June 19, 2015

Abstract

This paper studies power indices based on average representations of a weighted game. If restricted to account for the lack of power of dummy voters, average representations become coherent measures of voting power, with power distributions being proportional to the distribution of weights in the average representation. This makes these indices representation-compatible, a property not fulfilled by classical power indices. Average representations can be tailored to reveal the equivalence classes of voters defined by the Isbell desirability relation, which leads to a pair of new power indices that ascribes equal power to all members of an equivalence class.

Keywords: average representation; power index; proportionality between weights and power

1 Introduction

We commonly represent a weighted voting game using an integer-valued vector of voting weights (w_1, w_2, \dots, w_n) and an integer quota q . The vector of weights conveys the number of votes each of the n voters commands. The game involves each voter casting all her votes as a bloc either for or against a motion. The motion is passed if the total number of votes cast by the voters in favor of the motion is greater than or equal to q ; otherwise, the motion is rejected. In this paper, we introduce two new measures of power for weighted games, and study the properties of a family of representation-compatible power indices that now includes four measures.

Written as $[q; w_1, w_2, \dots, w_n]$, a representation conveys the set of winning coalitions of the weighted game. For example, winning coalitions for a game represented by $[51; 47, 46, 5, 2]$ are

$$\{\{1, 2\}, \{1, 3\}, \{2, 3\}, \{1, 2, 3\}, \{1, 2, 4\}, \{1, 3, 4\}, \{2, 3, 4\}, \{1, 2, 3, 4\}\}.$$

This set allows us to compute the voting power of the voters. A voter is critical to a winning coalition if the coalition becomes a losing one should she withdraw her support. No voter is critical in a coalition of all voters $\{1, 2, 3, 4\}$. The first voter is critical in $\{1, 2\}$, $\{1, 2, 4\}$, $\{1, 3\}$ and $\{1, 3, 4\}$. The largest three voters acting together can pass a motion, but none of them would be critical to the success of the coalition $\{1, 2, 3\}$. Since each of the three large voters are critical in exactly four winning coalitions, they should be equally powerful. The smallest voter

*Austrian Institute of Economic Research (WIFO), Austria. E-mail: serguei.kaniovski@wifo.ac.at.

†Department of Mathematics, University of Bayreuth, Germany. E-mail: sascha.kurz@uni-bayreuth.de.

is a dummy (Definition 2.4), because she is irrelevant to the success of any coalition. The above considerations suggest $(1/3, 1/3, 1/3, 0)$ as a plausible distribution of voting power. Note that the three voters are equally powerful despite their unequal weights. The distribution of weights $(0.47, 0.46, 0.05, 0.02)$ is markedly different from the distribution of power. This difference would decrease if we chose to represent the above game using $[51; 34, 33, 33, 0]$. It would completely disappear if we chose the rational-valued representation $[2/3; 1/3, 1/3, 1/3, 0]$.

Although the set of winning coalitions uniquely defines a weighted game, there are infinitely many representations consistent with any given set of winning coalitions. If we adhere to a total of 100 votes among three voters and a quota of 51, then there will be 8924 rational-valued weight distributions consistent with the power vector $(1/3, 1/3, 1/3, 0)$. If the quota itself is considered to be part of the specification, then there will be 79800 possibilities to represent the game. Scaling the quota and weights in any of these representations by the same factor would preserve the set of winning coalitions and consequently define the same weighted game.

Since any admissible representation defines the game, the multiplicity of representations has no bearing on the definition of a weighted game. The multiplicity poses a problem if we want to design a weighted game (a voting institution such as a parliament) with a given distribution of power or to compare the distribution of power to the distribution of weights. Whereas imposing additional criteria can reduce the number of feasible representations and even identify a unique appropriate representation in sufficiently small, weighted games¹, the multiplicity makes unclear which representation the power distribution should be compared to. The average representations can reasonably be compared to power distributions of various power indices, as they uniquely summarize the set of admissible representations.

The proportionality of power and weight has received significant attention in the literature. It has been noted that none of the classical power indices yield power distributions that coincide with weight distributions for all weighted games. The observation that the distribution of voting power is different from the distribution of voting weight has been one of the motivating factors behind the development of the theory of power measurement in weighted games (Felsenthal and Machover 2005). Two recent theoretical studies provide conditions for which the weight distribution and the power distribution coincide. These results are available for the Banzhaf index by Houy and Zwicker (2014) and the nucleolus by Kurz, Napel and Nohn (2014). An exception is the recently introduced Minimum Sum Representation Index (MSRI) index by Freixas and Kaniowski (2014), which is specifically designed to fulfill proportionality.

The average representations come very close to being valid measures of power for weighted games. If restricted to account for the lack of power of dummy voters, average representations become coherent measures of voting power, with power distributions being proportional to the distribution of weights in the average representation. Restricting the polytope implied by the set of minimal winning and maximal losing coalitions yields average representations that are dummy-revealing. These restricted average representations satisfy Freixas and Gambarelli's (1997) coherency criteria for power indices, which are essentially equivalent to the widely accepted 'minimal adequacy postulate' by Felsenthal and Machover (1998) (p. 222). These indices of voting power, called AWI and ARI, are based on restricted average representations that respect proportionality between power and weight (Kaniowski and Kurz 2015).

The above modification of an average representation suggests that we can endow the indices

¹We could minimize the total sum of integral voting weights to obtain a unique representation for $n \leq 7$, as in Freixas and Molinero (2009), or Freixas and Kurz (2014). For other options, see Application 9.9 in Crama and Hammer (2011).

with further qualities by tailoring the polytope. Restrictions based on the equivalence classes of voters defined by the Isbell desirability relation lead to another pair of power indices that ascribes equal power to all members of an equivalence class. The two new measure of voting power introduced in this paper are specifically designed to recognize the equivalence of voters. We thus propose two new power indices that respect proportionality between power and weight, are dummy-revealing as well as type-revealing. Together with AWI and ARI proposed in Kaniovski and Kurz (2015), the new type-revealing indices, called AWTI and ARTI, complete the family of representation-compatible power measures studied in this paper.

In the next section, we recall the preliminaries required to define representation-compatible power indices. Section 3 defines the indices, verifies their coherency as measures of power and discusses computational issues. The computation of representation-compatible indices involves the integration of monomials on highly-dimensional polytopes with rational vertices. The main drawback of these indices is the computational burden of numerical integration.² Section 4 first compares the power distributions generated by representation-compatible indices to power distributions according to the Banzhaf (1965) and Shapley and Shubik (1954) indices in small weighted games, and then discusses their vulnerabilities to certain anomalies, commonly referred to as voting paradoxes. Section 5 discusses some aspects of the integer-valued representations that have been recently used by Freixas and Kaniovski (2014) to construct a power index. It turns out that average representations and the MSRI are related. The final section offers concluding remarks and ideas for future research.

2 Notation and preliminaries

2.1 Simple games and weighted games

A (monotonic) simple game is the most general type of binary voting game.

