apparent BET surface area as measured by water vapour adsorption, whilst the BET C constant was very high at 1800. The high value of the BET C constant implies that there was a strong localisation of the water monolayer on the clean chromium dioxide surface; probably to such an extent that the cross-sectional area of the adsorbed water molecule (an apparent value of  $10.6 \text{ \AA}^2$  was assumed for the purposes of the calculations) was greatly influenced by the nature of the adsorbent. Thus, the value for the apparent BET surface area,  $S_{\text{BET}}^{\text{W}}$ , may be in error.

By way of comparison, it is interesting to note that in the case of water vapour adsorption on thorium oxide surfaces, Holmes and his co-workers<sup>4</sup> have constructed the BET plots using the desorption branch of the irreversible isotherms. The adsorption branches were not used to calculate BET surface areas because of the initial chemisorption of water vapour by the thorium oxide surfaces. When this procedure was performed in the present case, for water vapour adsorption on the clean chromium dioxide surface, a BET plot showing excellent linearity was obtained in the relative pressure range of 0.05 to 0.3 Po; the corresponding values of  $S_{\text{BET}}^{\text{W}}$  and the BET C constant, as calculated using this plot, were  $8.1 \text{ m}^2\text{g}^{-1}$  and 620 respectively. Thus, the value of C still reflects the high reactivity of the clean chromium dioxide surface,

whilst the value of  $S_{\text{BET}}^{\text{W}}$  may represent the apparent water BET surface area more realistically.

The water vapour isotherm determined on the mercury-contaminated surface of chromium dioxide (Fig. 5.4), was reversible at high relative pressures but exhibited hysteresis from a relative pressure of about 0.7 Po to zero relative pressure. However, perhaps of greatest significance, is the dramatic change in the shape of the adsorption branch. For ease of comparison, the adsorption branch is also shown superposed (as a dashed line) on the isotherm determined on the clean chromium dioxide surface (Fig. 5.3). The BET plot, constructed using the adsorption data, was reasonably linear in a relative pressure range of 0.1 to 0.3 Po: the apparent BET surface area as measured by water vapour adsorption was  $10.4 \text{ m}^2\text{g}^{-1}$ , whilst the value of the BET C constant was less than 10. From this result it is inferred that the adsorption of mercury vapour has considerably reduced the reactivity of the chromium dioxide surface.

The third water vapour isotherm, determined on the mercury-contaminated surface of chromium dioxide in the presence of mercury vapour (Fig. 5.5), revealed that the general shape of the adsorption branch was further changed very little, as compared to that of the second isotherm (Fig. 5.4). The BET plot, constructed using the adsorption data, was very similar to that described for the second isotherm, yielding identical values of  $S_{\text{BET}}^{\text{W}}$  and C; i.e.  $10.4 \text{ m}^2\text{g}^{-1}$  and  $< 10$  respectively. However, the isotherm exhibited an increased degree of reversibility at high relative pressures, low pressure 'hysteresis' commencing at about 0.45 Po. The interesting, and somewhat unusual, low pressure 'hysteresis loop' was the result of an additional experiment to confirm<sup>2</sup> that the low pressure 'hysteresis' was, in fact, a

consequence of mercury vapour adsorption on the chromium dioxide surface.

At the point on the isotherm where the apparent relative pressure in the system had been reduced to about 0.27  $P_0$  (i.e. point 'A' in Fig. 5.5), the chromium dioxide sample was left exposed to the mercury-contaminated atmosphere over a period of 64 hours, adsorption measurements being made at periodic intervals of about 20 hours. The vertical region of the 'hysteresis loop' was interpreted as being a direct consequence of the increased time of exposure of the sample to both mercury vapour (low partial pressure) and water vapour. At point 'B', the pressure in the system was progressively reduced again, each desorption point being recorded after an interval of about 3 hours. At point 'C', outgassing of the chromium dioxide sample at 25°C was commenced, mercury vapour adsorption then becoming particularly pronounced (as indicated by the points located on the ordinate at  $P/P_0 = 0$  in Fig. 5.5.).

Thus, mercury vapour adsorption on a chromium dioxide surface in the presence of water vapour may well occur over a wide range of relative pressure, the rate of adsorption increasing with the partial pressure of mercury vapour.

The progressive increase in the reversibility, at high relative pressures, of the successive water vapour isotherms probably indicates that mercury, irreversibly adsorbed by the chromium dioxide, was blocking very fine pores which, in the case of the clean surface, were just accessible to penetration by water molecules. In the case of nitrogen adsorption on chromium dioxide, reversible isotherms were obtained with no indication of the presence of porosity.<sup>5</sup> However, it must be borne in mind that a conventional volumetric technique was employed for the

determination of the nitrogen isotherms: i.e. the adsorbent was always exposed to mercury vapour. At the present time, it is not known whether the fine pores present in the chromium dioxide sample (as apparently revealed by water vapour adsorption), were also accessible to penetration by nitrogen molecules.

### 5.3 Interaction of Chromium Oxides and Mercury Vapour

Samples of chromia gel A1 were calcined in air at selected temperatures between  $100^{\circ}$  and  $1000^{\circ}\text{C}$  (in  $50^{\circ}$  increments to  $500^{\circ}\text{C}$ , and  $100^{\circ}$  increments to  $1000^{\circ}\text{C}$ ), and then exposed (in a low vacuum of about  $10^{-2}$  torr) to mercury vapour at  $25^{\circ}\text{C}$  for a period of 5 days. The samples so treated were analysed for mercury content, using the atomic absorption technique described in Section 3.9.

The presence of mercury was found in those samples of gel A1 that had been calcined at temperatures in the range of  $150^{\circ}$  -  $450^{\circ}\text{C}$ . The greatest mercury content was observed in the case of the sample, A1(300), calcined at  $300^{\circ}\text{C}$ . In order to see if the adsorbed mercury could be removed by outgassing at high temperatures, A1(300) was progressively outgassed at temperatures between  $100^{\circ}\text{C}$  and  $1000^{\circ}\text{C}$  (duration of 2 hours at each temperature), and small samples, at  $50^{\circ}\text{C}$  increments, removed for analysis. Little significant variation in the respective mercury contents were found in the case of those samples outgassed at temperatures up to  $350^{\circ}\text{C}$ ; at  $400^{\circ}\text{C}$ , however, the mercury content was considerably reduced (from  $80\text{ mg g}^{-1}$  to  $15\text{ mg g}^{-1}$ ), whilst at temperatures of  $500^{\circ}\text{C}$  and above, the presence of mercury could not be detected.

These results indicated that chromia gels activated towards mercury vapour adsorption when calcined at temperatures in the range of about  $150^{\circ}$

to 450°C; particularly so at about 300°C. Furthermore, the species formed as a result of the mercury vapour adsorption appeared to be stable at temperatures up to about 400°C, thereafter presumably decomposing to yield mercury. On the basis of these results, it is tentatively proposed that the adsorption of mercury vapour by certain chromium oxides, leads to the formation of a mercury chromate (or chromates), e.g.  $\text{HgCrO}_4$ , or possibly a 'chromite', e.g.  $\text{HgCr}_2\text{O}_4$ .

Aurivillius,<sup>6,7</sup> in a series of extensive studies of mercury (II) salts, prepared the mercury (II) chromate anhydrate,  $\text{HgCrO}_4$ , and the hemihydrate,  $\text{HgCrO}_4 \cdot (\text{H}_2\text{O})_{0.5}$ , by reaction of mercuric oxide with chromium (VI) oxide and water. Similarly, Lamure and Colas<sup>8</sup> have prepared the mercury 'chromite',  $\text{HgCr}_2\text{O}_4$ , (possibly the spinel-type structure,<sup>9</sup>  $\text{HgO} \cdot \text{Cr}_2\text{O}_3$ ) from mercuric oxide and chromium (III) oxide. It is known<sup>3,10,11</sup> that chromium oxide gels calcined at temperatures in the range of about 100°C to 400°C, contain appreciable proportions of chromium (VI) oxide in their surface layers, particularly<sup>11</sup> when calcined at 300°C. Furthermore, chromia gels calcined at temperatures above 150°C readily chemisorb oxygen<sup>12</sup> which, according to Narasimha Rao and Kesavulu,<sup>13</sup> is especially pronounced at 300°C; this may facilitate the oxidation of mercury on the surface of the 'activated' chromia. In addition, pure mercury is readily oxidised at 25°C in moist air, whereas this is not the case in the absence of water vapour.<sup>14</sup>

Thus, it seems likely that the surface of an 'activated' chromia will promote the reaction, at 25°C, between mercury and  $\text{CrO}_3$  or  $\text{CrO}_2$  to yield a mercury chromate and/or a 'chromite'. However, it must also be recognised that the 'adsorbed' mercury may simply be present on the chromium oxide surface, as mercuric oxide. Presumably, the elimination of a mercury compound from the chromium oxide surface, on outgassing at

temperatures above about  $350^{\circ}\text{C}$ , is explained by the decomposition of these compounds at around this temperature. For example: the 'chromite',  $\text{HgCr}_2\text{O}_4$ , decomposes<sup>8</sup> at  $360^{\circ}\text{C}$ ; the hemihydrate,  $\text{HgCrO}_4 \cdot (\text{H}_2\text{O})_{0.5}$ , is dehydrated<sup>6</sup> at about  $200^{\circ}\text{C}$  to yield the anhydrate which, in turn, decomposes<sup>15</sup> at about  $320^{\circ}\text{C}$ ; whilst the dissociation of mercuric oxide commences<sup>16</sup> at temperatures just above the boiling point of mercury, i.e.  $357^{\circ}\text{C}$  (at 760 torr).

#### 5.4 Mercury Vapour Adsorption on other Adsorbents

Considering the widespread use of mercury as a manometric fluid in gas adsorption systems, there are surprisingly few reported investigations concerning the adsorption of mercury vapour, or its influence on the adsorption of other vapours. Coolidge<sup>17</sup> established that the adsorption of mercury vapour at  $20^{\circ}\text{C}$  on charcoal was negligible, and would not interfere with other charcoal-vapour equilibria. A similar conclusion was reached more recently, by Miles,<sup>18</sup> who showed that the presence of mercury vapour did not affect the adsorption isotherms of hydrocarbon vapours on charcoal. Campbell and Duthie<sup>19</sup> studied the variation in the apparent BET surface area, as measured by krypton adsorption, of a nickel film before, and after, the chemisorption of mercury vapour: they found that the apparent surface area reached a steady value on completion of the third adsorbed layer of mercury. Recently, Liebich and Fink<sup>20</sup> have observed that mercury vapour was adsorbed by certain porous Aerosil silicas (surface areas of  $335 \text{ m}^2\text{g}^{-1}$  and  $202 \text{ m}^2\text{g}^{-1}$ , as measured by nitrogen adsorption).

It is interesting to note, by way of comparison, that Barrer and his co-workers<sup>21,22</sup> have extended the early work of Grandjean<sup>23</sup> and Wyart<sup>24</sup> in connection with the very high uptake (as much as 60% by weight) of mercury vapour by the zeolite, chabazite. Barrer and

Woodhead<sup>21</sup> found that in the presence of air, or oxygen, mercury vapour was irreversibly adsorbed by chabazite; i.e. mercury vapour and oxygen underwent at temperatures  $> 200^{\circ}\text{C}$  an irreversible intercrystalline chemisorption. In fact, on carrying out successive cycles of exposure to mercury vapour followed by removal of vapour, these workers obtained a picture for the irreversible adsorption of mercury vapour, that is very similar to that shown in Fig. 5.1 in the present work concerning the mercury-chromium oxide system. In contrast, however, mercury vapour was reversibly adsorbed by chabazite in the absence of air or oxygen.

RESULTS AND DISCUSSION III

GAS ADSORPTION AND RELATED STUDIES ON THE CHROMIUM OXIDES

In Sections 6.1 to 6.4 of the present chapter, the characterisation of the hydrous chromium oxides, and the possible role of orthorhombic chromium oxy-hydroxide and of chromium dioxide, are discussed: conclusions are drawn concerning the conditions of gel preparation, particularly in relation to the variation of the precipitation pH. In Sections 6.5 and 6.6, the analysis and interpretation of the nitrogen, argon and water vapour adsorption data are presented: the discussion is primarily concerned with the textural properties of the gels, notably in respect to the pH of precipitation and the effect of subsequent heat treatment of a gel precipitated at high pH.

