1**Abstract**

2

3Rugby Union is a complex, high-intensity intermittent collision sport with emphasis placed on players 4possessing high lean body-mass and low body-fat. After an 8-12 week pre-season focused on physiological 5adaptations, emphasis shifts towards competitive performance. However, there are no objective data on the 6physiological demands or energy intake (EI) and expenditure (EE) for elite players during this period. 7Accordingly, in-season training load using GPS and session RPE (sRPE), alongside six-day assessments of 8EE and EI were measured in 44 elite Rugby Union players. Mean weekly distance covered was 7827 ± 954 9m and 9572 ± 1233 m with a total mean weekly sRPE of 1776 ± 355 and 1523 ± 434 AU for forwards and 10backs, respectively. Mean weekly EI was 16.6 ± 1.5 and 14.2 ± 1.2 MJ, and EE was 15.9 ± 0.5 and 14 ± 0.5 11MJ. Mean carbohydrate intake was 3.5 ± 0.8 and 3.4 ± 0.7 g.kg^{-1} body mass, protein intake was 2.7 ± 0.3 and 12$2.7 \pm 0.5$ g.kg^{-1} body mass, and fat intake was 1.4 ± 0.2 and 1.4 ± 0.3 g.kg^{-1} body mass. All players who 13completed the food diary self-selected a 'low' carbohydrate 'high' protein diet during the early part of the 14week, with carbohydrate intake increasing in the days leading up to a match, resulting in the mean EI 15matching EE. Based on EE and training load data, the EI and composition seems appropriate, although 16further research is required to evaluate if this diet is optimal for match day performance.

19 **Introduction**

20   Rugby Union (RU) is a high impact collision sport played over 80 minutes, which is split into two

21 forty-minute halves. RU is characterized by frequent bouts of high intensity exercise such as sprinting,

22 accelerations, tackling, scrummaging, rucking and mauling (Roberts, Trewartha, Higgitt, El-Abd, & Stokes,

23 2008) and is predominantly aerobic in nature. Players are classified as either forwards or backs, with the

24 forwards tending to be heavier and stronger compared with the backs who tend to be leaner and faster

25 (Duthie, Pyne, & Hooper, 2003). During a typical rugby union game, players will cover 68 m·min^{-1} (Cahill,

26 Lamb, Worsfold, Headey, & Murray, 2013), which is much lower than locomotive rates described for

27 Australian football, ~123 m·min^{-1}; (Kempton, Sullivan, Bilsborough, Cordy, & Coutts, 2015), rugby league,

28 ~85 m·min^{-1} (Waldron, Twist, Highton, Worsfold, & Daniels, 2011) and soccer, ~104 m·min^{-1} (Varley,

29 Gabbett, & Aughey, 2014). Activities such as rucking, mauling, scrummaging and lineouts are likely

30 explanations for the lower locomotive rates observed between rugby union and other football codes.

31   A typical in-season in rugby union lasts approximately 34-36 weeks followed by 3-6 weeks of rest

32 time depending on whether play off stages are reached. The central focus of the in-season is peak

33 performance during competition. Strategies to prepare for, and optimally recover from competition are

34 therefore the objectives of this period with emphasis also placed on the maintenance of body composition to

35 values attained at the end of pre-season (Bradley et al., 2014). An understanding of players' day-to-day

36 training and energy requirements is essential to avoid residual fatigue (Gamble, 2006), in the identification of

37 appropriate recovery strategies, and to determine appropriate training loads to maximise performance

38 (Fowles, 2006). While researchers have investigated the movement patterns and physiological demands of

39 matches (Cunniffe, Proctor, Baker, & Davies, 2009; Duthie et al., 2003), there are no data currently available

40 on the internal and external demands, or the energy intakes and expenditures of elite rugby union players

41 during the in-season period.

42   The daily nutritional intake of an athlete should meet the fuel requirements of high training

43 intensities and competition, promote optimal recovery, and provide essential micronutrients for general

44 health and well being. Data have previously been published on the nutritional intakes of elite rugby union

45players during training (Bradley et al., 2014); however, these data looked specifically at the pre-season with

46training and nutrition tailored towards physiological adaptation. Transition from the pre-season to in-season

47shifts focus from physiological adaptation to competition preparation and recovery, with training

48programmes modified to reflect this transition and consequently nutritional intakes must also be modified to

49meet training and competition requirements. To the authors' knowledge, no data evaluating the nutritional

50intake of elite rugby union players during in-season training is available and, as such, evidence-based

51recommendations regarding the energy requirements to fuel a rugby player's training plan in-season are

52currently lacking.