Definition 2.1 *A simple game v is a mapping $v : 2^N \rightarrow \{0, 1\}$, where $N = \{1, \dots, n\}$ is the set of voters, such that $v(\emptyset) = 0$, $v(N) = 1$, and $v(S) \leq v(T)$ for all $S \subseteq T \subseteq N$ (monotonicity).*

A subset $S \subseteq N$ is called a coalition of v . There are 2^n such coalitions in a simple game with n voters. A coalition S is winning if $v(S) = 1$, and losing if $v(S) = 0$. The monotonicity ensures that enlarging a winning coalition cannot make it a losing one, which is a sensible assumption.

A winning coalition S is called a *minimal winning coalition* if none of its proper subsets are winning. Similarly, a losing coalition T is called a *maximal losing coalition* if none of its proper supersets are losing. The set of minimal winning coalitions \mathcal{W}^m , or the set of maximal losing coalitions \mathcal{L}^m , uniquely defines a simple game. For the game represented by [51; 47, 46, 5, 2], the set of minimal winning coalitions is given by $\{\{1, 2\}, \{1, 3\}, \{2, 3\}\}$. We define a simple game using the set of minimal winning coalitions as opposed to the set of winning coalitions, as the former definition is more compact.

A weighted game is a simple game that admits a representation $[q; w_1, w_2, \dots, w_n]$.

Definition 2.2 *A simple game v is weighted, if there exist real numbers $w_1, \dots, w_n \geq 0$ and $q > 0$, such that*

$$\sum_{s \in S} w_s \geq q \iff v(S) = 1,$$

²Programs for computing the indices are available from the authors upon request.

for all $S \subseteq N$. We write: $(N, v) = [q; w_1, \dots, w_n]$.

In this paper, we consider weighted games, as this type of binary voting games is most relevant to the applied power measurement and institutional design. A common institution that uses weighted voting for decision making is the shareholder assembly in a corporation. The voting weight of a shareholder equals the number of ordinary shares she holds. This example also includes voting by the member states in multilateral institutions such as the World Bank and the IMF. In the political arena, voting in parliaments can be viewed as a weighted game, provided party discipline is absolute. The frequently studied voting in the Council of Ministers of the EU can be viewed, with some simplification of the double-majority voting rule stipulated by the Lisbon Treaty, as a weighted game. In the examples above, the voting weights are non-negative integers. The conditions required for a simple game to be a weighted game have been studied extensively in the literature.³

2.2 Equivalence classes of voters

The equivalence classes serve two purposes. They partition the set of voters according to their effect on the decisiveness of coalitions. Any reasonable measure of voting power should, therefore, recognize the equivalence classes. Second, while each majority game has an infinite number of representations, the number of possible partitions of all games with a given number of voters is finite. The qualifier ‘for all games’ then stands for ‘all feasible partitions of players in classes’. Our comparisons between power indices presented in Section 4 were obtained using this set of games, where each game is defined by its minimum sum representation.⁴

Definition 2.3 *Given a simple game v , we say that two voters $i, j \in N$ are equivalent, denoted by $i \simeq j$, if we have $v(S \cup \{i\}) = v(S \cup \{j\})$ for all $S \subseteq N \setminus \{i, j\}$.*

The relation \simeq is an equivalence relation and partitions the set of voters N into, say t , disjoint subsets N_1, \dots, N_t – the equivalence classes of voters. Roughly speaking, adding voter i instead of voter j to any coalition S will have the same or better effect on its decisiveness, making i a more desirable addition for the voters comprising S . The following three types of voters deserve special attention.

Definition 2.4 *Given a simple game v , a voter $i \in N$ with $v(S) = v(S \cup \{i\})$ for all $S \subseteq N \setminus \{i\}$ is called a dummy.*

A dummy has no bearing on the success of a coalition she is a member of, and is, therefore, powerless.

Definition 2.5 *Given a simple game v , a voter $i \in N$ such that i is contained in all minimal winning coalitions is called a vetoer.*

Any voter in a minimal winning coalition is critical to the success of the coalitions. This means that a voter present in all minimal winning coalitions has the power of a veto.

Definition 2.6 *Given a simple game v , a voter $i \in N$ such that $\{i\}$ is the unique minimal winning coalition is called a dictator.*

³See, Taylor and Zwicker (1999). For a survey, see Chapter 9.8 in Crama and Hammer (2011).

⁴See, Freixas and Pons (2010).

Being a dictator is the strongest form of having a veto. A dictator has all the power, rendering all other voters dummies.

Let us now recall some well-known facts about representations of weighted games:

Lemma 2.7 *Each weighted game v admits a representation (q, w_1, \dots, w_n) with $w_1, \dots, w_n \geq 0$, $q > 0$, and*

- (1) $\sum_{i=1}^n w_i = 1$, $q \in (0, 1]$;
- (2) $\sum_{i=1}^n w_i = 1$, and $w_i = 0$ for all dummies $i \in N$;
- (3) $q \in \mathbb{N}$, $w_i \in \mathbb{N}$;
- (4) $q \in \mathbb{N}$, $w_i \in \mathbb{N}$, $w_i = w_j$ for all $i \simeq j$, and $w_i = 0$ for all dummies $i \in N$.

We call (1) a normalized representation, and (3) an integer representation. Whenever we have $w_i = w_j$ for all $i \simeq j$, we say that the representation is *type-revealing*. A representation with $w_i = 0$ for all dummies $i \in N$ is called *dummy-revealing*. Given a general (integer) representation, the problem of verifying that a voter is a dummy is coNP-complete (Theorem 4.4 in Chalkiadakis, Elkind and Wooldridge (2011)). The generating functions offer an efficient way of finding dummy players in weighted voting games (Bilbao, Fernández, Losada and López 2000).

2.3 Coherent power measures

Let \mathcal{S}_n denote the set of simple games on n voters, and $\mathcal{W}_n \subset \mathcal{S}_n$ the set of weighted games on n voters.

Definition 2.8 *A power index for $\mathcal{C} \in \{\mathcal{S}_n, \mathcal{W}_n \mid n \in \mathbb{N}\}$ is a mapping $g : \mathcal{C} \rightarrow \mathbb{R}^n$, where n denotes the number of voters in each game of \mathcal{C} .*

We define a vector-valued power index by defining its element g_i , the voting power of voter i . A power index should satisfy the following essential properties:

Definition 2.9 *Let $g : \mathcal{C} \rightarrow \mathbb{R}^{|N|} = (g_i)_{i \in N}$ be a power index for \mathcal{C} . We say that*

- (1) *g is symmetric if for all $v \in \mathcal{C}$ and any bijection $\tau : N \rightarrow \tau$ we have $g_{\tau(i)}(\tau v) = g_i(v)$, where $\tau v(S) = v(\tau(S))$ for all $S \subseteq N$;*
- (2) *g is positive if $g_i(v) \geq 0$ and $g(v) \neq 0$ for all $v \in \mathcal{C}$;*
- (3) *g is efficient if $\sum_{i=1}^n g_i(v) = 1$ for all $v \in \mathcal{C}$;*
- (4) *g satisfies the dummy property if for all $v \in \mathcal{C}$ and all dummies i of v we have $g_i(v) = 0$.*

Any positive power index g can be made efficient by rescaling: $g'_i(v) = g_i(v) / \sum_{i=1}^n g_i(v)$. Rescaling turns the Penrose-Banzhaf absolute measure into the Banzhaf index. The Banzhaf index and the Shapley-Shubik index have all the above properties.