A. CHARACTERISATION OF THE HYDROUS CHROMIUM OXIDES

6.1 Preparation and Purity of the Chromium Oxide Gels

The conditions of preparation, washing and drying of the chromia gels have been described in Section 3.1; the details are summarised in Table 3.1. The gels were washed until the aqueous eluent was found to be free of ammonium and nitrate ions respectively, as indicated by negative responses to conventional semimicro qualitative tests.<sup>1</sup>

However, it is well known<sup>2-5</sup> that hydrous chromium oxide prepared by precipitation from aqueous solution invariably contains adsorbed impurities which are very difficult to remove. It was therefore to be expected that the chromium oxide gels prepared in this work would be contaminated with ammonium nitrate. This was confirmed by the evolved gas analysis (EGA) using a mass spectrometer to identify some of the gaseous products.

As already explained in Section 3.8 the evolved gas sampling technique (Murphy<sup>6</sup>) was used to characterise the products evolved on heating each gel at 250°C under a partial vacuum. Water and nitrogen were the major constituents, together comprising (on average) about 95% by volume of the total product. In the case of the A-series and S-series gels, small quantities of nitric oxide and nitrous oxide were also found as well as a trace amount of ammonia; for the B-series gels, trace amounts of ammonia and carbon dioxide were found, in addition to the major constituents - water and nitrogen. An earlier detailed mass spectrometric study by Fenerty,<sup>7</sup> of the gaseous products obtained on heating chromium oxide gels, produced similar results.

Fenerty<sup>7</sup> and Friedman and his co-workers<sup>8</sup> have shown that a trace amount of water will initiate the exothermic decomposition of ammonium nitrate at about 180°C: the decomposition products are nitrous oxide and water, with a trace amount of nitric oxide. The evolution of small quantities of nitric and nitrous oxide respectively, from the hydrous gels (A-series and S-series) was thus attributed to the thermal decomposition of ammonium nitrate, present as an adsorbed impurity. In the case of the gels (B-series) prepared using the

Burwell method<sup>9</sup> the trace amounts of ammonia and carbon dioxide present in the evolved gases were attributed to the thermal decomposition of urea, adsorbed on the gels as an impurity. It has been shown<sup>7</sup> that nitrous oxide is not catalytically decomposed (to yield nitrogen and oxygen) at the surface of chromium oxide at 200°C, and furthermore, that ammonia (if originally adsorbed) is neither decomposed nor oxidised. Thus, the relatively large quantities of nitrogen present in the evolved gases were attributed to nitrogen (in the case of the A-series and S-series gels), or air (in the case of the B-series gels), originally adsorbed on, or trapped within, the hydrous chromium oxides.

The conditions of preparation of chromia gel A<sub>4</sub> merit particular attention. Gel A<sub>4</sub> precipitated slowly from the (originally clear) mother liquor of gel A<sub>3</sub> and was, therefore, formed under conditions of both high pH and relatively very high ammonia concentration. Ideally, ammonia should not be employed as a precipitation reagent for chromium oxide gels, since an excess of ammonia may easily lead to the formation of complex amines.<sup>10</sup> If, in addition, the concentration of ammonium salts is high (as was the case for gel A<sub>4</sub>), the hydroxide may not be precipitated from such amines despite the fact<sup>11</sup> that Cr(OH)<sub>3</sub> is a dominant form of existence of chromium in aqueous solution of pH value in the range 5 to 13. Furthermore, as already stated, chromium oxide gels when precipitated from solutions containing alkalis, are apt to contain adsorbed alkali salts; to obtain a hydrous oxide gel in a purer state a milder precipitating reagent, such as potassium iodide-iodate mixture,<sup>12</sup> must be used. However, the present work was directly concerned with the

effect of variation of the pH during precipitation on the subsequent gas adsorption properties of the chromia gels. Ammonia is a convenient reagent for such a purpose.

The fact that any precipitate resulted at all under such conditions would indicate that gel A<sub>4</sub> is not wholly a chromium ammine. The violet colour of the mother liquor after filtration of gel A<sub>3</sub> (mother liquors from all other gel preparations were colourless) was indicative,<sup>13</sup> however, of either a hexaquo chromium (III) compound, e.g.  $[\text{Cr}(\text{H}_2\text{O})_6](\text{OH})_3$  or possibly a lower ammine derivative, e.g.  $[\text{Cr}(\text{NH}_3)_2(\text{H}_2\text{O})_4](\text{OH})_3$ . The latter compound (insoluble in water) may be formed by the slow progressive replacement of the ammonia ligands in a higher ammine derivative, e.g.  $[\text{Cr}(\text{NH}_3)_6](\text{OH})_3$ ; such amines, where the number of  $\text{NH}_3$  ligands exceeds two, are soluble in water. However, the violet mother liquor after removal of gel A<sub>3</sub> was not consistent with the presence of higher ammine derivatives, namely, orange-yellow.<sup>13</sup> Thus, it seems more likely that the violet colour was due to the presence of the hexaquo chromic ion,  $[\text{Cr}(\text{H}_2\text{O})_6]^{3+}$ , which slowly changed by a condensation-polymerisation mechanism (cf. Section 1.3) to the blue-grey precipitate designated gel A<sub>4</sub>, and a colourless mother liquor.

That gel A<sub>4</sub> was indeed a hydrous chromium oxide was confirmed by the fact that, in general, the thermograms obtained from the DTA and DSC studies (Section 6.2) were similar to those for the other gels. Furthermore, the fragmentation pattern of the mass spectrum of the gases evolved by gel A<sub>4</sub> on heating was very similar to those obtained for the chromia gels of the A-series and S-series respectively, and did not show more than the usual trace amount of ammonia.

## 6.2 Differential Thermal Analysis (DTA) and Differential Scanning Calorimetry (DSC)

Brief details of the DTA and DSC apparatuses, and the techniques and conditions employed, were given in Sections 3.4 and 3.5 respectively. In confirmation of previous work<sup>7,14</sup> the curves were not significantly changed by a variation in the rate of heating, within the ranges of 2.5° to 10°C per minute and 8° to 32°C per minute, for the DTA and DSC respectively; furthermore, satisfactory reproducibility was obtained with different specimens of the same sample. In the case of chromia gels, the thermal processes occurring below about 250°C are, in general, independent of the nature of the surrounding atmosphere;<sup>7,14,15</sup> nevertheless, peak temperatures on the DTA and DSC thermograms respectively, for a given thermal process were often not identical, temperature differences of about 5° - 15°C being observed. However, it should be noted that DTA and DSC are dynamic techniques, and are therefore dependent on experimental conditions.<sup>16</sup> Above about 250°C, the thermal reactions are generally dependent on the nature of the surrounding atmosphere,<sup>7,14,15</sup> and it was therefore not surprising to observe large differences between the thermograms obtained for the chromia gels, by DTA (static atmosphere of air) on the one hand, and DSC (dynamic atmosphere of nitrogen) on the other. The main purpose of the DSC work was to try to correlate the gases evolved by the gels on heating with particular peaks on the calorimetric curve.

### Chromia Gels

In general, the sequence of thermal changes which occurred in the DTA was common to most of the chromia gels studied, although the magnitude of each effect varied from one gel to another; furthermore,

\* M = peak multiplicity, i.e. s = singlet, d = doublet.

\*\* parentheses used to denote an indistinct broad peak.

the curves were similar to those previously widely reported.<sup>7,14,15,17,18</sup> For this reason, with the exception of an idealised curve shown as Fig. 6.1a, the DTA and DSC thermograms are not reproduced in Figure form here, the relevant data being tabulated for the DTA (Table 6.1) and particular features of each discussed.

A broad endothermic peak was observed in all the DTA and DSC curves (shown in idealised form in Fig. 6.1a), the maxima of which varied between about 160° to 185°C for the DTA and between about 140° to 170°C for the DSC, and was attributed to the loss of 'free' water from the gel leading to the formation of the trihydrate;<sup>18</sup> i.e. the considerable quantity of water that is held by a freshly formed gel in both the form of coordinated water within the bulk and adsorbed water at its surface. The nature of the response of the thermal conductivity gas detector coupled to the DSC apparatus, confirmed that the gas evolved by the gel during the process responsible for the broad endothermic peak probably consisted almost entirely of water vapour and nitrogen. The inference that nitrogen was present is made from the results of the mass spectrometric EGA discussed in Section 6.1; nitrogen was employed as the carrier gas for the thermal conductivity detector and therefore, the relatively small additional amounts of nitrogen evolved by the sample would not have caused a significant effect on the signal from the detector.

The location on the gas detector trace of the maximum of the peak caused by the evolution of free water, appeared to be a function of the pH during precipitation of the gel: thus, progressive increase in this pH appeared to be associated with a displacement of the peak maximum from 152° to 187°C over the pH range investigated. In addition,

the shape of the peak appeared to change with the pH, such that the peak was skewed, and broadened, on the high temperature side of the maximum with increase in the precipitation pH (cf. Fig. 6.1b).

These comments are rather tentative, especially as difficulty was occasionally experienced in maintaining balanced gas flows through the thermal conductivity detector system; but they appear to support the views developed in Section 6.3 that the structural water content of the gel is increased with increase in the pH of precipitation. Furthermore, the findings are in keeping with the suggestion by Fenerty<sup>7</sup> that the broad endotherm may in fact be associated with two maxima, at about 120° to 140°C and 180° to 210°C respectively, i.e. with distinct 'types' of free water.

Gel S2 was the only chromia sample to exhibit an exothermic peak (fairly strong) at 240°C in the DTA curve. Sing and his co-workers<sup>15</sup> have suggested that an exothermic peak at about 230°C is associated with the formation of crystalline orthorhombic chromium oxy-hydroxide (CrOOH), which has been identified by electron diffraction studies<sup>15</sup> in chromia gels calcined at 250°C in air; furthermore, it appears that the crystalline monohydrate is only formed if the gel contains sufficient water trapped within large granules. Sing and his co-workers<sup>15</sup> have further suggested that the DTA curve does not depend on the conditions of the formation, but rather on the after-treatment, of the gel. The mechanism of the formation of the oxy-hydroxide structure is suggested to be similar to the hydrothermal process involved in the formation of boehmite, namely that the monohydrate results from the rehydration of a primary decomposition product.<sup>19,20</sup> In partial support of these suggestions

is the recent work of Smyshlyaev and his co-workers,<sup>21</sup> where it has been found that repeated washing of an amorphous (to x-rays) chromia gel with water at 90°C resulted in a discernible x-ray pattern for the washed material. It is the view of the present author, however, that both the conditions during preparation and after-treatment of the gel affect the subsequent DTA curves: this is discussed further.

Many studies<sup>17,18,22,23</sup> of chromia gels, including the majority of those described in the present work, have not revealed the presence of the exothermic peak at about 230°C in the DTA curves; on the other hand, a number of studies have revealed (almost without exception, on gels prepared using the Burwell method<sup>9</sup>) the presence of a strong exothermic peak in this region.<sup>7,14,15</sup> However, it is possible that the relative intensities of endothermic (dehydration) and exothermic (oxidation) processes, proceeding simultaneously, are such that the processes effectively neutralise one another and a discernible peak is not observed. This may be particularly the case in the present work: the gel preparation conditions were varied (notably the pH) in an attempt to increase the 'structural' water (i.e. water bound as hydroxyl groups) content of the gel; such water would undoubtedly be removed from the gel, on heating, at a higher temperature than that for the 'free' water. For the latter type of water, its removal leaves an unstable structure which either collapses, or crystallises, to a more stable phase, i.e. the monohydrate, and an exothermic peak is observed at about 230°C. In those cases where an exothermic peak at about 230°C is not observed, the implication may be that the monohydrate, albeit not crystalline,

is already present in the gel (probably confined to the surface layers).

It is difficult, of course, to apply a similar agreement to gels B6 and B8 to explain the absence of the exothermic peak at about 230°C, especially in view of the presence of the peak obtained in previous work on gels prepared using the Burwell method. However, a possible clue to the reasons for the observed difference in this respect may be found in work relating to the conditions of preparation of gels using the Burwell method. For example: Krleza and Sljukic<sup>24</sup> have found that the geometry of the reaction vessel and the occurrence of localised heating, affect the form of the precipitate; similarly, Cross and Leach<sup>25</sup> have commented on the varying degrees of stirring efficiency of different gel preparations. In the present instance, the reaction mixture for gels B6 and B8 respectively, was stirred extremely vigorously - a practice that was seldom adopted in earlier published work.