53 For team sports such as Rugby Union, daily carbohydrate (CHO) intakes have traditionally been

54high. However, in recent years many rugby players have adopted a lower CHO diet during the beginning of a

55training week in attempts to maintain or reduce body fat (Morton, Robertson, Sutton, & MacLaren, 2010)

56maximize adaptations to training (Morton et al., 2009). Thereafter, intakes are increased in the day(s) leading

57up to a match to maximize glycogen stores. For example, Bradley et al. (2014) reported carbohydrate intakes

58of 3.3 ± 0.7 and 4.1 ± 0.4 g·kg^{-1} for forwards and backs, respectively, during a rugby union pre-season. These

59data are similar to those reported in professional soccer players (3.4 g·kg^{-1}[Maughan, 1997]), but lower than intakes

60generally suggested for team sports engaged in moderate exercise programmes where values of 5-7 g·kg^{-1}

61have been recommended (Burke, Hawley, Wong, & Jeukendrup, 2011). To date however there are no data

62on typical macronutrient intakes of elite rugby players during in-season training.

63 To implement a valid nutritional plan it is important to understand the day-to-day energy

64requirements of an athlete. Due to the physicality of rugby, the measurement of energy expenditure (EE) is

65somewhat difficult given that many of the tools available would not be suitable either through danger to the

66athlete or to the equipment. Currently the doubly labelled water (DLW) stable isotope method is considered

67the gold standard for measuring EE (Ekelund, Yngve, Westerterp, & Sjostrom, 2002), despite not allowing

68day-to-day comparisons to be made. Multi-sensor, wearable body monitoring technology might therefore

69provide an effective means of assessing daily EE in rugby players.

70   Although Bradley et al., (2014) has reported the training demands and nutritional intakes of an elite

71rugby union pre-season, to date there are no studies showing the training demands and energy intakes and

72expenditures during the competitive season. Due to the importance of competitive performance, these data

73would be of great significance to the strength and conditioning professional to allow informed decisions to

74be made with regards to players' diets during this competitive period. Therefore the aim of this study was to

751) characterize the weekly external and internal training demands of a rugby union in-season using GPS

76technology and session RPE (sRPE); 2) evaluate the typical energy intakes and macro- and micronutrient

77intakes, and 3) analyse the energy expenditures of elite rugby union players during the in-season period.

78

79**Methods**

80*Study design*

81Players began in-season training at the rugby club after a 12-week pre-season period. The first week of in-

82season training started in early October and this was classed as Week 13. Players then began 3 x 12-week in-

83season training macrocycles as prescribed by the club. During the 'in season', running activity was

84monitored at every training session using GPS technology and session RPE (sRPE) was used to quantify the

85overall training load. Body composition assessment and food diaries were completed as part of the club's

86normal in-season training regime and were routinely performed by all of the players who were therefore

87familiar with each test. During weeks 32 (n = 5), 33 (n = 5) and 34 (n = 4) of the season 14 players wore

88Senseware armbands and completed a detailed seven-day food diary to assess energy expenditure and

89nutrient intake. A typical in-season training week is depicted in Table 1.

90

91*Participants*

92   Forty-four elite rugby union players currently playing in the European Rabo Direct Pro 12 league

93volunteered for this study. Based on playing position, these were divided in sub-groups of forwards (n= 24)

94and backs (n = 20). The sample population was collected on the first team squad that included 12 current

95international players and four British & Irish Lions. Of the 44 players that completed the 'in-season' season,

96all completed sRPE and anthropometric assessments every 8-weeks. All 44 players also trained wearing the

97GPS units at some stage during the competitive season although only 17 players wore units during any one

98training session due to the availability of equipment. Only 14 players (seven forwards and seven backs) from

99the squad of 44 players completed the energy expenditure and dietary analysis due to time constraints on the

100players and limited equipment. A summary of the participant characteristics can be seen in Table 2. The local

101ethics committee of Liverpool John Moores University granted ethical approval for the study. All

102participants provided written informed consent before commencement of the study and all participants were

103greater than 18 years of age (age range 21-34 years old).