In addition to the above properties, any reasonable measure of voting power should recognize the equivalence classes of voters. To formalize this property, we need the notion of desirability introduced in Isbell (1956):

Definition 2.10 Given a simple v , we write $i \succeq j$, if we have $v(S \cup \{i\}) \geq v(S \cup \{j\})$ for all $S \subseteq N \setminus \{i, j\}$ and say that voter i is at least as desirable as voter j .

We can have $i \succeq j$ and $j \succeq i$, if and only if $i \simeq j$. In this case, voters i and j are equivalent in the sense of belonging to the same equivalence class. We say $i \succ j$, if $i \succeq j$ and $i \not\simeq j$. In an arbitrary simple game, we can have $i \not\succeq j$ and $j \not\succeq i$. In this case, the two voters $i, j \in N$ are incomparable. To exclude this possibility, a class of games narrower than simple games but still more general than weighted voting games has been proposed by Isbell (1956) and elaborated in Taylor and Zwicker (1999).

Definition 2.11 A simple game v is called complete, if we have $i \succeq j$ or $j \succeq i$ (including both possibilities) for all voters $i, j \in N$.

Taylor and Pacelli (2008) offer a test of completeness. A simple game is complete if it is swap robust, or if a one-for-one exchange of players between any two winning coalitions S and T leaves at least one of the two coalitions winning. One of the players in the swap must belong to S but not T , and the other must belong to T but not S .

It is important to emphasize that all weighted games are complete, so that the \succeq -relation induces a complete, or total, ordering of the voters. Given a representation (q, w_1, \dots, w_n) , $w_i \geq w_j$ implies $i \succeq j$, and $w_i = w_j$ implies $i \simeq j$. The implication $i \succ j$ from $w_i > w_j$ is only valid if the given representation preserves types formed by the partition of voters according to the equivalence relationship.

Being simple, a complete game can be defined by the set of minimal winning coalitions. For complete games, however, a still more parsimonious definition based on shift-minimal winning and shift-maximal losing coalitions is available.

Definition 2.12 Let v be a complete simple game, where $1 \succeq 2 \succeq \dots \succeq n$, and $S \subseteq N$ be a coalition. A coalition $T \subseteq N$ is a direct left-shift of S whenever there exists a voter $i \in S$ with $i - 1 \notin S$ such that $T = S \setminus \{i\} \cup \{i - 1\}$ for $i > 1$ or $T = S \cup \{n\}$ for $n \notin S$. Similarly, a coalition $T \subseteq N$ is a direct right-shift of S whenever there exists a voter $i \in S$ with $i + 1 \notin S$ such that $T = S \setminus \{i\} \cup \{i + 1\}$ for $i < n$ or $T = S \setminus \{n\}$ for $n \in S$.

A coalition T is a left-shift of S , if it arises as a sequence of direct left-shifts. Similarly, it is a right-shift of S if it arises as a sequence of direct right-shifts. A winning coalition S such that all right-shifts of S are losing is called shift-minimal winning. Similarly, a winning coalition S such that all left-shifts of S are winning is called shift-maximal losing.

A complete game is uniquely defined by either the set of shift-minimal winning coalitions, or the set of shift-maximal losing coalitions. The minimal winning coalitions of the game [51; 47, 46, 5, 2] discussed in the introduction are $\{\{1, 2\}, \{1, 3\}, \{2, 3\}\}$, while the maximal losing coalitions are $\{\{1, 4\}, \{2, 4\}, \{3, 4\}\}$. In this example, all minimal and maximal coalitions are also shift-minimal and shift-maximal. This is not the case in general. The shift coalitions form subsets of the set of their respective winning and losing coalitions. For example, the maximal losing coalitions of the game [5; 3, 2, 2, 1] are given by $\{\{1, 4\}, \{2, 3\}, \{2, 4\}, \{3, 4\}\}$, yet only the former two coalitions are shift-maximal losing.

Definition 2.13 A power index $g : \mathcal{C} \rightarrow \mathbb{R}^{|N|} = (g_i)_{i \in N}$ for \mathcal{C} satisfies strong monotonicity if we have $g_i(v) > g_j(v)$ for all $v \in \mathcal{C}$ and all voters with $i \succ j$ in v .

According to Freixas and Gambarelli (1997), a power index is coherent if it satisfies the four properties of Definition 2.9 and is strongly monotonic. Strongly monotonicity ensures that the power index recognizes the equivalence classes of voters.

2.4 Representation-compatibility

In the next section, we introduce two power indices for weighted games that respects the proportionality of power and weight. We call such power indices *representation-compatible*.

Definition 2.14 *A power index $g : \mathcal{W}_n \rightarrow \mathbb{R}^n$ for weighted games on n voters is called representation-compatible if $(g_1(v), \dots, g_n(v))$ is feasible for all $v \in \mathcal{W}_n$.*

The existing power measures are not representation-compatible in general. For example, the Banzhaf index (BZI) and the Shapley-Shubik index (SSI) are representation-compatible for $n \leq 3$ only. Table 1 compares all the weighted games with up to three voters in minimum sum integer representations to the respective power distribution according to the two measures.

Table 1: Representation-compatibility of the BZI and the SSI for $n \leq 3$.

Game	BZI	SSI	Game	BZI	SSI
[1; 1]	[1; 1]	[1; 1]	[2, 1, 1, 0]	$[\frac{6}{6}, \frac{3}{6}, \frac{3}{6}, \frac{0}{6}]$	$[\frac{6}{6}, \frac{3}{6}, \frac{3}{6}, \frac{0}{6}]$
[1; 1, 0]	$[\frac{2}{2}, \frac{2}{2}, \frac{0}{2}]$	$[\frac{2}{2}, \frac{2}{2}, \frac{0}{2}]$	[1; 1, 1, 1]	$[\frac{2}{6}, \frac{2}{6}, \frac{2}{6}, \frac{2}{6}]$	$[\frac{2}{6}, \frac{2}{6}, \frac{2}{6}, \frac{2}{6}]$
[1; 1, 1]	$[\frac{1}{2}, \frac{1}{2}, \frac{1}{2}]$	$[\frac{1}{2}, \frac{1}{2}, \frac{1}{2}]$	[2; 1, 1, 1]	$[\frac{4}{6}, \frac{2}{6}, \frac{2}{6}, \frac{2}{6}]$	$[\frac{4}{6}, \frac{2}{6}, \frac{2}{6}, \frac{2}{6}]$
[2, 1, 1]	$[\frac{2}{2}, \frac{1}{2}, \frac{1}{2}]$	$[\frac{2}{2}, \frac{1}{2}, \frac{1}{2}]$	[3; 1, 1, 1]	$[\frac{6}{6}, \frac{2}{6}, \frac{2}{6}, \frac{2}{6}]$	$[\frac{6}{6}, \frac{2}{6}, \frac{2}{6}, \frac{2}{6}]$
[1; 1, 0, 0]	$[\frac{6}{6}, \frac{6}{6}, \frac{0}{6}, \frac{0}{6}]$	$[\frac{6}{6}, \frac{6}{6}, \frac{0}{6}, \frac{0}{6}]$	[3; 2, 1, 1]	$[\frac{4}{5}, \frac{3}{5}, \frac{1}{5}, \frac{1}{5}]$	$[\frac{5}{6}, \frac{4}{6}, \frac{1}{6}, \frac{1}{6}]$
[1; 1, 1, 0]	$[\frac{3}{6}, \frac{3}{6}, \frac{3}{6}, \frac{0}{6}]$	$[\frac{3}{6}, \frac{3}{6}, \frac{3}{6}, \frac{0}{6}]$	[2; 2, 1, 1]	$[\frac{2}{5}, \frac{3}{5}, \frac{1}{5}, \frac{1}{5}]$	$[\frac{2}{6}, \frac{4}{6}, \frac{1}{6}, \frac{1}{6}]$