From Table 6.1, it will be seen that all gels exhibited an exothermic peak (generally broad, but fairly strong) in the range 312° to 353°C. This exothermic change was enhanced in an oxygen atmosphere, but considerably reduced, or even absent, in reducing or inert atmospheres. Detailed studies by Fenerty<sup>7</sup> and Carruthers<sup>14</sup> have shown that this peak can be attributed to the oxidation of surface Cr<sup>3+</sup> ions to chromium (VI) oxide; furthermore, the oxidation is not confined to the surface but extends appreciably into the bulk.

In the case of gel A4, the oxidation of surface Cr<sup>3+</sup> ions apparently occurred at a relatively high temperature, the maximum of the exothermic peak being observed at about 353°C; presumably, this is due to the fact that the surface area of this gel is relatively low ( $S_{\text{BET}}^{\text{N}} = 13 \text{ m}^2\text{g}^{-1}$ ), and therefore more energy is required to initiate

the oxidation in depth. Sorrentino and his co-workers<sup>26</sup> have also stressed a relationship between the surface area of hydrous oxides (including chromia) and their DTA curves.

For Gel A1, the exothermic peak corresponding to the oxidation of surface  $\text{Cr}^{3+}$  ions is recorded in Table 6.1 as a doublet, with fairly strong peaks of equal intensity at about  $312^{\circ}\text{C}$  and  $357^{\circ}\text{C}$  respectively; the implication would be either that the surface oxidation of  $\text{Cr}^{3+}$  is a two stage process, or that another, different, stage is also involved. Alternatively (and more probably), the exothermic peak represented as a doublet may in fact be a broad single peak, with a sharp endotherm (at about  $335^{\circ}\text{C}$ ) superposed; in support of this view, Fenerty<sup>7</sup> has observed a prominent maximum at about  $337^{\circ}\text{C}$  on the EGA curve for a chromia gel (determined using mass spectrometry), due to the evolution of water; furthermore, concurrent magnetic susceptibility measurements have indicated that ferromagnetic  $\text{CrO}_2$  is present in chromia gels calcined in air at about this temperature. Thus, an endothermic peak at  $335^{\circ}\text{C}$  (superposed on an exothermic peak centred at about the same temperature) may possibly be attributed to the endothermic reaction:

This reaction is discussed in more detail later, but here it is interesting to note that at temperatures in the range of  $500^{\circ}\text{C}$  to  $600^{\circ}\text{C}$ ,  $\text{CrO}_2$  undergoes an endothermic decomposition<sup>27</sup> to  $\alpha\text{-Cr}_2\text{O}_3$ . It is noteworthy that several of the DTA curves (including that for gel A1) obtained in the present work exhibited a broad and shallow endotherm at about  $550^{\circ}\text{C}$ ; thereby supporting the contention that  $\text{CrO}_2$  was formed by oxidation of orthorhombic  $\text{CrOOH}$  at about  $335^{\circ}\text{C}$ , on

calcination of gel A1 in air. Sing and his co-workers<sup>27</sup> have shown that an alternative source of  $\text{CrO}_2$ , namely the decomposition of  $\text{CrO}_3$  at about  $350^\circ\text{C}$ , probably contributes no more than a few percent to the total amount of  $\text{CrO}_2$  found in some calcined gels.

We turn now to the final thermal effect which occurred on heating the hydrous chromium (III) oxide: that which is usually referred to as the "glow phenomenon", and characterises<sup>28</sup> the transformation of amorphous chromium (III) oxide into crystalline  $\alpha\text{-Cr}_2\text{O}_3$ . The glow phenomenon occurs at about  $400^\circ\text{C}$  in air; heating in an atmosphere of hydrogen or nitrogen, or under vacuum, serves to delay the glow exotherm until a higher temperature (up to about  $600^\circ\text{C}$ ), but it does not eliminate the effect.<sup>7,15,28</sup> The exotherm is especially strong when oxygen is re-admitted to the system, and it has been concluded<sup>7</sup> that the exothermic crystallisation is associated, to some extent, with oxidation-reduction processes.

From Table 6.1, it will be seen that the variation in the temperature at which the exothermic peak was observed for the various gels (in air), covered the range of  $403^\circ\text{C}$  to  $442^\circ\text{C}$ . As already discussed in relation to the oxidation of surface  $\text{Cr}^{3+}$  ions, the unusually high temperature of  $442^\circ\text{C}$  for the glow of gel A4 may possibly be attributed to its relatively low surface area. In the case of gels B6 and B8 respectively, the glow temperature was also relatively high, but in addition, the exothermic transformation was resolved into two peaks indicating a two stage process. Although the apparent surface area of these gels was very high ( $S_{\text{BET}}^{\text{N}}$  about  $500 \text{ m}^2\text{g}^{-1}$ ), it should be noted that the gels were essentially microporous and that the external surface area was very low, which may account for the relatively high

glow temperature. Of particular interest is the case of gels B6 and B8 however, was the occurrence of the exothermic peak as a doublet, the spacing of the individual peaks corresponding to about 5°C. It has been observed<sup>7</sup> that this phenomenon occurs for gels with relatively large amounts of chromium in the Cr<sup>6+</sup> state; the first peak (associated with a slight decrease in sample mass) has been attributed to the decomposition of CrO<sub>3</sub> which, in turn, initiates in some way the sudden strongly exothermic transformation to α-Cr<sub>2</sub>O<sub>3</sub>, thereby giving rise to the second peak.

#### Orthorhombic Chromium Oxy-Hydroxide and Chromium Dioxide

As already mentioned, previous investigations of the bulk and surface properties of hydrous chromium (III) oxides have revealed the formation of the orthorhombic chromium oxy-hydroxide, CrOOH, and the ferromagnetic chromium dioxide, CrO<sub>2</sub>, in certain cases when chromia gels are calcined under hydrothermal and oxidising conditions.<sup>7,14,15,28</sup> It was considered that an investigation of the thermal decomposition of these oxides in various atmospheres, using the DTA technique, might clarify the relationship between the oxides, and also their possible role in the calcination of chromia gels.

Preliminary DTA experiments in which pure samples of orthorhombic CrOOH and CrO<sub>2</sub> respectively, were heated in atmospheres of air, oxygen, nitrogen and hydrogen revealed that these oxides were easily interconverted under normal atmospheric pressure. However, it was later decided to carry out a more detailed study of these interesting oxides, and the work was therefore handed over to Dr. M.A. Alario Franco (Brunel University). In addition to confirming<sup>29</sup> the present author's earlier DTA work (described below), the results of this study provided

the major evidence for the nature of the interconversion reaction of orthorhombic  $\text{CrOOH}$  and  $\text{CrO}_2$ . Alario Franco's contribution to the subject matter of the present thesis comprised the characterisation of the various substances involved in the overall reaction (by x-ray powder diffraction and magnetic susceptibility measurements).

In air, the decomposition of the orthorhombic  $\text{CrOOH}$  occurred in three stages: a pronounced exotherm at about  $255^\circ\text{C}$ , a pronounced endotherm at about  $500^\circ\text{C}$ , and a smaller, broader endotherm at about  $550^\circ\text{C}$ . The exothermic reaction was enhanced in oxygen (peak at  $240^\circ\text{C}$ ), but was suppressed in both nitrogen and hydrogen; in vacuum, the exotherm was delayed until a temperature of about  $365^\circ\text{C}$ . In air, no change in crystal structure could be detected by x-ray diffraction, but after heating to  $400^\circ\text{C}$  in oxygen the strongest lines of  $\text{CrO}_2$  were apparent (sample nearly black in colour), in addition to the  $\text{CrOOH}$  x-ray pattern. These results indicate that the exothermic peak at  $240^\circ\text{C}$  ( $255^\circ\text{C}$  in air) corresponds to the decomposition and oxidation of some  $\text{CrOOH}$  to  $\text{CrO}_2$ , probably in the surface layers.

The endothermic peak at about  $500^\circ\text{C}$  in air was associated with the formation of  $\text{CrO}_2$  and some  $\text{Cr}_2\text{O}_3$ . In oxygen, the endotherm was enhanced and was observed at  $450^\circ\text{C}$ ; the product was now  $\text{CrO}_2$ , with no detectable  $\text{Cr}_2\text{O}_3$ . The endothermic peak was absent in an atmosphere of nitrogen or hydrogen and the original orthorhombic structure appeared to remain unchanged until about  $600^\circ\text{C}$ .

The decomposition of  $\text{CrO}_2$  to  $\alpha\text{-Cr}_2\text{O}_3$  caused the second endotherm at about  $550^\circ\text{C}$  in air or oxygen. In vacuum, the endotherm was very pronounced, whereas in nitrogen or hydrogen it was broadened, reduced in intensity, and delayed until about  $600^\circ\text{C}$ , when the conversion of

the CrOOH to  $\alpha$ -Cr<sub>2</sub>O<sub>3</sub> occurred.

The thermal decomposition of CrO<sub>2</sub> in air or oxygen occurred in two stages, broad endothermic peaks being observed at about 510°C and 550°C respectively. X-ray diffraction revealed that the first stage did not produce any detectable change in the crystal structure, whereas the second led to a rearrangement of the lattice to the stable  $\alpha$ -Cr<sub>2</sub>O<sub>3</sub>. In nitrogen, the DTA curve revealed barely discernible endotherms at about 460°C and 570°C respectively, whereas in vacuum, only one endothermic peak was observed at about 560°C. These results indicate that the tetragonal CrO<sub>2</sub> (rutile) structure is stabilised to some extent in an oxidising atmosphere.

The DTA curve obtained on heating CrO<sub>2</sub> in hydrogen proved especially interesting. A very pronounced exothermic peak at about 315°C corresponded to the quantitative reduction of CrO<sub>2</sub> to the orthorhombic CrOOH, as characterised by x-ray diffraction. At about 600°C, a broad and shallow endothermic peak revealed that the CrOOH so formed was decomposed to  $\alpha$ -Cr<sub>2</sub>O<sub>3</sub>. If, however, the DTA run was interrupted immediately after the occurrence of the exothermic peak at 315°C, the CrOOH behaved in an analogous manner to that already described for pure orthorhombic CrOOH, when subjected to calcination in air or oxygen, i.e. it was reconverted to CrO<sub>2</sub>.

Thus, the interconversion of bulk orthorhombic CrOOH and CrO<sub>2</sub>, and their decomposition to  $\alpha$ -Cr<sub>2</sub>O<sub>3</sub>, under normal atmospheric pressure may be summarised by the scheme:

Furthermore, the solid-state interconversion of orthorhombic chromium oxy-hydroxide (green) and tetragonal chromium dioxide (black) is an example of a topotactic reaction,<sup>15,30</sup> where a three-dimensional similarity exists between the structures of the starting material and the product. Although Shannon<sup>31</sup> has postulated that the decomposition of  $\text{CrO}_2$  (tetragonal rutile structure) to  $\alpha\text{-Cr}_2\text{O}_3$  (rhombohedral corundum structure) at  $550^\circ\text{C}$  is also an example of a topotactic reaction, the structure of  $\alpha\text{-Cr}_2\text{O}_3$  is too compact to permit the entry of H atoms into the lattice and therefore it cannot be converted to orthorhombic  $\text{CrOOH}$  (as in the case of  $\text{CrO}_2$ ).<sup>29</sup>

Finally, it should be noted that the DTA curves discussed here for  $\text{CrOOH}$  and  $\text{CrO}_2$ , respectively, were quite different from those discussed earlier for hydrous chromium (III) oxides. The very pronounced exotherm associated with the glow phenomenon was not observed in the course of transformation of  $\text{CrO}_2$  to  $\alpha\text{-Cr}_2\text{O}_3$ . On this evidence, therefore, it seems likely that even under the most favourable conditions (e.g. preparation at high pH or heating in oxygen), the formation of  $\text{CrOOH}$  and  $\text{CrO}_2$  is probably restricted to the surface layers of a chromia gel.

### 6.3 Thermal Dehydration of the Chromia Gels

Samples of the chromia gels were outgassed, to constant weight, at various temperatures up to  $250^\circ\text{C}$  and the weight loss of each gel plotted as a function of the temperature. In this section, the weight loss plots so obtained are discussed.

In order to make a comparison between all the chromia gels under identical outgassing conditions, the plots were constructed by

simultaneously outgassing the gels at selected temperatures in a vacuum oven: the weight loss at a particular temperature was determined by periodically removing the samples (into a desiccator) and weighing them on a manual balance as rapidly as possible; the process was repeated until constant weight was achieved (generally after about 48 hours), the weight loss being entirely attributed to the removal of water. The outgassed pressure at each point was about  $10^{-2}$  torr. Ideally, the weight loss of the gels ought to have been determined in situ using the spring balance (outgassing to lower than  $10^{-4}$  torr). However, it was not, of course, possible to study more than one sample at a time in such a manner, using the spring balance described in Section 3.17.