104**Procedures**

105*Quantification of weekly external and internal training load*

106   Distances covered by forwards and backs during field sessions over four 'typical' in-season weeks

107were assessed using GPS technology. Seventeen GPS units were rotated around the team ensuring that all

108positions were accounted for during each training session. Movements were recorded using a Minimax S4

109GPS unit (Catapult Innovations, Melbourne, Australia) sampling at a frequency of 10 Hz. A recent review

110has demonstrated that 10 Hz units provide more accurate and reliable data compared with lower sampling

111frequency devices (Cummins, Orr, O'Connor, & West, 2013). Indeed, the 10 Hz units used in this study are

112two to three times more accurate at detecting changes in velocity, and up to six-fold more reliable than

113devices sampling at 5 Hz (Varley, Fairweather, & Aughey, 2012). The CV of these units across a range of

114speeds have been reported as 3.1 to 8.3% at a constant velocity, 3.6 to 5.9% for accelerations and 3.6 to

11511.3% for decelerations (Varley et al., 2012). GPS units were used to collect data on total distance (m) and

116relative distance covered in standing (0-2.0 $m \cdot s^{-1}$), walking (2.0-4.4 $m \cdot s^{-1}$), jogging (4.4- 5.6 $m \cdot s^{-1}$), high-

117speed running (5.6-7.5 $m \cdot s^{-1}$) and sprinting (7.5 + $m \cdot s^{-1}$) based on the clubs in-house classification of speed

118zones. Tri-axial accelerometers and gyroscopes sampling at 100 Hz, also provided data on the number of

119maximal accelerations (>5 $m \cdot s^{-2}$), physical collisions, and repeated high-intensity efforts (RHIE). A RHIE

120was defined as three consecutive efforts (sprint, contact or acceleration) each separated by less than 21 s

121(Gabbett, Wiig, & Spencer, 2013). The unit was worn in a fitted neoprene vest, on the upper back of the

122players. Quantification of gym and pitch session training loads was also assessed using the session rating of

123perceived exertion (sRPE), (Foster et al., 2001). Using a modified 10-point Borg Scale (Borg, Hassmen, &

124Lagerstrom, 1987) individual RPEs were provided by each player ~20 minutes after a training session from

125which sRPE (AU) was calculated by multiplying RPE by total training time or total number of repetitions x

126RPE for field or gym sessions, respectively.

127

128**Energy intake (EI)**

129   A six-day food diary was used to analyze the macronutrient and micronutrient and reported as days

130away from a match (Game day -5, -4, -3, -2, -1 and game day +1) in megajoules (MJ). This time period is

131believed to provide reasonably accurate and precise estimations of habitual energy and macronutrient

132consumption (Braakhuis, Meredith, Cox, Hopkins, & Burke, 2003). Players were instructed to document a

133complete account of all foods and fluids ingested over a six-day period, with careful attention to detail such

134as timing of intakes, volumes and quantities, and specific brand names where possible. The nutrient intakes

135were calculated using Nutritics professional diet analysis software (Nutritics LTD, Ireland) to obtain energy

136and macro- and micronutrient composition. Each athlete's individual physical activity was known from the

137weekly training schedule.

138

139**Energy expenditure (EE)**

140SenseWear Pro2 wearable armband (SWA; BodyMedia, USA) was used to assess the energy expenditure of

141the players. Five armbands were rotated between the athletes over a three-week period during the same

142macrocycle. Athletes wore the armband 24-hours a day for six consecutive days, except during water or

143heavy contact based activities. The SWA were removed on match day to avoid disruption during match

144preparations and also due to contacts sustained during competition. Studies have demonstrated that the SWA

145provides accurate results for energy expenditure during low-to-moderate intensity physical exercise with a

146threshold for accurate measurements at intensities of around ten METs (Drenowatz & Eisenmann, 2011).

147However, given that the compendium of physical activities indicates an intensity of 8.3 METs for rugby

148union competition (Ainsworth et al., 2011), the use of SWA for rugby union appears appropriate. The

149armband was worn on the back of the upper right arm and utilized a two-axis accelerometer, heat flux sensor,

150galvanic skin response sensor, skin temperature sensor, and a near-body ambient temperature sensor to

151capture data leading to the calculation of energy expenditure. SenseWear computer software (BodyMedia,

152USA) was used to analyze player energy expenditure and reported as days away from competition (Game

153day -5, -4, -3, -2, -1 and game day +1) in MJ. 07:00 was chosen as the 24-hour start point determined by

154average player wake-up time according to the clubs daily monitoring.