For $n \geq 4$, one can easily find examples in which the Shapley-Shubik power vector is not representation-compatible. For example, take the representation [3; 2, 1, 1, 1]. The corresponding Shapley-Shubik power vector is given by $(\frac{1}{2}, \frac{1}{6}, \frac{1}{6}, \frac{1}{6})$. Since $\{2, 3, 4\}$ is a winning coalition with weight $\frac{1}{2}$, and $\{1\}$ is a losing coalition with weight $\frac{1}{2}$, the Shapley-Shubik power vector cannot be a representation of the game. The same counter-example also applies for the Banzhaf index, since in this game the two power vectors coincide. Houy and Zwicker (2014) characterize the set of representations that is compatible with the Banzhaf index in a general weighted game.

It is not a coincidence that some power vectors in Table 1 occur several times. This follows from duality.

Definition 2.15 *Let $v : 2^N \rightarrow \{0, 1\}$ be a simple game and \mathcal{W} its set of winning coalitions, \mathcal{L} its set of losing coalitions. By $v^d : 2^N \rightarrow \{0, 1\}$, with $v^d(S) = 1 - v(N \setminus S)$ for all $S \subseteq N$, we denote its dual game.*

The Shapley-Shubik power vector, as well as the Banzhaf vector, of a simple game v coincides with that of its dual game v^d .⁵ The result follows because v and v^d may also coincide. A weighted representation for the dual game can be obtained from a representation of the original game:

⁵See, for example, the discussion in Chapter 6.2 in Felsenthal and Machover (1998).

Lemma 2.16 *Let v be a weighted game with integer representation (q, w_1, \dots, w_n) , and let $w(S) = \sum_{i \in S} w_i$, then*

$$(w(N) - q + 1, w_1, \dots, w_n)$$

is an representation of its dual game v^d .

3 Representation-compatible power indices

The power indices studied in this paper use the following notions of feasibility and representation-compatibility. The first notion applies to a normalized vector of voting weights, whereas the second notion applies to a representation.

Definition 3.1 *Given a weighted game v , a vector (q, w_1, \dots, w_n) is a representation of v if $v = [q; w_1, \dots, w_n]$. A weight vector (w_1, \dots, w_n) is called feasible for v if there exists a quota q such that $(q; w_1, \dots, w_n)$ is a representation of v .*

For a normalized vector of weights to be feasible, it must fulfill the linear inequality constraints imposed by the set of minimal winning coalitions and the set of maximal losing coalitions.

Lemma 3.2 *The set of all normalized weight vectors $w \in \mathbb{R}_{\geq 0}^n$, $\sum_{i=1}^n w_i = 1$ being feasible for a given weighted game v is given by the intersection*

$$\sum_{i \in S} w_i > \sum_{i \in T} w_i$$

for all pairs (S, T) , where S is a minimal winning and T is a maximal losing coalition of v .

Similarly, for a representation to be valid, or compatible with a given weighted game, it must fulfill the linear inequality constraints imposed by the set of minimal winning coalitions and the maximal losing coalitions of the game.

Lemma 3.3 *The set of all normalized representations $(q, w) \in \mathbb{R}_{\geq 0}^{n+1}$, $q \in (0, 1]$, $\sum_{i=1}^n w_i = 1$ representing a given weighted game v is given by the intersection*

$$\sum_{i \in S} w_i \geq q, \quad \sum_{i \in T} w_i < q$$

for all minimal winning coalitions S and all maximal losing coalitions T .

The two sets of linear inequalities define convex polytopes in Euclidean space.

The following lemma shows that we can replace the strict inequalities by the corresponding non-strict inequalities, because after the elimination of one weight, the resulting polytopes (defined below) are full dimensional. The dimensions are n in the case of the polytope defined in Lemma 3.3, and $n - 1$ in the case of the polytope defined in (Lemma 3.2). We have,

Lemma 3.4 *For each weighted game v there exist positive real numbers $\tilde{q}, \tilde{w}_1, \dots, \tilde{w}_{n-1}$, and a parameter $\alpha > 0$, such that*

$$\left(\tilde{q} + \delta_0, \tilde{w}_1 + \delta_1, \dots, \tilde{w}_{n-1} + \delta_{n-1}, 1 - \sum_{i=1}^{n-1} (\tilde{w}_i + \delta_i) \right)$$

is a normalized representation of v for all $\delta_i \in [-\alpha, \alpha]$, $0 \leq i \leq n - 1$.

PROOF. Let (q, w_1, \dots, w_n) be an integer representation of v . Consequently, the weight of each winning coalition is at least q , and the weight of each losing coalition is at most $q - 1$. Since $((n + 1)q, (n + 1)w_1 + 1, \dots, (n + 1)w_n)$ is also an integer representation of v , we additionally assume, without any loss of generality, that $w_i \geq 1$ for all $1 \leq i \leq n$. One can easily check that

$$\left(q - \frac{2}{5} + \tilde{\delta}_0, w_1 + \tilde{\delta}_1, \dots, w_n + \tilde{\delta}_n \right)$$

is a representation of v for all $\tilde{\delta}_i \in [-\frac{1}{5n}, \frac{1}{5n}]$, $0 \leq i \leq n$. With $s = \sum_{i=1}^n w_i$, let $\tilde{q} = \frac{1}{s} \cdot (q - \frac{2}{5})$ and $\tilde{w}_i = \frac{1}{s} \cdot w_i$ for all $1 \leq i \leq n - 1$. The choice of a suitable α is fiddly. For example, $\alpha = \frac{1}{5ns}$ is too large, whereas $\alpha = \frac{1}{10ns}$ works, but the existence is guaranteed by construction. \square

To formally define the polytopes, let \mathcal{W}^m be the set of minimal winning coalitions and \mathcal{L}^m the set of maximal losing coalitions. The weight polytope is given by

$$\mathbf{V}(v) = \left\{ w \in \mathbb{R}_{\geq 0}^n \mid \sum_{i=1}^n w_i = 1, w(S) \geq w(T) \quad \forall S \in \mathcal{W}^m, T \in \mathcal{L}^m \right\}.$$

The representation polytope is given by

$$\mathbf{R}(v) = \left\{ (q, w) \in \mathbb{R}_{\geq 0}^{n+1} \mid \sum_{i=1}^n w_i = 1, w(S) \geq q \quad \forall S \in \mathcal{W}^m, w(T) \leq q \quad \forall T \in \mathcal{L}^m \right\}.$$