In the discussion of these results it is helpful to recall that the precipitation of hydrous metal oxides is more complicated than most precipitation processes because the nucleation and growth cannot be described simply by deposition of ionic or molecular species.<sup>32</sup> Instead, a variety of chemical reactions occur, e.g. hydrolysis, condensation and formation of polynuclear species involving different ligands (in addition to  $\text{OH}^-$ ), which may all be very sensitive to small changes in pH. Hydrogels, or hydrous oxide precipitates, freshly formed from highly solvated  $\text{Cr}^{3+}$  ions, are usually poorly ordered and retain considerable amounts of 'free' water (sorbed and coordinated molecules). As the localised hydroxide or oxy-hydroxide structure develops with ageing, water molecules are replaced by  $\text{OH}^-$  and  $\text{O}^{2-}$  ions.<sup>33</sup> Furthermore, the presence of the concentrated atmosphere of water ligands around each  $\text{Cr}^{3+}$  ion, both in solution and in the freshly formed precipitate, has been shown<sup>34</sup> to have a great effect on the process of formation and ageing of a chromia gel.

Thus, it was expected that an increase in the pH of precipitation (or gelation) would provide an effective means of displacing the coordinated water during the formation of a chromia gel. It was already known<sup>35</sup> that in the case of precipitated hydrous alumina, the formation of the oxy-hydroxide (boehmitic) structure is facilitated by an increase in the pH of precipitation. Similarly, in the case of silica gels, Halberstadt and his co-workers<sup>36</sup> have observed that the pH of precipitation has a profound influence on the gel structure. The results of the present work about to be discussed serve to show that a similar effect is to be observed in the case of hydrous chromium oxides.

Representative weight loss/temperature plots for the chromia gels are shown in Fig. 6.2. Virtually identical plots were found for gels B7, B8 and B9 respectively, which in turn, were rather similar to Curve 1 in Fig. 6.2 for gel B6: there was no detectable difference in the nature of the water contents of these gels despite the fact that the initial drying out of the gels can scarcely have been uniform (see B-series gels, Section 3.1). In a similar manner, the plots (represented by Curve 2 in Fig. 6.2) for gels A1 and A3 respectively, each precipitated at pH 10.5, were also virtually identical up to a temperature of about 250°C. Unfortunately, there was insufficient sample available to carry out a weight loss study on gel S2 (pH 8.6), to complete the set.

It is clear from Fig. 6.2 that an increase in the pH of precipitation of the gel is associated with a decrease in the removal of water from the gel, at least at temperatures of up to about 170°C. This result would indicate that, with increase in the precipitation pH, a greater proportion of the 'water' in the gel is present as 'structural

water', i.e. as hydroxyl groups. A similar finding was discussed in relation to the DTA and DSC studies on the gels (Section 6.2).

Ignition of the gels at  $1100^{\circ}\text{C}$  revealed that the overall weight loss of each gel was about 46% w/w. Assuming that this overall loss is entirely due to the removal of water, then the remaining water associated with a gel outgassed at about  $170^{\circ}\text{C}$  (from Fig. 6.2) corresponds closely, with the exception of gel A<sub>4</sub>, to a molecular formula for the outgassed gel of  $\text{Cr}_2\text{O}_3 \cdot \text{H}_2\text{O}$ , i.e. the monohydrate,  $\text{CrOOH}$ . On outgassing the gels above about  $250^{\circ}\text{C}$ , the weight loss plots become fairly similar, the loss presumably being associated with the removal of structural water: however, it is interesting to note that at about  $170^{\circ}\text{C}$ , the plots in Fig. 6.2 intersect, such that for a given temperature above  $170^{\circ}\text{C}$ , the weight loss of the high pH gels (particularly gel A<sub>3</sub>) is greater. This higher loss is almost certainly associated with the greater proportion of structural water in the high pH gels; for the gels precipitated below pH 10.5, a higher weight loss is observed below about  $170^{\circ}\text{C}$ , i.e. due to a greater proportion of 'free' water.

Finally, in the present discussion, we turn to the particularly noteworthy behaviour of gel A<sub>4</sub> on outgassing at temperatures of up to  $250^{\circ}\text{C}$ . It will be recalled that this gel precipitated very slowly at pH 10.5, over a period of about 3 days, from the mother liquor remaining after the rapid precipitation (and isolation) of gel A<sub>3</sub> (see Sections 3.1 and 6.1). Chalyi and his co-workers<sup>37</sup> have found that slowly precipitated chromia gel contains less non-structural water than rapidly precipitated chromia gel. The appreciable difference between Curve 1 (slowly precipitated gel A<sub>4</sub>) and Curve 2 (rapidly

precipitated gel A3) in Fig. 6.2, clearly supports this view: the weight loss of gel A<sub>4</sub>, due to the removal of the non-structural water content of the gel, was, on average, about 7% less than that for gel A3 at temperatures up to about 180°C.

In addition, the weight loss plot for gel A<sub>4</sub> (Curve 1 in Fig. 6.2) exhibits an inflexion at about 125°C, followed by a steep rise to about 200°C; i.e. indicative of a two stage process. In this context, it is interesting to note that Fenerty<sup>7</sup> has suggested that the initial broad endotherm observed in the DTA curve of a chromia gel, may be associated with the removal of two types of non-structural water: at about 120° - 140°C and at about 180° - 210°C respectively. This view is supported by the extensive investigations by Chalyi and his co-workers<sup>38</sup> that the non-structural water in chromia gels is present in the adsorbed and absorbed states respectively.

#### 6.4 X-ray Powder Diffraction and Electron Microscopy Studies

The techniques employed for the x-ray powder diffraction and electron microscope studies were briefly described in Sections 3.6 and 3.7 respectively. Unfortunately, the results of these studies proved to be of little assistance to the present work.

##### X-ray Powder Diffraction Studies

Well-defined x-ray diffraction patterns were observed in the case of the pure crystalline samples of orthorhombic CrOOH and CrO<sub>2</sub>, the d-spacings of which were in reasonable agreement with those previously reported for these oxides.<sup>39,40</sup> However, no discernible patterns were obtained for any of the chromia gels, after exposure of the samples to CuK<sub>α</sub> radiation for varying periods of up to 12 hours. In the case of a sample of gel A3 which was progressively outgassed at

various temperatures up to  $1000^{\circ}\text{C}$  (and held at this temperature for 17 hours), the crystallite size of the  $\alpha\text{-Cr}_2\text{O}_3$  so formed was still too small to result in anything more than a diffraction pattern in which extremely broadened lines were just visible. Giovanoli<sup>41</sup> has commented on a similar difficulty in the study of chromia gels by x-ray powder diffraction, failing to find the slightest trace of crystalline phases in gels even after prolonged treatment of samples in oxygen at  $380^{\circ}\text{C}$ . By way of contrast, however, it is interesting to note that Ratnasamy and Leonard<sup>42</sup>, using x-ray scattering techniques particularly suitable for the study of amorphous materials, claimed to have identified crystalline  $\text{Cr}(\text{OH})_3$  in a chromia gel dried in air at  $25^{\circ}\text{C}$ : particularly pertinent to the present work is the fact that the gel was prepared at pH 10.5, using the method developed by the present author;<sup>43</sup> namely that described in Section 3.1 for the A-series chromia gels. Thus, it is possible that some of the chromia gels studied in the present work, particularly those prepared at high pH, may in fact have contained crystalline phases but that the crystallites were far too small (and contained a high density of imperfections) to be detected by x-ray powder diffraction techniques, the gels therefore appearing to be amorphous.

### Electron Microscopy

Transmission electron microscopy of the chromia gels at various magnifications up to about  $50,000\times$  proved especially disappointing, the subsequent micrographs revealing little detail. Immediately a sample was subjected to the electron beam the gel was rapidly dehydrated, the particles coalescing to form a mass that was virtually opaque to the electron beam. Under such conditions, the temperature of the

specimen may rise by several hundred degrees,<sup>44</sup> resulting in drastic changes in the gel; any information concerning the original texture of the gel would almost certainly be lost.

The examination of labile materials using a scanning electron microscope, however, is not, by virtue of the different techniques employed, prone to the same undesirable side effects such as beam heating. On the other hand, the magnifications obtainable with such instruments are, at present, relatively very low; in the present work, the highest satisfactory magnification attained was 14,000x. Although the definition of the electron micrographs so obtained was excellent, with little or no obvious signs of change in the texture etc. of the gels, the information derived from the photographs was little more than of a general nature.

Little difference was observed between gels A1, A2, A3 and S2; the gels appeared to possess an 'open' texture, with well dispersed particles of a small size. In the case of gel A4, the appearance was very similar, but the texture of the gel appeared to be more open, with less aggregation of the particles.

No differences in appearance were observed between gels B7, B8 and B9 (for which no organic solvents were used in the washing process), the gels consisting of large vitreous angular particles. In the case of gel B6, however, where organic solvents were employed in the washing process, the particle size was very much smaller, the particles being fairly divided and more rounded; in fact, rather similar to the A-series gels.

The scanning electron micrographs (mags. 1000 - 14,000x) of gel A3 outgassed at 1000°C for 17 hours, did not reveal any particles with sharply defined edges that could be associated with the presence of a crystalline solid.

## B. GAS ADSORPTION ON THE HYDROUS CHROMIUM OXIDES

The experimental techniques employed for the gas adsorption measurements were described in Sections 3.16 (for nitrogen and argon adsorption) and 3.20 (for water vapour adsorption). The experimental data for nitrogen, argon and water vapour adsorption on the chromium oxides are presented, in tabulated form, in Appendices 3,4 and 5 respectively. Representative isotherms are shown in Figures 6.3 to 6.8, and 6.12 to 6.18; whilst typical  $\alpha_s$ -plots of the adsorption data are shown in Figures 6.9, 6.10, 6.19 and 6.20 respectively.

### 6.5 Sorptive Properties of Chromia Gels Outgassed at 25°C

The BET surface areas,  $S_{\text{BET}}^{\text{N}}$ ,  $S_{\text{BET}}^{\text{Ar}}$  and  $S_{\text{BET}}^{\text{W}}$  respectively, together with the corresponding BET C constants, of various gels (CrOOH and CrO<sub>2</sub> are included for purposes of comparison) outgassed at 25°C are summarised in Table 6.2. The BET method, and the value of the cross-sectional area ( $A_m$ ) of the adsorbate for nitrogen and water respectively, were described in Section 2.3, where reference was made to the uncertainty concerning the respective values of  $A_m$  and  $P_0$  (the saturation vapour pressure SVP) of argon at -196°C. For reasons discussed in Section 4.1, the value of  $P_0$  used throughout the present work for argon adsorption at -196°C (i.e. below the bulk triple point of argon) is that of solid argon (e.g. 190.6 torr at -196.0°C<sup>45</sup>).

Although a number of comparisons have been reported<sup>46,47</sup> between BET areas calculated from nitrogen and argon isotherms, the findings are largely inconclusive presumably because the adsorbents were not

sufficiently well characterised. However, the effective value of  $A_m$  for argon must depend to some extent on the nature of the adsorbent. Recent investigations<sup>48,49</sup> of argon and nitrogen adsorption on non-porous oxides have revealed that a value of  $A_m = 18.2 \text{ \AA}^2$  for argon should be adopted, for non-porous oxide and hydroxylated oxide surfaces, in order to obtain agreement with the nitrogen area. Such an ad hoc approach may not be wholly acceptable<sup>46</sup> since argon isotherms frequently display an indistinct point B. Furthermore, it has been found<sup>49,50</sup> that the apparent cross-sectional area of argon is reduced if the adsorbent is microporous. Thus, the value of  $A_m = 18.2 \text{ \AA}^2$  adopted in the present work for the apparent cross-sectional area of argon, though suspect in absolute validity is acceptable for comparative purposes.

### The Adsorption Isotherms

With the exception of gels B6 and B8, the nitrogen isotherms determined on the chromia gels outgassed at 25°C were Type II in the Brunauer classification<sup>51</sup> (Section 2.1, Fig. 2.1); nitrogen adsorption on gel B2 (Carruthers<sup>14</sup>) was very low in the BET region (Section 2.3), the surface area,  $S_{\text{BET}}^{\text{N}}$ , being less than 1 m<sup>2</sup>g<sup>-1</sup>. In the case of gel B6, the steep initial part of the nitrogen isotherm was characteristic of an adsorbent possessing both micropores and mesopores, i.e. Type I and IV character; whilst in the case of gel B8, the isotherm was predominantly Type I in character.