155Statistical analysis

156   Statistical tests were performed using the Statistical Package for the Social Sciences (SPSS, Version

15718). All data were initially checked for normality. Differences between positional groups in mean weekly

158external (GPS) and internal (sRPE) training load measures were assessed using separate independent *t*-tests.

159Differences between EE and EI for forwards and backs were analyzed using a two-way mixed design

160analysis of variance (ANOVA). Differences between macronutrient intakes across time were analyzed using

161a one-way repeated measures ANOVA. If Mauchley's test of sphericity indicated a minimum level of

162violation, as assessed by a Greenhouse Geisser epsilon (ε) of ≥ 0.75, data were corrected using the Huynh-

163Feldt ε. If Mauchley's test of sphericity was violated (Greenhouse Geisser ε of ≤ 0.75) data was corrected

164using the Greenhouse Geisser ε (Field, 2007). If any significant *F* values were observed least significant

165difference (LSD) tests were performed *post hoc* to determine where any significant differences occurred. An

166alpha value of $P \leq 0.05$ was utilized for all tests. All data are expressed as mean (SD).

167

168Results

169

170*Weekly external and internal training load*

171The backs had significantly higher mean weekly total distances ($P<0.0005$) than forwards, comprising more

172standing ($P=0.002$), walking ($P=0.002$), jogging ($P<0.0005$) high-speed running ($P<0.0005$) and sprinting

173($P=0.004$). The backs performed more accelerations ($P=0.0005$) but less contacts ($P<0.0005$) than forwards

174during a training week. However, there was no difference in the weekly number of RHIE during training

175between the forwards and backs ($P=0.15$). The total weekly sRPE was not different between positions

176(P=0.13), with values of 1776 (355) AU and 1523 (434) AU for forwards and backs, respectively. All

177external and internal training load data are presented in Table 3.

178

179**Energy intake and expenditure**

180   Energy intake (EI) and expenditure (EE) over the six assessment days, presented in megajoules

181(MJ), are shown in Figure 1. Mean EI and EE was 16.6 (1.25) MJ and 15.9 (0.53) MJ, and 14.2 (1.2) MJ and

18214 (0.47) MJ for forwards and backs, respectively. There was a significant time x condition interaction for EI

183and EE intake over the course of the training week ($P<0.0005$). *Post hoc* analysis confirmed that there was a

184significant change in EI ($P<0.0005$) and EE ($P<0.0005$) intake over the week. EI was significantly lower

185than EE on GD-5 ($P=0.022$) and GD-4 ($P=0.002$), and significantly higher on GD-1 ($P=0.002$) and GD+1

186($P=0.014$) for the forwards. EI was significantly lower than EE on GD-5 ($P=0.01$), GD-4 ($P<0.0005$) and

187GD-3 ($P=0.042$), and significantly higher on GD-1 ($P<0.0005$) and GD+1 ($P<0.0005$) for the backs. EE

188($P=0.024$) and EI ($P=0.046$) were significantly different from GD-5 for forwards. EE ($P=0.033$) and EI

189($P=0.045$) were significantly different from GD-5 for the backs on GD-2 and GD-1 respectively. The

190forwards elicited significantly higher weekly EI ($P=0.0006$) and EE ($P=0.002$) than the backs.

191

192**Macronutrient profile**

193   Macronutrient intakes from six-day food diaries (presented in g·kg^{-1} body mass) can be seen in

194Figure 2. There was no difference ($P=0.53$) in mean weekly CHO intake between the forwards and backs,

195with values of 3.5 (0.8) g·kg^{-1} (38% total calories) and 3.4 (0.7) g·kg^{-1} (37% total calories), respectively.

196Similarly, mean weekly protein intake between the forwards was 2.7 (0.5) g·kg^{-1} (30% total calories)

197compared to backs 2.7 (0.3) g·kg^{-1} (30% of total calories) and was not different (*P*=0.97). Mean fat intake

198was also similar between positions (*P*=0.8), with values of 1.4 (0.2) and 1.4 (0.3) g·kg^{-1} (32 and 33% of total

199calories) for forwards and backs, respectively.