Let us illustrate the computation of average normalized weights on the example discussed in the introduction. The weight polytope $\mathbf{V} = \mathbf{V}(v)$ of the game $v = [51; 47, 46, 5, 2]$ is defined by the following system of inequalities

$$\begin{aligned} w_1 + w_2 &\geq w_1 + w_4, & w_1 + w_2 &\geq w_2 + w_4, & w_1 + w_2 &\geq w_3 + w_4, \\ w_1 + w_3 &\geq w_1 + w_4, & w_1 + w_3 &\geq w_2 + w_4, & w_1 + w_3 &\geq w_3 + w_4, \\ w_2 + w_3 &\geq w_1 + w_4, & w_2 + w_3 &\geq w_2 + w_4, & w_2 + w_3 &\geq w_3 + w_4, \end{aligned}$$

in addition to $w_1 + w_2 + w_3 + w_4 = 1$ and $w_i \geq 0$. Eliminating redundant inequalities yields

$$w_1 + w_2 \geq w_3 + w_4, \quad w_1 + w_3 \geq w_2 + w_4, \quad w_2 + w_3 \geq w_1 + w_4, \quad w_4 \geq 0, \quad w_1 + w_2 + w_3 + w_4 = 1.$$

The variables w_1, w_2, w_3 are symmetric. By assuming a specific ordering of these variables, we can decompose the integration domain \mathbf{V} into six parts \mathbf{P} , such that the resulting six integrals are equal. Moreover, it suffices to compute the average normalized weight for voter 4, because

$$\int_{\mathbf{V}} w_1 \, d\mathbf{V} = \int_{\mathbf{V}} w_2 \, d\mathbf{V} = \int_{\mathbf{V}} w_3 \, d\mathbf{V}.$$

Let the ordering be $w_1 \geq w_2 \geq w_3$. Substituting $w_1 = 1 - w_2 - w_3 - w_4$ yields

$$\mathbf{P} = \left\{ (w_2, w_3, w_4) \in \mathbb{R}^3 \mid w_2 \geq w_3 \geq w_4 \geq 0, 2w_2 \geq 1 - 2w_3, 2w_2 \leq 1 - w_3 - w_4 \right\}.$$

To obtain the integration domain \mathbf{P} , note that $\max\{w_4 \mid w \in \mathbf{V}\} = \frac{1}{4}$. Since $w_1 \geq w_2 \geq w_3 \geq w_4$ and $w_1 + w_2 + w_3 + w_4 = 1$, the maximum of w_3 given w_4 is $\frac{1-w_4}{3}$. Therefore,

$$\begin{aligned} \int_{\mathbf{V}} f(w_4) \, d\mathbf{V} &= 6 \int_{\mathbf{P}} f(w_4) \, d\mathbf{P} = 6 \int_0^{\frac{1}{4}} \int_{w_4}^{\frac{(1-w_4)/3}{\max(w_3, 1/2-w_3)}}^{\frac{(1-w_4)/3}{\max(w_3, 1/2-w_3)}} \int_{\max(w_3, 1/2-w_3)}^{\frac{(1-w_4)/3}{\max(w_3, 1/2-w_3)}} f(w_4) \, dw_2 \, dw_3 \, dw_4 \\ &= 6 \int_0^{\frac{1}{4}} \int_{w_4}^{\frac{1}{4}} \int_{1/2-w_3}^{\frac{(1-w_3-w_4)/2}{1/2-w_3}} f(w_4) \, dw_2 \, dw_3 \, dw_4 + \\ &\quad + 6 \int_0^{\frac{1}{4}} \int_{\frac{1}{4}}^{\frac{(1-w_4)/3}{\max(w_3, 1/2-w_3)}} \int_{w_3}^{\frac{(1-w_3-w_4)/2}{\max(w_3, 1/2-w_3)}} f(w_4) \, dw_2 \, dw_3 \, dw_4. \end{aligned}$$

Setting $f(w_4) = 1$ yields $\frac{1}{96}$ as the volume of \mathbf{V} , whereas setting $f(w_4) = w_4$ yields $\frac{1}{1536}$. The average normalized weight of voter 4 thus equals $\frac{1}{16}$. The remaining average weights sum to $\frac{15}{16}$.

Replacing $f(w_4)$ by w_1, w_2, w_3 yields $\frac{19}{4608}, \frac{5}{2304}$ and $\frac{1}{288}$. By the symmetry of w_1, w_2, w_3 ,

$$\int_{\mathbf{V}} w_1 \, d\mathbf{V} = \int_{\mathbf{V}} w_2 \, d\mathbf{V} = \int_{\mathbf{V}} w_3 \, d\mathbf{V} = 6 \int_{\mathbf{P}} \frac{\overbrace{w_1 + w_2 + w_3}^{=1-w_4}}{3} \, d\mathbf{P} = \frac{1}{3} \cdot \left(\frac{19}{4608} + \frac{1}{288} + \frac{5}{2304} \right) = \frac{5}{1536}.$$

This yields the following vector of average normalized feasible weights $(\frac{5}{16}, \frac{5}{16}, \frac{5}{16}, \frac{1}{16})$.

We now consider the computation of the average representation based on the polytope \mathbf{R} . Since $w_1 \geq w_2 \geq w_3$, a valid quota q must fulfill $w_1 + w_4 = 1 - w_2 + w_3 \leq q \leq w_2 + w_3$, so that

$$\mathbf{R} = \mathbf{R}(v) = \{(q, w) \mid w \in \mathbf{V}, 1 - w_2 + w_3 \leq q \leq w_2 + w_3\}.$$

Following the above reasoning, we obtain

$$\begin{aligned} \int_{\mathbf{R}} f(q, w_4) \, d\mathbf{R} &= 6 \int_0^{\frac{1}{4}} \int_{w_4}^{\frac{(1-w_4)/3}{\max(w_3, 1/2-w_3)}} \int_{\max(w_3, 1/2-w_3)}^{\frac{(1-w_4)/3}{\max(w_3, 1/2-w_3)}} \int_{1-w_2-w_3}^{w_2+w_3} f(q, w_4) \, dq \, dw_2 \, dw_3 \, dw_4 \\ &= 6 \int_0^{\frac{1}{4}} \int_{w_4}^{\frac{1}{4}} \int_{1/2-w_3}^{\frac{(1-w_3-w_4)/2}{1/2-w_3}} \int_{1-w_2-w_3}^{w_2+w_3} f(q, w_4) \, dq \, dw_2 \, dw_3 \, dw_4 + \\ &\quad + 6 \int_0^{\frac{1}{4}} \int_{\frac{1}{4}}^{\frac{(1-w_4)/3}{\max(w_3, 1/2-w_3)}} \int_{w_3}^{\frac{(1-w_3-w_4)/2}{\max(w_3, 1/2-w_3)}} \int_{1-w_2-w_3}^{w_2+w_3} f(q, w_4) \, dq \, dw_2 \, dw_3 \, dw_4. \end{aligned}$$

Setting $f(q, w_4) = 1$ yields $\frac{1}{1152}$ as the volume of the polytope \mathbf{R} . For $f(q, w_4) = w_4$ we obtain $\frac{1}{23040}$, so that the average representation of voter 4 is given by $\frac{1}{20}$. The average representation of the game reads $(\frac{1}{2}, \frac{19}{60}, \frac{19}{60}, \frac{19}{60}, \frac{1}{20})$. The average quota can be obtained by setting $f(q, w_4) = q$.