The nitrogen isotherm on gel A1 (Curve A in Fig. 6.3), precipitated at pH 10.5, exhibited a narrow hysteresis loop in the capillary condensation range, indicating the presence of a small amount of mesoporosity, whilst the nitrogen isotherms on gels A2 and S2 (Curves

B and C respectively, in Fig. 6.3) were reversible. When, however, these isotherms were compared with the isotherm determined on a non-porous chromium oxide reference adsorbent,<sup>43</sup> using the empirical  $\alpha_s$ -method (Section 2.4), it was seen that gel A2 (precipitated at pH 9.1) also possessed a small degree of mesoporosity. Thus, the  $\alpha_s$ -plot for gel S2 (Curve D in Fig. 6.9), precipitated at pH 8.6, is linear over a wide range of relative pressure, viz. 0.05 - 0.85; whereas the  $\alpha_s$ -plots on gels A1 and A2 (Curves B and C respectively, in Fig. 6.9) are linear in the monolayer range and thereafter show a slight upward deviation (more pronounced in the case of gel A1) - due to capillary condensation. For purposes of comparison, the  $\alpha_s$ -plot for nitrogen adsorption on orthorhombic CrOOH is included in Fig. 6.9 (Curve A): the wide range of linearity clearly demonstrates that the sample of CrOOH outgassed at 25°C was non-porous and therefore suitable as a reference adsorbent.

The respective shapes of the nitrogen isotherms determined on gels B6 and B8, precipitated at about pH 6 using the Burwell method,<sup>9</sup> are in sharp contrast to those determined on both the A-series and on the S-series gels. The isotherm on gel B6 (Curve A in Fig. 6.4) indicates that the gel is predominantly microporous, but in addition, that it probably contains some pores in the mesopore range: the well-defined hysteresis loop, Type E in the de Boer classification,<sup>52</sup> is characteristic of ink-bottle type pores<sup>53</sup> suggesting that the pores in gel B6 are mixed, in both shape and size. In contrast, the typically Type I isotherm obtained on gel B8 (Curve B in Fig. 6.4) is reversible over the complete range of relative pressure. Clearly, both gels are microporous (gel B6 containing mesopores in addition) but, although the

gels originate from a single preparation, the different after-treatment of the two portions of the fresh gel has resulted in a striking modification of the texture of the fresh gel. It will be recalled (Section 3.1, B-series gels) that the portion designated gel B6 was washed with aliquots of water, acetone and ether, whilst the portion designated gel B8 was washed with water only; each was then dried at room temperature in a current of dry air. In the former case, the replacement of the gel water, before drying of the gel, by a liquid with a lower surface tension than that of water, namely acetone or ether, has resulted in an apparent increase in both the surface area,  $S_{\text{BET}}^{\text{N}}$ , (cf. Table 6.2) and pore volume,  $V_{\text{P}}^{\text{N}}$ , of the gel. Taylor<sup>54</sup> has observed a very similar effect when chromia gels were washed with pentane prior to drying.

The values of  $V_{\text{P}}^{\text{N}}$ , about  $0.33 \text{ cm}^3 \text{ g}^{-1}$  and  $0.12 \text{ cm}^3 \text{ g}^{-1}$  for gels B6 and B8 respectively, were assessed from the plateau of the Type I isotherms in Fig. 6.4 (assuming that the uptake at saturation represented the pore volume<sup>55</sup>). However, it should be noted that these values of  $V_{\text{P}}^{\text{N}}$  do not necessarily represent the true pore volume of the gels, but only the volume available to nitrogen. Thus, from a consideration of the apparent values of  $S_{\text{BET}}^{\text{N}}$  and  $S_{\text{BET}}^{\text{W}}$  for gels B6 and B8 (recorded in Column Nos. 5 and 9 of Table 6.2), it is evident that there is a molecular sieve effect<sup>43,56</sup> as between nitrogen and water in the case of gel B8 but not in the case of gel B6: the nitrogen area is about 35% less than that as measured by water, whereas the apparent nitrogen and water areas are very similar in the case of gel B6.

Thus, the method of washing of a chromia gel may radically change, or eliminate, the molecular sieve properties of the freshly formed gel.

The surface area of gel B8 was probably entirely associated with micropores, whereas for gel B6, precipitated under identical conditions to gel B8 but washed with organic solvents prior to drying, a more open texture resulted. From the slope of the upper linear region of the  $\alpha_s$ -plot (Curve A in Fig. 6.10) of the nitrogen isotherm on gel B6, it was found that this gel possessed a small external area of about  $21 \text{ m}^2\text{g}^{-1}$ , (by application of equation 2.14 in Section 2.4).

In general, the argon isotherms on the gels (where determined) were very similar to the corresponding nitrogen isotherms. An exception was observed in the case of the argon isotherm determined on gel A2: the isotherm (shown in Fig. 6.5) exhibited a broad and well-defined hysteresis loop (Type E in the de Boer classification<sup>52</sup>) which closed abruptly at a relative pressure of 0.35  $P_0$ , whereas the nitrogen isotherm (Curve B in Fig. 6.3) was completely reversible; furthermore, the apparent argon area,  $S_{\text{BET}}^{\text{Ar}}$ , was  $300 \text{ m}^2\text{g}^{-1}$  as compared to the nitrogen area,  $S_{\text{BET}}^{\text{N}}$ , of  $82 \text{ m}^2\text{g}^{-1}$  (Table 6.2). However, it must be noted that whereas the nitrogen isotherm was determined on the fresh gel, the argon isotherm was determined eighteen months later. This may well be the result of drastic ageing of the gel, with the development of mesoporosity. However, in the absence of an argon isotherm determined on the fresh gel, and a nitrogen isotherm determined after eighteen months, it cannot be ruled out that a genuine difference in the sorptive properties of gel A2, between nitrogen and argon, existed in the fresh gel.

In the case of the Type II argon isotherms, because the uptake was plotted as a function of  $P/P_0(s)$  (where  $P_0(s)$  was the SVP of solid argon), the isotherm crossed the ordinate at unity relative pressure instead of approaching it asymptotically: examples are provided by

Fig. 6.5, and Curve A in Fig. 6.7.

Representative water vapour isotherms determined on chromia gels outgassed at 25°C are shown in Fig. 6.6. All the water isotherms exhibited hysteresis extending over the full range of relative pressure but, in general, little or no permanent retention of water by the sample was observed on re-outgassing the gels at 25°C. The hysteresis was almost certainly, therefore, associated with the penetration of water vapour into the bulk of the gel, rather than a chemical change of the surface of the gel. In general, the shapes of the water vapour adsorption isotherms were very similar to those for the corresponding nitrogen adsorption isotherms.

In the case of gel B6, the Type IV character of the isotherm was more pronounced for water vapour adsorption (Curve C in Fig. 6.6) than for nitrogen adsorption (Curve A in Fig. 6.4); i.e. the presence of mesopores in gel B6, in addition to micropores, was more apparent from the water vapour isotherm. The hysteresis exhibited by the water isotherm on gel B6 comprised two main types: high pressure hysteresis, similar to a Type E loop<sup>52</sup> (characteristic of ink-bottle type pores and which, but for the occurrence of a penetration effect, would probably have closed at about 0.35 Po), followed by low pressure hysteresis extending to zero relative pressure and associated with the penetration of water vapour into the bulk of the gel.

In Fig. 6.7, the Type II nitrogen, argon and water vapour isotherms respectively, determined on gel A4 outgassed at 25°C are shown: the isotherms for nitrogen and argon adsorption were completely reversible, whereas the water isotherm exhibited hysteresis extending to zero relative pressure with, on this occasion, some permanent retention

of water. The interesting feature revealed by these isotherms is the large difference between the BET surface areas for both nitrogen and argon on the one hand, and water vapour on the other: whereas the nitrogen and argon areas were in substantial agreement at about  $13 \text{ m}^2\text{g}^{-1}$ , with water the apparent area was about  $215 \text{ m}^2\text{g}^{-1}$  (Table 6.2).

It will be recalled (Section 3.1, A-series gels) that gel A<sub>4</sub> precipitated relatively very slowly and it seems likely, therefore, that large particles were formed. Consequently, nitrogen or argon adsorption took place on a small external area, whereas water sorption took place within fine micropores that were too narrow to permit the entry, to any appreciable extent, of nitrogen (or argon) molecules. The  $\alpha_s$ -plot for nitrogen adsorption on this gel is shown as Curve B in Fig. 6.10: the deviation from linearity at low relative pressures supports the view that gel A<sub>4</sub> contained pores in the micropore range (width  $< 20 \text{ \AA}$ ).

Finally, we turn briefly to a general problem encountered during gas adsorption studies on chromia gels (and on many other gel systems); namely the labile nature of the gels, and the associated difficulty in obtaining reproducible isotherms on chromia gels outgassed at  $25^\circ\text{C}$ .

In Fig. 6.8, Curve A represents the nitrogen isotherm determined after outgassing gel A<sub>1</sub> at  $25^\circ\text{C}$  for 32 hours; on completion of the isotherm (duration one day) the gel was re-outgassed for a further period of 18 hours and the isotherm re-determined (Curve B in Fig. 6.8). The rapid ageing process of gel A<sub>1</sub> during this short period has resulted in a substantial displacement of the multilayer region of the second isotherm to higher relative pressure: furthermore, this change was accompanied by a reduction in the nitrogen area of the gel; from about  $144 \text{ m}^2\text{g}^{-1}$  to about  $128 \text{ m}^2\text{g}^{-1}$ .

Clearly, outgassing of gel A1 at 25°C led to a metastable structure of the gel, which changed both whilst a given isotherm was being determined and also on outgassing prior to the determination of a further isotherm. A similar effect was observed in the case of the other chromia gels which exhibited Type II isotherms, including chromia gels studied by other workers,<sup>57,58</sup> but was less noticeable in the case of the microporous gels, e.g. gels B6 and B8.

#### Comparison of the Nitrogen, Argon and Water BET Surface Areas of the Gels

In the previous section, reference was made to the fact that certain of the chromia gels, when outgassed at 25°C, exhibited molecular sieve properties: in these cases, the water vapour sorption capacity was high, whereas the pore volume available to nitrogen (and occasionally argon) was comparatively small, or almost non-existent. The results of certain experiments on nitrogen, argon and water vapour adsorption respectively, summarised in Table 6.2, help to illustrate why the surface properties of hydrous chromium oxides are so sensitive to the conditions of preparation and the removal of water.

In Section 6.3, it was mentioned that hydrous chromium oxide precipitates, freshly formed from hexaquo  $\text{Cr}^{3+}$  ions, are usually poorly ordered and retain considerable amounts of free water. When the gel is outgassed at 25°C, however, the free water (sorbed and coordinated) is removed without a drastic structural change or collapse of the solid framework; although, as shown in Fig. 6.8,

some changes in the textural properties of the gel occur. The gel then appears to act as a molecular sieve, the cavities remaining in the vicinity of the cations on removal of the ligand water being available for the sorption of water vapour, but not for nitrogen (and presumably, larger adsorbate molecules). It has been shown<sup>14,43</sup> that on heating a gel which exhibited a molecular sieve effect to about 280°C, the small cavities appeared to migrate and aggregate with the increase in thermal energy: the gel became mesoporous, as indicated by a change in the isotherm shape, good agreement being obtained between the values of pore volume as assessed by nitrogen and water sorption.

The molecular sieve character of the chromia gels (B-series), prepared at about pH 6 using the Burwell method, is especially interesting. In the extreme case, nitrogen uptake on gel B2 (prepared by Carruthers<sup>14</sup>) was barely detectable ( $S_{\text{BET}}^{\text{N}} < 1 \text{ m}^2\text{g}^{-1}$ ), whereas the apparent water area was about 286  $\text{m}^2\text{g}^{-1}$ . Similarly, but to a lesser degree, gel B8 exhibited a preferential affinity for water vapour; whilst in the case of gel B6, replacement of the gel water by acetone prior to drying led to a pore-widening process and consequently, good agreement between the apparent values of  $S_{\text{BET}}^{\text{N}}$  and  $S_{\text{BET}}^{\text{W}}$ .