200   For forwards CHO intake changed during the week (*P*=0.004), with *post hoc* analysis confirming a

201higher CHO intake on GD-4 (*P*=0.036) and GD-1 (P=0.008) compared with GD-5 (the first day of the

202week). This coincided with changes in protein intake during the same period (*P*=0.008), which comprised an

203increase in protein intake on GD-1 (*P*<0.0005) and GD+1 (*P*=0.049) compared with GD-5. Fat intake for

204forwards did not change during the week (*P*=0.093). CHO intake also changed during the week for backs

205(*P*=0.003), with a higher CHO intake on GD-2 (*P*=0.003) and GD-1 (*P*=0.014) compared with GD-5.

206Similarly, there was a significant difference in protein intake across the week (*P*<0.0005), with *post hoc*

207analysis confirming an increase in protein intake on GD-4 (*P*=0.045) and GD-2 (*P*=0.026), GD-1 (P<0.0005)

208and GD+1 (*P*=0.004) compared with GD-5. Fat intake did change during the week (*P*=0.003), whereby

209values increased on GD-1 (P=0.0005) and GD+1 (P=0.014) compared with GD-5.

210

211**Micronutrient profile**

212   Daily average micronutrient intakes for the squad taken from six-day food diaries can be seen in

213Table 3. Mean micronutrient intakes met and exceeded RDA's for physical activity for all minerals and

214vitamins apart from vitamin K which fell 24µg under this RDA but met and exceeded the RDA for general

215health.

216**Discussion**

217   The aims of the present study were 1) to quantify the external and internal training loads during a

218typical in-season training week for elite rugby union players and 2), evaluate the EI and EE of elite rugby

219players during the competitive season. It is reported for the first time that distances of ~8-10 km are covered

220by elite rugby union forwards and backs during a typical in-season week, which equates to a total weekly

221internal load of ~1500 - 1800 AU. We also report that the daily EE and EI of elite rugby union players

222during this same training period are 14-16 and 14-17 MJ, respectively. Our data also demonstrate

223considerable variation in the day-to-day energy EE with peak EE occurring early in the week and tapering

224down in preparation for competition. Interestingly, although EI also varied on a day-to-day basis, the

225temporal pattern did not match EE with EI being the lowest when EI was the highest and EI increasing in

226preparation for game-day. This inverse pattern may be essential to allow players to load with carbohydrate in

227preparation for game day without excessive total energy intake during the week which over the course of the

228season may lead to unwanted gains in body fat.

229   GPS analysis of the training sessions revealed that weekly total distances of 7.8 ± 1 km and 9.6 ± 1.2

230km were covered by forwards and backs, respectively. These distances were achieved over a five-day period

231as players were given rest days before and after game day. Backs covered more distance in all speed zones,

232along with a greater number of maximal accelerations but less collisions than forwards. These differences

233probably reflect the contrasting training regimes between rugby union forwards and backs. For example,

234forwards engage in more activities that involve tackling, rucking, mauling and line-outs, while the backs

235perform more acceleration and ball-in-hand running play. Interestingly, the frequency of RHIE was similar

236for positional groups despite clear differences in the movement characteristics of forwards and backs. This is

237probably explained by how the GPS software detects RHIE, which is defined as three consecutive efforts

238(sprint, contact or acceleration) each separated by <21 s (Gabbett et al., 2013). So, while both positional

239groups perform a similar number of high intensity bouts, the movement actions that determine the RHIE are

240likely to be different between forwards and backs.

241   Weekly sRPE of ~1778 and ~1522 AU were observed for forwards and backs. These values are

242lower than those seen in an elite rugby union players during pre-season (~2900-3400 AU; (Bradley et al.,

2432014) and reflects the periodization of a rugby training programme. Indeed, lower training loads during the

244competitive season are deliberately administered to allow optimal recovery and for players to peak around

245games, whereas higher training loads are used in the pre-season when physiological adaptation is key and

246competition not a priority. Despite experiencing a higher external load during a training week, forwards did

247exhibit a higher internal load (sRPE) than backs. While sRPE is an appropriate measure of training load in

248rugby players (Lovell, Sirotic, Impellizzeri & Coutts, 2013), variances in perceptual responses will be

249influenced by several internal and external factors. Here, differences in perceived weekly load between

250positions is probably explained by higher number of collisions experienced in training by forwards. Indeed,

251collisions have been purported to contribute significantly to the variance in sRPE between players during

252rugby training (Lovell et al., 2013). Our findings reaffirm the complexity of factors influencing perceptual

253measures of training load and the necessity to adopt both internal and external measures to monitor training

254in rugby.