To round off the example, we mention that in small games integrals such as those can be evaluated using the software **LattE** by Baldoni, Berline, De Loera, Dutra, Köppe, Moreinis,

Pinto, Vergne and Wu (2014).⁶ Computing average weights in games with many players may require numerical integration based on Monte Carlo methods, such as hit-and-run.

The average normalized weights and the average representation come close to fulfilling the criteria for coherent measures of voting power provided in Definition 2.9. By construction, they are symmetric, positive, efficient and strongly monotonic according to Definition 2.13. Strong monotonicity in the sense of Isbell's desirability relation in Definition 2.10 follows, because $i \succ j$ implies $w_i > w_j$ in each representation of a given weighted game. However, they do not satisfy the dummy property, as this property was not accounted for in the underlying set of inequalities. Indeed, in the above example the fourth voter is a dummy, yet her weight in the vector of average weights power does not vanish.

To ensure coherency we restrict the polytopes so that all dummies receive the value of zero. The dummy-revealing weight polytope is given by

$$\mathbf{V}^d(v) = \mathbf{V}(v) \cap \{w \in \mathbb{R}_{\geq 0}^n \mid w_i = 0 \quad \forall i \in D\}.$$

The dummy-revealing representation polytope is given by

$$\mathbf{R}^d(v) = \mathbf{R}(v) \cap \{w \in \mathbb{R}_{\geq 0}^n \mid w_i = 0 \quad \forall i \in D\}.$$

From Lemma 3.4 we conclude that the $(t-1)$ -dimensional volume of $\mathbf{V}^d(v)$ and the t -dimensional volume of $\mathbf{R}^d(v)$ is non-zero for each weighted game v , where $1 \leq t \leq n$ denotes the number of non-dummy voters of v . We can now use the restricted polytopes $\mathbf{V}^d(v)$ and $\mathbf{R}^d(v)$ to define the power indices.

Definition 3.5 *The average weight index of voter i in a weighted game v is given by*

$$AWI_i(v) = \frac{\int_{\mathbf{V}^d} w_i \, d w}{\int_{\mathbf{V}^d} d w}.$$

Similarly, the average representation index of voter i in a weighted game v is given by

$$ARI_i(v) = \frac{\int_{\mathbf{R}^d} w_i \, d(q, w)}{\int_{\mathbf{R}^d} d(q, w)}.$$

In the above definition, all integrals are understood as multiple integrals.

It is important to note that dummy-related restrictions are irrelevant for computation. In fact, the more dummy voters a game has, the simpler the power computations are. We can safely remove the dummies prior to computing the indices. The validity of this procedure follows from the following result, which also holds for the Banzhaf index. Given a weighted game $v : 2^N \rightarrow \{0, 1\}$ with the set of dummy voters $D \subset N$, we define the dummy-reduced game $v' : 2^{N \setminus D} \rightarrow \{0, 1\}$ via $v'(T) = v(T)$ for all $T \subseteq N \setminus D$. All dummies receive the value of zero in the outcome vector.

Lemma 3.6 *Given a sequence of power indices $g^n : \mathcal{C}_n \rightarrow \mathbb{R}^n$ for all $n \in \mathbb{N}$, let $\tilde{g}^n : \mathcal{C}_n \rightarrow \mathbb{R}^n$ be defined via $\tilde{g}_i^n(v) = g_i^m(v')$ for all non-dummies i and by $\tilde{g}_j^n(v) = 0$ for all dummies j , where m is the number of non-dummies in v and v' arises from v by removing the dummies. The power index \tilde{g}^n now satisfies the dummy property.*

⁶Our programs use LattE. They can be downloaded from <http://serguei.kaniovski.wifo.ac.at/>.

We call \tilde{g}^n the dummy-revealing version of a given sequence of power indices g^n . The above lemma shows that the presence of dummies reduces the dimension of the polytopes, thus simplifying computations.

Tables A.1 and A.2 of Appendix A.2 list power distributions according to the AWI and ARI for all weighted games with up to five voters. Power distributions in games with fewer than five voters can be obtained from games in which the additional voters are assumed to be dummies. For example, the power distribution in the game $[3;2,1,1]$, in which none of the three voters is a dummy, is given by the first three coordinates of the power vector for the game $[3;2,1,1,0,0]$, in which the additional two voters are dummies. This holds for each of the four power indices.

Ensuring that AWI and ARI preserve the types of voters implied in the equivalence relations of Definition 2.3 requires imposing the following type-revealing restrictions on the polytopes.

$$\begin{aligned} \mathbf{V}^t(v) &= \mathbf{V}^d(v) \cap \{w \in \mathbb{R}_{\geq 0}^n \mid w_i = w_j \quad \forall i, j \in N \text{ s.t. } i \simeq j\}, \\ \mathbf{R}^t(v) &= \mathbf{R}^d(v) \cap \{w \in \mathbb{R}_{\geq 0}^n \mid w_i = w_j \quad \forall i, j \in N \text{ s.t. } i \simeq j\}. \end{aligned}$$

Lemma 3.4 implies that $(t - 1)$ -dimensional volume of $\mathbf{V}^t(v)$ and the t -dimensional volume of $\mathbf{R}^t(v)$ is non-zero for each weighted game v , where $1 \leq t \leq n$ denotes the number of equivalence classes of voters of v , excluding the dummy voters. Note that the dimension of the polytopes for the type-revealing indices are typically smaller than for the AWI and ARI. The case of $t = n$ can be handled separately, as in this case all voters are by definition equally powerful.

Tables A.3 and A.4 of Appendix A.2 list the type-revealing versions of AWI and ARI, called AWTI and ARTI, for all weighted games with up to four voters. A formal definition of the type-revealing indices is completely analogous to Definition 3.5. The computation of AWTI and ARTI follows the same procedures described the example above, except that it uses the restricted versions of the polytopes instead of their unrestricted counterparts. A complete example of the above calculations is provided in Appendix A.1.

We conclude the presentation of the power indices with a remark on duality (Definition 2.15).

Lemma 3.7 *The average weight index (AWI) and the average representation index (ARI) coincide for the pairs of a weighted game v and its dual v^d .*

PROOF. According to Lemma 2.16, the integer representations of v and v^d are in bijection. Let (q, w_1, \dots, w_n) be a normalized representation of v , then $(1 - q + \varepsilon, w_1, \dots, w_n)$ is a normalized representation of v^d for a sufficiently small $\varepsilon > 0$, as $q \in (0, 1]$. If we require that the weight of each winning coalition in the dual game strictly exceed the quota, then we can choose $1 - q$ as a quota for the dual game, while also retaining the weights. In view of Lemma 3.4, this difference between a strict and non-strict inequality can be neglected when computing the indices, which proves the lemma. \square

4 The properties of representation-compatible power indices

The common criteria for choosing an index include the existence of a game-theoretic axiomatization, consistency with certain stochastic models of voting or immunity to certain voting paradoxes. Table 2 compares the four power indices (AWI, ARI, AWTI, ARTI) to several existing power indices. Some of these power indices are well-known, whereas others have only recently been introduced. All indices introduced in this paper are coherent measures of power; they satisfy **Null**, **Eff**, **Invar** and **Str.Mon** (Definition 2.9). Most researchers agree that a

power index should at least be coherent. Yet two well-known power indices by Deegan and Packel (1978) and Holler (1982) violate monotonicity, and are therefore not coherent.