The relationship between variation of the pH of the precipitation medium and the sorptive properties of the gel, has been examined in the case of hydrous aluminium oxide<sup>59-61</sup> and of silica gels:<sup>62,63</sup> it was found that these gel systems, when outgassed at room temperature, exhibited the greatest preferential affinity for water vapour sorption when precipitated at the lowest pH values; furthermore, in general,

the isotherms were characteristic of microporous solids, i.e. Type I. In the case of hydrous chromium oxides a similar study does not appear to have been made, although molecular sieve effects, as between nitrogen and water vapour, have been reported.<sup>57,64</sup> The results summarised in Table 6.2 serve to show that, in general, the nature of the porosity in chromia gels is closely associated with the pH of precipitation.

Although gels A2 (pH 9.1) and S2 (pH 8.6) showed some molecular sieve character, gel A1 (pH 10.5) did not appear to have any significant preferential affinity for water vapour rather than nitrogen. The nature of the  $\alpha_s$ -plots for the nitrogen isotherms determined on these gels (shown in Fig. 6.9), shows that the increase in the value of  $S_{\text{BET}}^{\text{N}}$  with pH was associated with the development of mesoporosity in gels A1 and A2. Cross and Leach<sup>25</sup> have similarly found that the precipitation of chromia gels at low pH (about pH 5) results in a microporous gel, whilst at higher pH the gel tends to be mesoporous. This type of secondary pore structure is probably formed as a result of aggregation-cementation, an ageing process which is promoted by the reduction in the degree of solvation at the solid-liquid interface.<sup>65</sup>

When comparing the results for water sorption by the silica samples (Section 4.2, Table 4.1), it proved helpful to express the uptake of water vapour, at a relative pressure of 0.2  $P_0$ , on a unit area basis (using the corresponding  $S_{\text{BET}}^{\text{N}}$  value). In Column 11 of Table 6.2 the results for water sorption by the chromia gels is expressed in a similar manner. Thus, it will be seen that, with the exception of gels A4, B6 and B8 (discussed in the previous Section), an increase in the pH of the gel precipitation is

accompanied by a decrease in the sorption of water vapour per unit area of the gel.

In the case of gels A1 and A3 (each precipitated at pH 10.5) the significant difference between the water uptakes at 0.2 Po, i.e. 21.8 and 32.1  $\mu\text{mole m}^{-2}$  respectively, may be associated with the four-fold increase in the concentration of ammonia solution employed for gel A3 (Section 3.1, Table 3.1). It is known that the sorptive properties of outgassed hydrous chromium oxides are particularly sensitive in respect of the concentration of the reactants,<sup>14,15</sup> including the sequence and rate at which the solutions are mixed,<sup>66,67</sup> used in the preparation of the gels: in a manner similar to that found for alumina gels,<sup>61</sup> an increase in concentration led to a marked decrease in the  $S_{\text{BET}}^{\text{N}}$  value of the chromia gel. The change in the conditions of preparation of gel A4, relative to those of the other gels, was particularly marked; this may explain why gel A4, prepared at high pH, exhibited a high preferential affinity for water vapour.

In all cases, water sorption by the chromia gels outgassed at 25°C was very much greater than in the case of silica gels similarly outgassed (cf. silica gels E and J in Table 4.1, Chapter 4). It seems likely that the high affinity for water, exhibited by chromia, is associated with a marked tendency for hydration in depth of poorly ordered cations, e.g.  $\text{Cr}^{3+}$  originally solvated and not fully coordinated in the oxide structure. Sing and his co-workers<sup>60</sup> have found that certain hydrous alumina gels, outgassed at room temperature, exhibit similar high preferential affinities for water vapour.

N, non-porous; Me, mesoporous; Mic, microporous

In contrast, the non-porous sample of crystalline orthorhombic chromium oxy-hydroxide exhibited much less affinity for water vapour, the uptake at a relative pressure of 0.2 Po corresponding to 3.4  $\mu\text{mole m}^{-2}$ . In the case of the sample of  $\text{CrO}_2$ , believed to be essentially non-porous,<sup>43</sup> the uptake of water vapour at 0.2 Po corresponded to a close-packed water monolayer; i.e. 15.7  $\mu\text{mole m}^{-2}$  (taking the molecular cross-sectional area of water as 10.6  $\text{\AA}^2$ ). It should be noted, however, that the results recorded in Table 6.2 of certain experiments on nitrogen and water vapour adsorption on  $\text{CrO}_2$ , were obtained after the occurrence of mercury adsorption on the surface of the  $\text{CrO}_2$  sample (cf. Section 5.2).

#### 6.6 Sorptive Properties of Chromia Gel A3 Outgassed at Various Temperatures up to 1000°C

The sample outgassing procedure was described in Sections 3.15 and 3.19 for the volumetric and gravimetric techniques respectively. Mercury vapour was present, both during the outgassing and the determination of the isotherm, in the case of nitrogen and argon adsorption respectively, but absent throughout the determination of the water vapour isotherms. Where reference is made to a particular specimen of gel A3, the temperature and the duration of the outgassing treatment of the gel is designated as indicated in the following examples: A3(25)64V was a sample of gel A3 outgassed at 25°C for 64 hours; whilst A3(1000)17V was a sample of gel A3 outgassed at 1000°C for 17 hours. In a similar manner, B3(880)2 was a sample of gel B3 calcined at 880°C for 2 hours in air, the sample being subsequently outgassed at 25°C prior to the isotherm determination

(Carruthers<sup>14</sup>). The outgassing of gel A3 at the temperatures indicated in Table 6.3 was carried out sequentially, without exposure of the sample to air at any stage during the determination of the isotherms: nitrogen and argon isotherms were determined consecutively on the same specimen of gel A3, whilst the water vapour isotherms were determined on another sample of the gel similarly treated.

The BET surface areas,  $S_{\text{BET}}^{\text{N}}$ ,  $S_{\text{BET}}^{\text{Ar}}$  and  $S_{\text{BET}}^{\text{W}}$  for nitrogen, argon and water vapour adsorption respectively, together with the corresponding BET C constants, of gel A3 outgassed at selected temperatures up to 1000°C are summarised in Table 6.3: the variation of the BET surface area of the gel, as a function of outgassing temperature, is presented for each adsorbate in graphical form as Fig. 6.11. Representative nitrogen isotherms determined on gel A3 are analysed as  $\alpha_s$ -plots in Figs. 6.9 and 6.20, whilst Frenkel-Halsey-Hill (FHH) plots are summarised in Tables 6.4 and 6.5.

#### Interpretation and Analysis of the Adsorption Isotherms

Isotherms representative of nitrogen, argon and water vapour adsorption respectively, determined on gel A3 outgassed at various temperatures up to 1000°C, are reproduced as Figs. 6.12 - 6.18: the general shape of the curves is similar to that of a Type II isotherm.<sup>51</sup> In the case of nitrogen and argon adsorption, the majority of the isotherms were completely reversible. In contrast, however, all the water vapour isotherms, with the exception of the repeat determination on gel A3 outgassed at 1000°C (Curve C in Fig. 6.18), exhibited hysteresis extending over the complete range of relative pressure: in the case of the repeat water vapour isotherm determined

on A3(1000)17V, a hysteresis loop was obtained which closed at a relative pressure of about 0.3 Po. Furthermore, on re-outgassing, at 25°C, of a specimen of gel A3 after the determination of a particular water vapour isotherm, some permanent retention of water by the specimen was observed, the degree of which decreased with increase in temperature of outgassing: i.e. in addition to the usual penetration of water into the bulk of a chromia gel (Section 6.5), surface rehydration of gel A3 occurred on exposure of a specimen to water vapour. Permanent retention of water was not observed in the case of gel A3 initially outgassed at 25°C, i.e. Curve C in Fig. 6.12.

The nitrogen, argon and water vapour adsorption isotherms determined on A3(150)15V were initially identical (up to relative pressures of about 0.9 Po) to the corresponding isotherms determined on the gel outgassed at 25°C, i.e. A3(25)64V: practically no significant change was observed in the respective values of the BET surface areas, or those of the BET C constants (cf. Table 6.3 and Fig. 6.11). This result indicates that there was little disturbance of the gel structure on outgassing the gel at 150°C.

From Fig. 6.11 it is apparent, however, that in the case of A3(300)20V, the nitrogen and argon BET surface areas were each increased by about 30%, whilst the area as measured by water adsorption decreased by about 35%; indicating that some rearrangement of the gel structure occurred on outgassing gel A3 at 300°C. The nature of this change is indicated by the  $\alpha_s$ -plots shown in Figs. 6.19 and 6.20. The selection of suitable non-porous reference surfaces poses a special problem with chromium oxide gels, because heat treatment leads to changes in both the texture and the chemical structure. Ideally, a different standard isotherm should be employed for each well-characterised

oxide, or hydroxide, structure (e.g.  $\text{CrOOH}$ ,  $\text{Cr}_2\text{O}_3$ ,  $\text{CrO}_2$ ,  $\text{CrO}_3$ ). In the present instance, however, the purpose of an analysis of the isotherms using the  $\alpha_s$ -method was to detect the changes which occurred on progressively outgassing gel A3 at increasing temperatures; it was felt that this was best served by comparing the nitrogen isotherms (for example) determined on the heat treated material, with that determined on the gel outgassed at  $25^\circ\text{C}$ , i.e. A3(25)64V.

In order to establish the nature of any porosity present in A3(25)64V, the nitrogen isotherm determined on this specimen was compared, as an  $\alpha_s$ -plot, with that determined on the pure sample of orthorhombic chromium oxy-hydroxide - an adsorbent which was established (Section 6.5) as being non-porous. Accordingly, the  $\alpha_s$ -plot of the nitrogen isotherm determined on A3(25)64V is shown as Curve A in Fig. 6.19. The plot is linear in a relative pressure range of 0.1 to 0.75; but the slight deviations from linearity at low, and at high, relative pressures are indicative of a small degree of microporosity and mesoporosity respectively, in gel A3(25)64V. The positive intercept (in association with the wide range of linearity) of Curve B in Fig. 6.19 indicates that the degree of microporosity was increased on outgassing gel A3 at  $300^\circ\text{C}$ , whereas further outgassing at  $440^\circ\text{C}$  resulted in a loss of microporosity to a degree similar to that originally found in A3(25)64V (cf. Curve C in Fig. 6.19). The increase in the degree of microporosity of A3(300)20V, together with the enhanced values of  $S_{\text{BET}}^{\text{N}}$  and  $S_{\text{BET}}^{\text{Ar}}$  respectively, is probably associated with the removal of water molecules, present in the adsorbed and absorbed states, from the gel (cf. Sections 6.2 and 6.3).

In Fig. 6.20, the nitrogen isotherms determined on the heat treated samples of gel A3 are compared, as  $\alpha_s$ -plots, with that determined on A3(25)64V. The comments made concerning the  $\alpha_s$ -plots in Fig. 6.19 are reinforced by Curves A, B and C respectively in Fig. 6.20: the wide range of linearity of the  $\alpha_s$ -plots, extending to relative pressures of about 0.9 Po, suggests that there was no increase in the degree of mesoporosity originally present in A3(25)64V, on outgassing gel A3 at temperatures up to 440°C. It is interesting to note, however, that although Curves A and B in Fig. 6.20 are parallel (indicating that the surfaces of A3(150)15V and A3(300)20V were probably similar) the downward deviation from linearity of Curve B at relative pressures below about 0.1 Po, is indicative of a disturbance of the nitrogen monolayer on A3(300)20V. It would appear that there is a greater enthalpy of adsorption in the case of A3(300)20V than for A3(150)15V. This result may be associated with the fact that mercury vapour was almost certainly chemisorbed on the surface of A3(300)20V, during the determination of the nitrogen and argon isotherms (cf. Section 5.1).

For nitrogen adsorption on gel A3 outgassed at 600°, 800° and 1000°C respectively, the relatively complex nature of the  $\alpha_s$ -plots (shown as Curves D, E and F respectively, in Fig. 6.20) confirm that a change in the chemistry of these surfaces resulted, after occurrence of the glow phenomenon at a temperature between 440° and 600°C: with the exception of the plot for A3(1000)17V, the range of linearity is restricted to a very narrow range of relative pressure. The deviation from linearity at high relative pressures in the case of Curves E and F, may be associated with the collapse

of the mesopore structure on outgassing gel A3 at 800° and 1000°C respectively. Certainly, the results summarised in Table 6.3 (and represented graphically in Fig. 6.11) serve to show that the occurrence of the glow phenomenon is accompanied by a drastic reduction in the surface area of gel A3; thereby confirming previous findings.<sup>14,43,68</sup>

During the progressive outgassing of gel A3, the sample bulk was observed to decrease considerably after outgassing at 150°C, i.e. the particles of gel A3 compacted. This apparent change in the bulk density was reflected by the presence of a small degree of high pressure hysteresis in the nitrogen and argon isotherms respectively, (cf. Figs. 6.13 and 6.15) first becoming apparent in the case of A3(150)15V, then carrying through the sequential isotherm determinations to A3(600)16V. Further outgassing at 800°C and 1000°C respectively, resulted in reversible nitrogen and argon isotherms (cf. Figs. 6.14 and 6.16 respectively). These results suggest that the compaction of the gel created an ill-defined pore structure, thereby allowing a small degree of inter-particle condensation of nitrogen (and argon) to occur. With collapse of the gel structure to  $\alpha\text{-Cr}_2\text{O}_3$ , this pore structure was removed.