255

256   Energy expenditure changed during the training week for both forwards and backs, with higher EE

257elicited during the first four days of the training week and significantly reducing around competition (Figure

2581). The six-day food diary also revealed changes in EI during the training week for both forwards and backs,

259following an inverse trend to EE (Figure 1). Fluctuations in EI represent lower intakes during the first 4-

260days of the training week concurrent with higher EE. This is likely attributed to rugby players attempting to

261reduce or maintain body fat before significantly increasing EI by increasing carbohydrate intake leading up

262to competition in an attempt to increase muscle glycogen stores. It is possible that players might have

263intentionally (Bingham, 1987; Deakin, 2000) underreported their total energy intake. However, since

264approximately half of the daily nutrition consumed was observed by the authors, including a meal provided

265on arrival at the club, whey protein before and after training, and a lunch provided post-training, this seems

266unlikely.

267   Although our data indicate lower training loads and total distances compared to those of rugby union

268players in pre-season (Bradley et al., 2014), mean EI was slightly higher in-season for both forwards (15.8

269cf. 14.8 MJ) and backs (14.1 cf. 13.3 MJ). We attribute this to players increasing total EI in the days leading

270up to competition. It must be stressed, however, that the pre-season study used a 24-hour dietary recall,

271which might compromise the comparison between the two studies. Interestingly, while EE and EI differ on a

272day-to-day basis, mean EE and EI were surprisingly similar for forwards (16.6 and 15.8 MJ) and backs (14.2

273and 14.1 MJ). This suggests that although athletes might fail to meet energy requirements on some training

274days, light training days or rest days before a game correspond with players increasing EI (mainly through

275CHO increases) to maximise muscle glycogen stores. The lower EI early in the week may be necessary to

276prevent a positive energy balance that over the course of a season could result in unwanted gain in body-fat.

277   Interestingly, all the players in the present study self-selected what could be classed as a low CHO /

278high protein diet for the first four days of the training week, and increased CHO intake the day before game

279day. This practice contravenes earlier recommendations for CHO intakes of 8-12 g·kg^{-1} (Burke, Kiens, &

280Ivy, 2004), as well as more recent guidelines that state values of 6-10 g.kg^{-1} (Burke et al., 2011) for athletes

281engaged in moderate to high intensity exercise lasting 1-3 hours. Therefore it could still be argued that

282players in the current study failed to meet the daily recommended CHO requirements. However, current

283guidelines also clearly state that CHO intakes should be designed to meet the fuel requirements of the

284training programme (Burke et al., 2011). We therefore propose that players are attempting to match

285carbohydrate intakes with training demands such that CHO intakes of 4-6 g·kg^{-1} body mass are not '*low*' and

286are in fact '*appropriate'* for this group of athletes providing CHO intake is increased in the day before and

287after a game. Given that CHO intake altered significantly over the week and was the main macronutrient

288contributor in the daily EI fluctuations, we suggest that the players are indeed following the recent guidelines

289and matching their CHO intakes to the fuel requirements of the training programme. Players could be using

290some periods of lower CHO intake to enhance training adaptions (Morton et al., 2009) and for the

291maintenance of low body fat (Morton et al., 2010), yet still increasing glycogen stores in preparation for

292competition (Hawley, Schabort, Noakes, & Dennis, 1997). Interestingly, backs utilized a two-day load

293compared with a single day by the forwards. This might reflect 1) a lower CHO intake in the first three days

294to reduce body fat or 2) a purposeful attempt to increase glycogen more aggressively than the forwards due

295to the varying physiological challenges of the positions.

296

297   This cycling of CHO intake reported in the present study might be a suitable way of maintaining

298weekly energy balance yet still allowing sufficient CHO intake as to increase muscle glycogen and thus

299enhance match day performance. Playing performance is however unquestionably improved with a high

300CHO diet leading up to team sport based games (Hawley et al., 1997; Jardine, Wiggins, Myburgh, & Noakes,

3011988), and although we have reported a significant increase in CHO intake in the days leading up to

302competition, the intakes reported in this study are still below recommended CHO intake for elite athletes

303(Burke et al., 2011). It is still possible that such intakes are not optimal for match day performance and future

304studies should now attempt to measure pre and post game muscle glycogen demands in elite rugby.