Table 2: Basic properties and immunities to voting paradoxes.

Index	Null	Eff	Invar	Str.Mon	Prop	Type-Rev	Bloc	Don	Bic.Meet
Shapley and Shubik (1954)	✓	✓	✓	✓			✓	✓	
Banzhaf (1965)	✓	✓	✓	✓					✓
Johnston (1978)	✓	✓	✓	✓					
Deegan and Packel (1978)	✓	✓	✓						
Holler (1982)	✓	✓	✓						
Freixas and Kaniovski (2014)	✓	✓	✓	✓	✓				✓
AWI	✓	✓	✓	✓	✓				
ARI	✓	✓	✓	✓	✓				
AWTI	✓	✓	✓	✓	✓	✓			
ARTI	✓	✓	✓	✓	✓	✓			

The defining property of the indices studied in this paper is representation-compatibility, which ensures proportionality (**Prop**) between power and weight. The MSR Index introduced in Freixas and Kaniovski (2014) is the only existing power index that has this property. The new indices (AWTI and ARWI) are type-revealing (**Typ.Rev**), a property unique to them. Proportionality between power and weight makes representation-compatible indices convenient measures of power.

4.1 Distributing parliamentary seats: an example

To illustrate this convenience, suppose we wish to fill the Austrian parliament (Nationalrat) following the general election of 2013. Six parties have attained the electoral threshold of 4 percent required to secure a seat in parliament. Their popular votes are listed in the first column of Table 3. The Austrian parliament uses the D’Hondt method to allocate 183 seats among the political parties that passed the threshold. The actual seat distribution is given in the second column.

Despite the fact that the D’Hondt method is not based on power computations, the resulting distribution of voting power in the parliament resembles the distribution of power implied in the popular vote. This occurs because the D’Hondt method tries to achieve proportionality, thus preserving the game representation implied in the popular vote for any given voting rule. In our example, the resemblance is complete. For example, under plurality voting rule we have the following weighted voting games based on popular votes and parliamentary seats, respectively: $[2215538; 1258605, 1125876, 962313, 582657, 268679, 232946]$ and $[92; 52, 47, 40, 24, 11, 9]$. The third column of Table 3 shows that these games have identical power distributions according to the Shapley-Shubik index (SSI).

Suppose that, instead of using the D’Hondt method, we allocated the parliamentary seats according to the distribution of power implied in the popular vote under plurality voting rule. For example, we could distribute the seats according to power distributions obtained from the SSI or AWI, with the implied seat distributions provided in Table 3. The distribution of seats according to the SSI index implies a different power distribution than the one given in the third column, as power vectors of the games $[92; 52, 47, 40, 24, 11, 9]$ and $[92; 67, 49, 49, 6, 6, 6]$ differ. On the contrary, $[92; 52, 47, 40, 24, 11, 9]$ and $[92; 63, 44, 44, 11, 11, 11]$ have identical power vectors according to the AWI. A seat distribution according to the AWI allows us to easily discern the power distribution from the weight distribution, because the AWI power vector is a representation of the game.

Table 3: Austrian Nationalrat election, 2013.

	Popular Votes	Seats	SSI	SSI Seats	AWI	AWI Seats
SPÖ	1,258,605	52	0.367	67	0.342	63
ÖVP	1,125,876	47	0.267	49	0.242	44
FPÖ	962,313	40	0.267	49	0.242	44
Green	582,657	24	0.033	6	0.058	11
Team Stronach	268,679	11	0.033	6	0.058	11
NEOS	232,946	9	0.033	6	0.058	11
Quota	2,215,538	92		92		92

The total number of parliamentary seats according to the AWI is 184 not 183. This rounding error can be rectified by subtracting one seat from the largest party, as this would leave the power distribution unchanged according to AWI.

The distribution of seats based on the AWI uses the representation provided by the popular votes as a template. A different problem is that of designing a weighted voting game with an arbitrary given power distribution – a problem of practical importance for institutional design. Although this inverse problem may not have an exact solution, an approximate solution for a representation-compatible power index can easily be found using a grid search for a quota that minimizes an objective function, say the sum of squared deviations between weights and powers. The desired power distribution becomes the weight distribution in the solution, appropriately rescaled should integer-valued voting weights be needed. This stands in contrast to the classical power indices, whose inverse problems are significantly more difficult.⁷

4.2 A comparison with the classical power indices

The above example shows that the SSI is not representation-compatible in games with more than three voters, and neither is the BZI. If a power vector is not representation-compatible, then it must lie outside the polytope containing the feasible weights. To get a broad picture on how representation-compatible power indices differ from the classical indices by Banzhaf (BZI) and Shapley-Shubik (SSI), for each game we compute the Euclidean distance between the six measures, and consider the distribution of the distances for all games of a given size.

Figure 1 shows the boxplots of the distances for all games with sizes up to a given n . Similarly to Tables in Appendix A.2, the games differ in their partitions in the equivalence sets, and are defined in terms of the minimum sum representations. The bar in the middle shows the median distance. The top whisker ranges from the 99% quantile to the 75% quantile. The bottom whisker ranges from the 25% quantile to the 1% quantile. The box thus covers the range of 25-75%.

The differences between the classical and representation-compatible indices become apparent as n increases. The bottom panels suggest that representation-compatible indices lie closer to each other than the BZI and SSI, the former appears to lie closer to representation-compatible indices than the latter. The median distance between the AWI and the SSI is slightly larger than the median distance between the BZI and the AWI. This may suggest that the BZI is more likely to be representation-compatible than the SSI. But a power index is representation-compatible if it lies in the interior of the dummy-revealing polytope $V^d(v)$, whose center of mass is the AWI

⁷See, for example, the fixed-point iteration methods for obtaining the inverse solution for the Banzhaf index in Aziz, Paterson and Leech (2007).

power vector. Being closer to the center of mass does not imply being closer to the boundary of the polytope.

Among the four representation-compatible indices, the AWI and ARI appear to lie closer to each other than their type-revealing versions. The distances between the representation-compatible indices decreases with an increasing n , which is not surprising given that polytopes containing representation-compatible power distributions are likely to shrink as n increases.