Carruthers and Sing<sup>68</sup> have found that, in the case of a microporous chromia gel prepared using the Burwell method, the drastic ageing which occurred in the low temperature range (i.e. less than about 200°C) was avoided by heating the gel in a vacuum; a large reduction in the value of  $S_{\text{BET}}^{\text{N}}$  was delayed until an outgassing temperature of about 250°C. A similar situation has been encountered with hydrous aluminum oxides<sup>59,65</sup> and with other inorganic gels.<sup>69,70</sup>

In the present work, it is noteworthy that a large reduction in the surface area of gel A3 (containing little microporosity) was not observed until an outgassing temperature of  $440^{\circ}\text{C}$  was exceeded. Low temperature ageing depends on the presence of free water in the gel, and presumably this water is removed more easily from a non-porous gel than that from a microporous gel.

The values of the BET C constants for nitrogen adsorption on gel A3 outgassed at temperatures of  $440^{\circ}\text{C}$ , and above, are recorded in Table 6.3 enclosed by parentheses to indicate that the validity of these values is suspect. It is apparent from the corresponding nitrogen isotherms, shown in Figs. 6.13 and 6.14, that the knee of the isotherm is both progressively sharpened and displaced towards very low relative pressures. This is indicative of a high degree of specific adsorbent-adsorbate interaction, localised nitrogen adsorption taking place on highly energetic sites. In order to obtain more meaningful values of the BET C constants, the BET analysis should be performed, for the nitrogen isotherms in question, in a narrow range of relative pressure lying outside the usual BET region of  $0.05 P_0$  to  $0.3 P_0$ . In the present work, however, insufficient experimental data were available at very low relative pressures to permit such an analysis.

With the exception of A3(600)16V, the argon isotherms determined on gel A3 (Figs. 6.15 and 6.16) exhibited curves in the monolayer region of the isotherm, that essentially retained the character of a Type II isotherm. Although it is frequently found that for argon adsorption on many surfaces the statistical monolayer is not a well-defined point on the isotherm,<sup>48</sup> it would appear that, in the

present instance, this is not the case for argon adsorption on certain chromium oxides: the BET C constants recorded in Table 6.3 for argon adsorption on gel A3 are all greater than 50, and therefore it would appear that the BET procedure may be used with reasonable confidence to locate the value of the monolayer capacity, and thence the argon BET surface area (bearing in mind the uncertainty concerning the cross-sectional area of the adsorbed argon molecule<sup>46,47</sup>). Thus, the fact that the interactions of the argon molecule with solid surfaces are essentially non-specific, appears to offer it an advantage over nitrogen in the present study of chromia gels outgassed at high temperatures.

The argon isotherms determined on gel A3 outgassed at temperatures of 600°C and above (Figs. 6.15 and 6.16), exhibited some stepwise character, albeit poorly-defined. To a lesser extent, stepwise character was also apparent in the case of the corresponding water vapour isotherms, whilst for nitrogen adsorption such an effect was barely discernible. Pierce and Ewing<sup>71</sup> investigated the requirements for the occurrence of stepwise isotherms: they concluded, that in addition to the need for a homogeneous surface, there must be strong lateral interactions between adsorbed molecules, and that the temperature of adsorption should be low enough to inhibit the thermal agitation of the adsorbate molecules. However, Zettlemyer and his co-workers<sup>72</sup> have shown that the geometry and chemical nature of the adsorbate are more essential requirements than that of low temperature.

Almost certainly, the surface of a chromia gel outgassed at temperatures between 600° and 1000°C, is predominantly heterogeneous

in the energetic sense, although prolonged treatment at high temperature of the  $\alpha$ -Cr<sub>2</sub>O<sub>3</sub> so formed probably results in an increased uniformity of the surface. However, it is interesting to note that Selim and his co-workers<sup>73</sup> have reported the presence of well-defined steps in the water vapour isotherms determined (at 35°C) on a chromia gel that was heated in air at 320°C for 3 hours. These workers have proposed that the presence of strong lateral interactions between adsorbate molecules is more important than the presence of surface homogeneity, in order for stepwise adsorption to occur. For the formation of the first water layer on the surface of certain chromia gels, the adsorbent-adsorbate interactions are probably stronger than the lateral interactions between the adsorbate molecules; when the surface becomes covered by the adsorbate, then adsorbate-adsorbate interactions will predominate, e.g. intermolecular hydrogen bonding.

#### The Frenkel-Halsey-Hill (FHH) Plots

The ranges of linearity of the various FHH plots for nitrogen, argon and water vapour adsorption respectively, on gel A3, are recorded in Table 6.4, together with the corresponding values of 'r' determined from the slopes of the plots (Section 2.4). For purposes of comparison, the FHH plots for nitrogen and for water vapour adsorption on orthorhombic CrOOH, CrO<sub>2</sub> and chromia gel B3(880)2 respectively, are summarised in Table 6.5.

Although the ranges of linearity of the FHH plots for nitrogen adsorption on gel A3 were not quite so wide as those found for nitrogen on non-porous silicas (cf. Table 4.2, Section 4.5), the plots nevertheless confirmed that the various samples of gel A3 (outgassed at temperatures between 25°C and 1000°C) contained only a small amount

of porosity. In general, the values of  $r$  (mean = 2.7) correspond fairly closely to the range of 2.5 - 2.75 reported<sup>74</sup> as typical for nitrogen adsorption on a polar surface. For nitrogen adsorption on the well-characterised reference chromium oxides, orthorhombic  $\text{CrOOH}$ ,  $\text{CrO}_2$  and gel B3(880)2 respectively, the FHH plots were linear over a wide range of relative pressure with very close agreement between the values of  $r$  (cf. Table 6.5). In the case of nitrogen and water vapour adsorption respectively, the values of  $r$  recorded in Tables 6.4 and 6.5 are characteristic<sup>75</sup> of specific adsorbent-adsorbate interactions.

In the case of argon adsorption on gel A3, the FHH plots exhibited severely restricted ranges of linearity, although in comparison to argon adsorption on the silicas, the upper limit was located at higher relative pressures (at about 0.9  $P_0$ ). The high values of  $r$  in the case of argon adsorption, on gel A3, therefore, probably possess little meaning.

The ranges of linearity of the FHH plots for water vapour adsorption on gel A3 were slightly more restricted than in the case of water adsorption on the silicas. However, the values of  $r$  (mean = 2.7) were characteristic of water vapour adsorption on hydrophilic surfaces, i.e.  $r$  = about 2.5 (Zettlemoyer<sup>74</sup>), whereas the value of  $r$  in the case of the hydroxylated silicas were consistently much lower. The greater hydrophilicity of a chromia surface (even after prolonged outgassing at 1000°C), as compared to a hydroxylated silica surface, is also reflected by the much higher uptakes of water vapour at an arbitrary relative pressure of 0.2  $P_0$  (expressed, in Tables 6.3 and 4.1 respectively, on a unit area basis using the corresponding nitrogen BET surface areas).

TABLE 6.3

Nitrogen, Argon and Water Vapour Adsorption on Chromia Gel A3 Outgassed at Temperatures up to 1000°C

| OUTGASSING TEMPERATURE (°C) | NITROGEN  |      | ARGON  |     | WATER   |     |  |
|-----------------------------|---|------|--|-----|---|-----|--|
|                             | BET   |      | BET  |     | BET   |     | SORPTION AT 0.2 Po (μ mole m <sup>-2</sup> ) |
|                             | S <sub>BET</sub> <sup>N</sup> (m <sup>2</sup> g <sup>-1</sup> ) | C    | S <sub>BET</sub> <sup>Ar</sup> (m <sup>2</sup> g <sup>-1</sup> ) | C   | S <sub>BET</sub> <sup>W</sup> (m <sup>2</sup> g <sup>-1</sup> ) | C   |  |

### GENERAL DISCUSSION AND CONCLUSIONS

The term "ageing" is used to connote all those irreversible structural or textural changes in the colloidal system which may occur after flocculation or gelation.<sup>1-3</sup> Ageing occurs when an "active" solid (i.e. one that is thermodynamically unstable in respect of surface area) is left in contact with an aqueous medium and also when the liquid phase is removed. It is now recognised<sup>3</sup> that water plays a key role in the ageing of hydroxides and hydrous oxides. The poorly organised flocculated hydroxide prepared from salts of hydrated cations usually contains large quantities of molecular water; this is partly sorbed (trapped within the framework and held at the gel surface) and partly associated with the cations.<sup>3,4</sup> Fenerty,<sup>5</sup> using diffuse reflectance spectra measurements, has shown that a considerable number of water molecules remain coordinated to chromium (III) ions in hydrous chromium oxides. The displacement of these water ligands is a prerequisite for the development of the hydroxide or oxy-hydroxide structure. Hydrous oxides of aluminium and iron (III) prepared under similar conditions to those of hydrous chromium (III) oxides, contain well defined oxy-hydroxide structures.<sup>6,7</sup> The formation of the hydroxide or oxy-hydroxide structures is facilitated<sup>8</sup> if hydrous aluminium oxide is precipitated at a high pH. The results discussed in Section 6.3 indicate that the development of an oxy-hydroxide structure (e.g. chromium

oxy-hydroxide,  $\text{CrOOH}$ ) is more pronounced in the case of a chromia gel precipitated at pH 10.5, than that of a gel precipitated at about pH 6.

Hydrous chromium (III) oxide may be regarded as a condensation polymer of  $\text{Cr}(\text{H}_2\text{O})_3(\text{OH})_3$  in which hydroxide, or oxide, ions act as bridges linking the chromium ions.<sup>5,9,10</sup> The pH of an aqueous suspension of a freshly formed chromia gel was observed to decrease with the time of ageing. Bye and Simpkin<sup>11</sup> have observed a similar effect, which has been attributed<sup>5</sup> to the continued growth of the polymer after precipitation. The decrease in pH of the gel suspension appears to be associated with a dehydration process occurring at the oxide-water interface, similar to that observed in the case of a hydrous iron (III) oxide.<sup>12</sup>

In the present work, gas adsorption measurements have indicated that in the case of hydrous chromium oxides outgassed at temperatures lower than about  $150^\circ\text{C}$ , the coordinated water is apparently removed with little structural change, the original solid framework remaining intact (for example, see Tables 6.3 and 6.4, and Curve 'A' in Fig. 6.20). Chromia gels precipitated at about pH 6 were found to be microporous. These gels, outgassed at  $25^\circ\text{C}$ , possessed molecular sieve properties; the sorption capacity for water was high, whereas the pore structure available to nitrogen (and presumably most other adsorbates) was small. A similar result has been reported in the case of certain hydrous aluminas.<sup>13</sup> The molecular sieve effect is attributed to the cavities remaining in the vicinity of the cations after removal of the ligand water. In contrast, however, the replacement of ligand molecules from the chromium (III) octahedra by hydroxide ions was facilitated by

precipitation of the gel at high pH i.e. 10.5. These gels, which possessed very little microporosity, did not exhibit a significant molecular sieve effect. The results summarised in Table 6.2 indicate that an increase in the pH of precipitation is accompanied by a decrease in the degree of the molecular sieve character of the chromia gels.

Carruthers<sup>14</sup> tentatively suggested that the conditions of mixing of the reactants are more important than the pH during the precipitation of a chromia gel. Although the manner in which the reactants are mixed undoubtedly plays an important role in controlling the properties of a chromia gel (particularly<sup>15</sup> in the case of a gel prepared using the Burwell method), the bulk and surface properties of chromia gels are especially sensitive to the pH of precipitation. The results of Cross and Leach<sup>16</sup> confirm this view: chromia gels prepared at about pH 5 possessed pore structures consisting almost entirely of micropores, whereas a gel prepared at pH 8.5 contained both micropores and mesopores.