305   Protein intakes of 2.7 g·kg^{-1} reported in the present study was similar to values reported in an elite

306rugby union pre-season (2.5 and 2.6 g g·kg^{-1}; (Bradley et al., 2014). These intakes are much higher than the

3071.4 g·kg^{-1} reported in soccer (Maughan, 1997) and 1.8 g·kg^{-1} described for strength based athletes (Tipton &

308Wolfe, 2004). However, to maintain muscle mass whilst decreasing body fat, protein intakes of 2.5 g·kg^{-1}

309have been recommended (Mettler, Mitchell, & Tipton, 2010) suggesting that the protein intakes in this study

310might in fact have been appropriate. Moreover, the athletes in the present study would have deliberately

311timed protein intakes around training in an attempt to maximise muscle protein synthesis, which might

312explain in these higher protein intakes. The backs significantly increased protein intake from four days

313before the match. However, this higher protein intake early in the week could simply be the lower CHO

314intake in this group early in the week with protein being used as a CHO substitute. Dietary fat intakes in the

315present study were approximately 1.4 g·kg^{-1} body mass, slightly higher than the current recommendations

316(Bishop, Blannin, Walsh, Robson, & Gleeson, 1999) but similar to those seen in elite Australian athletes

317(Burke et al., 2003). Consumption of oily fish, meats, and the use of cooking oils accounts for most of the fat

318intake, and although intakes were high, given the importance of healthy fats for performance it would be

319unwise to suggest a reduction in dietary fat intake.

320   Micronutrient intakes met and exceeded the RDAs for physical activity (Whiting & Barabash, 2006)

321for all minerals and vitamins apart from vitamin K, which fell slightly below the guidelines for physical

322activity (-24 µg, less than 1 small stem of broccoli, see Table 3). These values did, however, meet and

323exceeded the RDA for general health. Although supplement use is common practice in sport with 40 to

324100% of athletes using supplements (Baume, Hellemans, & Saugy, 2007), it seems inappropriate to

325supplement the athletes in this study with a multi-vitamin or a mega dose single vitamin supplement given

326the lack of any micronutrient deficiencies (Whiting & Barabash, 2006). The exception to this could be

327vitamin D with recent data suggesting the current RDA for general health is too low (Holick & Chen, 2008)

328and deficiencies are commonplace in many athletes (Close et al., 2013). Future studies might wish to

329investigate blood vitamin D concentrations in elite rugby players to further investigate this hypothesis.

330   Although this study provides novel data for the literature it is not without limitations, many of which

331are a direct consequence of collecting data from elite athletes outside of the controlled laboratory

332environment. These data were collected on a single professional rugby team, which may not accurately

333represent every rugby club, and therefore future studies might choose to collect data from a variety of teams.

334Finally, energy expenditure was not assessed on game day due to dangers associated with the use of the

335utilized EE technology in contact sports where physical collisions could cause damage to both player and

336equipment. The use of DLW over the course of a seven-day training week should now be performed. Energy

337intake was not assessed on game day to avoid adding to player's game day stresses while performing at an

338elite standard.

339

340   To conclude, for the first time this study has attempted to quantify the training demands and assess

341energy expenditure, intake and micronutrient intakes of elite rugby players during the in-season. We report

342that mean energy intake and expenditure followed an inverse trend, with expenditure exceeding intake during

343the first four-days of the training week and then reversed in the day leading up to competition with intake

344exceeding expenditure. This is likely due to a heavier training load and players desire to maintain body fat

345during the beginning of the training week, followed by a decrease in training load and increase in CHO

346intake leading up to competition in order to maximise glycogen stores. Interestingly, mean energy intake

347exceeded expenditure for both forwards and backs despite CHO consumption falling short of recommended

348guidelines. This is likely attributable to relatively low training loads and running distances that attempt to

349provide sufficient stimulus to maintain player strength and fitness during the in-season, while reducing

350residual fatigue and promoting competition preparation. Alongside no micronutrient deficiencies, the current

351dietary practices of these elite rugby players are sufficient to fuel training during the in-season, providing

352energy intake and CHO are increased leading up to a match. However, whether this intake is optimal for

353game day performance remains unknown.