It has been found<sup>17,18</sup> that the surface properties of silica gels are also profoundly influenced by the pH of precipitation; in this case, however, the mechanism is probably rather different, involving the catalytic action of hydroxyl ions. Thus, the size and degree of packing of the polysilicic acid units are influenced by the pH of formation of the silica hydrogel, but crystalline oxide or hydroxide structures do not develop.

The textural properties of a chromia gel, notably in the case of microporous gels, may be drastically changed according to the method employed to wash and 'dry' the gel. The use of acetone and

and diethyl ether to displace the gel water, for example, resulted in a marked change in the character of the nitrogen (Fig. 6.4) and water vapour isotherms (Curves B and C in Fig. 6.6) respectively, accompanied by an increase in the total pore volume of the gel. Taylor<sup>19</sup> reported a similar result when chromia gels were washed with pentane prior to drying; whilst Foster and Thorp<sup>18</sup> observed a pore-widening effect when silica gels were dried rapidly. The increased pore volume of the chromia gels is associated with a reduction in the capillary forces acting in the gel, achieved by replacing the gel water by a liquid of lower surface tension, e.g. acetone. If this liquid is removed above its critical temperature (by autoclaving), or the water removed from the wet gel by a process of freeze-drying then a chromia aerogel may be obtained.<sup>19</sup>

During the calcination of hydrous chromium oxides in air, the overall oxidation process  $\text{Cr}^{3+} \rightarrow \text{Cr}^{6+}$  is generally accompanied by micropore widening, whereas the reduction stage  $\text{Cr}^{6+} \rightarrow \text{Cr}^{3+}$ , which involves the crystallisation of  $\alpha\text{-Cr}_2\text{O}_3$ , is accompanied by the removal of pores and the loss of surface area.<sup>5,14</sup> Gels calcined in nitrogen (up to temperatures of about  $600^\circ\text{C}$ ) remain mesoporous because the crystal growth of  $\alpha\text{-Cr}_2\text{O}_3$  is delayed in an inert atmosphere.<sup>20</sup> The drastic low temperature ageing ( $< 200^\circ\text{C}$ ) that occurs in the case of many microporous chromias, due to the large amount of residual water assisting the formation of crystalline oxy-hydroxide, may be delayed until about  $250^\circ\text{C}$  by heating the gel in vacuum.<sup>20,21</sup>

The rigorous exclusion of water vapour from an oxide xerogel prevents further ageing at room temperature<sup>22</sup> and also considerably retards thermal ageing. However, water appears to play a dual role in the ageing

of hydrous oxides. Thus, the presence of a certain level of residual water appears to offer a measure of protection to the particles of a partially dried gel. For example, in the case of certain hydrous aluminas,<sup>3</sup> the surface area ( $S_{\text{BET}}^{\text{N}} \sim 300 \text{ m}^2\text{g}^{-1}$ ) was stabilised over periods of about a year - provided that the ratio of  $\text{H}_2\text{O} : \text{Al}_2\text{O}_3$  remained greater than 6 : 1. However, exposure of the outgassed gel to water vapour resulted in a drastic reduction in the surface area. Sing and Bye<sup>3</sup> proposed that the removal of water allowed a closer particle-particle contact so that ageing, presumably by a surface diffusion mechanism, was facilitated when water vapour was re-admitted to the system.

Nitrogen, argon and water vapour isotherms respectively, were determined on gel A3 outgassed at various temperatures between  $25^\circ$  and  $1000^\circ\text{C}$ . Gel A3, precipitated at pH 10.5, was found to contain small amounts of both microporosity and mesoporosity (using the  $\alpha_{\text{g}}$ -method; Curve A in Fig. 6.19). The degree of microporosity was increased at  $300^\circ\text{C}$ , but returned to the original ( $25^\circ\text{C}$ ) level after outgassing the gel at  $440^\circ\text{C}$ . The ill-defined mesopore structure which developed at temperatures between  $150^\circ$  and  $600^\circ\text{C}$  appeared to be associated with compaction and the cementation between neighbouring particles. This was removed at higher temperatures when the drastic reduction of surface area was accompanied by the crystallisation of  $\alpha\text{-Cr}_2\text{O}_3$  (Fig. 6.11). The mesoporous structure finally collapsed at about  $800^\circ\text{C}$ . The isotherms obtained after outgassing the gel at  $600^\circ$ ,  $800^\circ$  and  $1000^\circ\text{C}$  respectively, exhibited some stepwise character; this may be associated with a progressive increase in the homogeneity of the  $\alpha\text{-Cr}_2\text{O}_3$  surface. The original ( $25^\circ\text{C}$ ) surface area of the gel was preserved up to temperatures of about  $440^\circ\text{C}$ .

The nitrogen isotherms determined on gel A3 outgassed at temperatures above  $440^{\circ}\text{C}$ , were found to exhibit a sharp knee at very low relative pressures. This indicated that some nitrogen molecules were adsorbed on highly energetic sites (possibly exposed  $\text{Cr}^{3+}$  ions) whilst the remainder of the surface was covered at higher pressures. The values of the BET C constants (Table 6.3), which were unusually low for nitrogen adsorption, were related to the surface coverage in the normal BET region only, and therefore do not reflect the strong adsorbent-adsorbate interactions which occur at low surface coverage. On the other hand, the adsorbent-adsorbate interactions of argon are essentially non-specific, and therefore less sensitive to changes in the chemistry of the surface. In this respect, the argon BET C constants may provide a more reliable guide to the overall adsorbent-adsorbate interactions, than do the corresponding nitrogen values.

The adsorption of water vapour on oxides and other solids is known to be highly specific.<sup>23,24</sup> This appears to be due to the large field-dipole energy contribution to the total gas-solid interaction energy.<sup>24</sup> When this specific contribution is removed, or reduced, (e.g. by the dehydroxylation of silica) the water uptake is diminished, i.e. the surface tends to become hydrophobic. Zettlemoyer<sup>25</sup> and others<sup>23,26</sup> have concluded that on such surfaces adsorbed water molecules form clusters around residual or impurity polar sites.

It is clear that dehydrated chromium oxide surfaces do not exhibit the type of hydrophobic character displayed by a dehydroxylated silica, e.g. TK 800 outgassed at  $1000^{\circ}\text{C}$ . There seems

to be a closer similarity between chromium oxide and alumina, which has been shown<sup>27</sup> to develop hydrophilic character on dehydration. Kiselev and his co-workers<sup>23,28</sup> found that the surface rehydration of silica is a slow process and that a reversible water vapour isotherm was restored only after soaking the silica in liquid water, or by repeated adsorption and desorption experiments. A similar result was found in the case of TK 800 'soaked' in water vapour at a relative pressure of about 0.98 Po (cf. Fig. 4.4). In contrast, however, the surface of clean  $\alpha$ -Al<sub>2</sub>O<sub>3</sub> has a high affinity for water, with chemisorption taking place at low pressure, and physical adsorption on the hydrated surface.<sup>29</sup>

The results obtained in this work and in other related investigations<sup>29,30</sup> have provided evidence for the identification of six different mechanisms for the sorption of water by oxides:-

- (1) Hydrogen bonding between adsorbed water molecules and surface hydroxyl groups.
- (2) Hydrogen bonding between sorbed water molecules and hydroxyl groups in micropores.
- (3) Hydration of exposed surface cations by adsorbed water molecules.
- (4) Dissociative chemisorption of water with the formation of hydroxyl groups.
- (5) Hydration in depth of poorly ordered cations.
- (6) Hydroxide or oxy-hydroxide formation in depth.

Process 1 results in a 'standard' water isotherm and heat of immersion, but process 2 gives rise to abnormally high values of water uptake and heat of immersion - especially when the micropores are too narrow to accommodate other sorbate molecules. Process 3 is important

with alumina (and titania etc.), but is not operative with amorphous silica. Process 4 is fast with alumina, but slow with dehydroxylated silica. Processes 5 and 6 are always associated with ageing and are important with both alumina and chromia.

Finally, the occurrence and significance of mercury vapour adsorption should be noted. Chromium dioxide, and hydrous chromium oxides calcined (or outgassed) at temperatures between about 150° and 450°C, were found to exhibit a high affinity for mercury vapour. In the case of chromium dioxide, the adsorption of water vapour was significantly affected by the irreversible adsorption of mercury vapour on the surface. It seems likely that such effects may have passed unnoticed in earlier work. For example Taylor<sup>19</sup> studied the chemisorption of pure oxygen, at 25°C, on the surface of a chromium oxide gel previously activated at 400°C; the system was then evacuated to  $5 \times 10^{-5}$  torr with the aid of a mercury diffusion pump. Mercury was also employed as a manometric fluid in the system. It was observed that the weight of the catalyst continued to rise during the evacuation, a phenomenon that was tentatively ascribed to the desorption of water from the walls of the system. Furthermore, the weight increase was arrested when the system was flushed with pure helium at a pressure of 100 torr, but was reinstated when the system was re-evacuated to  $10^{-5}$  torr. In the light of the present work, it seems likely that Taylor was observing a weight increase due to mercury vapour adsorption by the activated chromia.

It is evident that in adsorption studies of vapours on chromium oxide, and perhaps other transition metal oxide gel systems, one is not entitled to assume that mercury vapour adsorption is negligible in the case of an adsorbent exposed to the vapour.

SILICA SPRING BALANCE PROGRAM. GENERAL USE. TRANSDUCER AND DVM  
PRESSURE MEASUREMENT. FOR BALANCE BUILT BY F.S.BAKER, UXBRIDGE 72'  
BEGIN

COMMENT. THIS IS A GENERAL PROGRAM FOR WATER ADSORPTION AT 25.0 C  
FOR COMPUTING THE ADSORPTION DATA FROM THE REBUILT, RECALIBRATED  
SILICA SPRING BALANCE. PRESSURE MEASUREMENT IS BY THE TRANSDUCER  
AND DIGITAL MILLI-VOLTMETER. THE TRANSDUCER, DVM AND SPRING WERE  
CALIBRATED DURING MARCH 1972 BY F.S.B. TRANSDUCER (SERIAL NO 1574)  
CALIBRATION FACTOR = 0.12411; SPRING CALIBRATION FACTOR = 10.7776.  
THIS PROGRAM CONVERTS READINGS FROM THE SILICA SPRING BALANCE IN  
LAB NO 120 TO P, LN P, P/PO, P/V(P0-P), TOTAL WEIGHT INCREASE AND  
TOTAL WEIGHT INCREASE PER GRAM. THE DATA TAPE SHOULD BE AS FOLLOWS.

1. NUMBER OF FIXED POINTS 2. FIRST FIXED POINT 3. NUMBER OF  
READINGS FOR THAT FIXED POINT 4. SPRING EXTENSION READINGS  
5. SECOND FIXED POINT ETC., 6. SAMPLE WEIGHT, SAMPLE DENSITY,  
BUCKET WEIGHT, INITIAL SPRING POSITION, P0 VALUE, THEN DIGITAL  
VOLTMETER READINGS IN MILLIVOLTS TERMINATED BY 0. THE PROGRAM  
PRINTS OUT P, LN P, P/PO, P/V(P0-P), TOTAL WEIGHT INCREASE,  
WEIGHT INCREASE PER GRAM, THE BET XM AND C VALUES TOGETHER WITH  
THE SURFACE AREA, SLOPE, INTERCEPT AND REGRESSION COEFFICIENT.

Calibration Factors

SVP of water at 25.0°C = 2.3756 cm of Hg at 0°C  
 = 2.3853 cm of Hg at 22.5°C

Quartz spring calibration factor = 10.7776 mg/cm at 26.5°C

Silicone oil manometer calibration factor:

= 0.07753 cm of Hg at 0°C per cm of oil at 22.5°C  
 = 0.07785 cm of Hg at 22.5°C per cm of oil at 22.5°C

Transducer/DVM calibration factor:

= 0.12411 cm of Hg at 0°C per mV  
 = 0.12462 cm of Hg at 22.5°C per mV

Serial No. of Transducer = 2574

Serial No. of DVM = 4451

MERCURY VAPOUR ADSORPTION DATA

Water Vapour Adsorption on Chromium Dioxide

Systematic mercury vapour adsorption experiment (FSB 23) constructed as follows:

- 23-1 - Hg vapour completely absent during both outgassing and isotherm.
- 23-2 - Hg vapour present during outgassing but absent during isotherm.
- 23-3 - Hg vapour present, both during outgassing and isotherm.