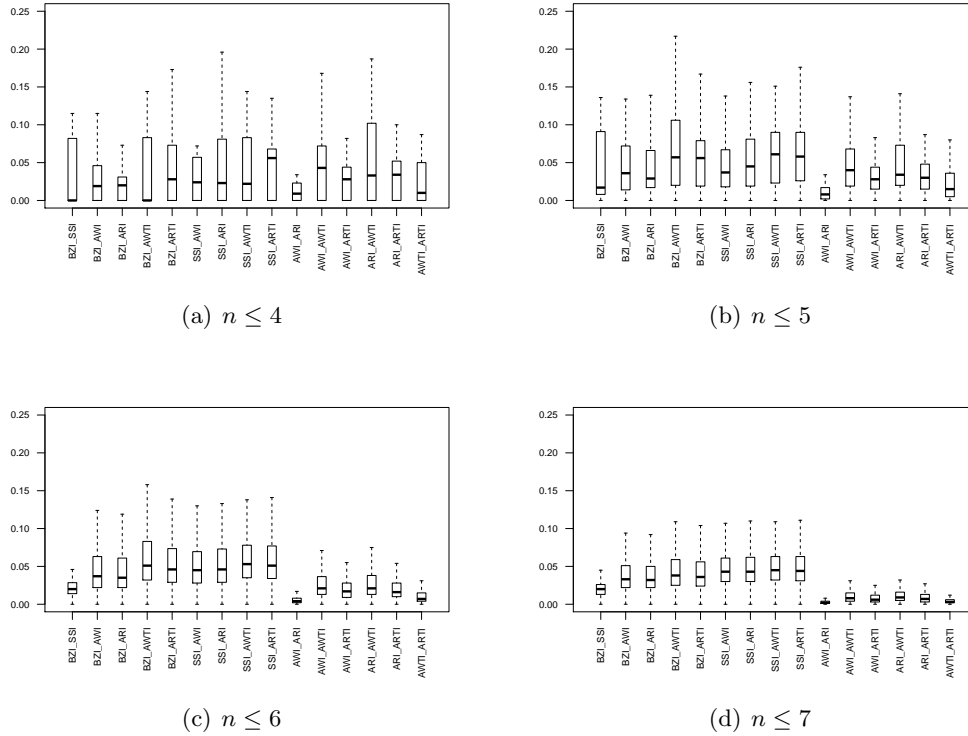

Figure 1: The distribution of Euclidean distances between the indices.

4.3 Immunities to voting paradoxes

Felsenthal and Machover (1998) identify three voting paradoxes to which any reasonable measure of power should not be liable. These are the bloc (**Bloc**), donation (**Don**) and bicameral meet (**Bic.Meet**) paradoxes. In the following, we provide examples showing that all of representation-compatible indices are liable to these paradoxes, so they have nothing to recommend in this department. But since none of the existing indices have all the required immunities, the question of which index to use cannot be settled based on immunity to paradoxes alone.

Bloc paradox: Respecting the bloc postulate means that if two or more voters form a bloc by adding their votes, the power of the bloc should not be lesser than the power of either voter alone. Table 4 provides an example of a game, in which the smallest two voters form a bloc by joining their voting weights, and lose power as a result, if only slightly. The BZI and the SSI do not show the paradox in this example, although examples are known in which the BZI is liable to the bloc paradox. Also, the MSRI of Freixas and Kaniovski (2014) displays the bloc paradox in this example.

Table 4: Block paradox in game [37;25,20,17,15,9,6,2,1].

Weight	25	20	17	15	9	6	2	1
BZI	0.274	0.226	0.188	0.168	0.063	0.053	0.0240	0.005
SSI	0.287	0.230	0.196	0.163	0.054	0.046	0.0202	0.004
MSRI	0.262	0.213	0.180	0.148	0.082	0.066	0.0328	0.016
AWI	0.267	0.226	0.196	0.140	0.082	0.056	0.0283	0.006
ARI	0.266	0.224	0.194	0.140	0.082	0.057	0.0288	0.007
AWTI	0.267	0.226	0.196	0.140	0.082	0.056	0.0283	0.006
ARTI	0.266	0.224	0.194	0.140	0.082	0.057	0.0288	0.007
Weight	25	20	17	15	9	6	3	0
BZI	0.282	0.223	0.185	0.165	0.068	0.049	0.0291	0
SSI	0.293	0.226	0.193	0.160	0.060	0.043	0.0262	0
MSRI	0.273	0.212	0.182	0.152	0.091	0.061	0.0303	0
AWI	0.272	0.225	0.197	0.140	0.087	0.051	0.0281	0
ARI	0.272	0.224	0.195	0.141	0.087	0.052	0.0284	0
AWTI	0.272	0.225	0.197	0.140	0.087	0.051	0.0281	0
ARTI	0.272	0.224	0.195	0.141	0.087	0.052	0.0284	0

Donation paradox: Respecting donation means that if one voter gives some of her votes to another, the power of the donor should not increase as a result. Felsenthal and Machover (1998) provide examples in which the Banzhaf and Johnston indices show both bloc and donation paradoxes. Freixas and Molinero (2010) study the frequency of the occurrence of the donation paradox in weighted games with a small number of players, providing examples for the Banzhaf and Johnston indices. The Shapley-Shubik index is immune to both the bloc and donation paradoxes. Freixas and Kaniowski (2014) provide an example, which also shows that the MSR index is liable to the donation paradox.

Table 5: Donation paradox in game [13;9,4,3,2,1].

Weight	9	4	3	2	1

The example in Table 5 shows that representation-compatible indices are liable to the donation paradox. In the game $[13; 9, 4, 3, 2, 1]$, the largest voter gains power by donating one vote to the second largest voter according to the Shapley-Shubik index, but gains power according to all other indices. In example, the BZI and the MSRI shows the donation paradox. The Shapley-Shubik index is immune to both the bloc and donation paradoxes.

The bicameral meet: An index of power respects bicameral meet if the ratio of powers of any two voters belonging to the same assembly prior to a merge with a different assembly is preserved in the joint assembly. This property is useful when measuring the voting power of shareholders, because the relative powers of shareholders comprising a minority voting assembly with a total voting weight, represented by their joint holdings, carries over to the grand voting assembly, represented by the total worth of the company.

The bicameral meet of two simple voting games (N_1, \mathcal{W}_1) and (N_2, \mathcal{W}_2) is a simple voting game (N, \mathcal{W}) , with an assembly $N = N_1 \cup N_2$, and a set of winning coalitions $\mathcal{W} = \{S \subseteq N : S = S_1 \cup S_2, S_1 \in \mathcal{W}_1, S_2 \in \mathcal{W}_2\}$. The two assemblies have no voters in common, so $N_1 \cap N_2 = \emptyset$. The bicameral meet postulate requires that if i and j are non-null voters in a game (N_1, \mathcal{W}_1) , then the ratio of power of voter i to the power of voter j in the joint game (N, \mathcal{W}) should be equal to the ratio of their powers in the original game (N_1, \mathcal{W}_1) .

Table 6: Added blocker paradox in game $[3; 2, 1, 1] \cup [5; 5] = [8; 2, 1, 1, 5]$.

Freixas and Kaniovski (2014) prove that a bicameral meet of two complete games is complete if at least one of the two constituent games has only one minimum winning coalition. A special case of the bicameral meet postulate is the added blocker postulate, which says that adding a vetoer (Definition 2.5) to a weighted game should not change the ratio of powers of any two incumbent voters. If an index is liable to an added blocker paradox, it is also liable to the bicameral meet postulate, see Felsenthal and Machover (1998) (p. 270). In Table 7, we use their example to shows that neither of representation-compatible indices satisfies the bicameral meet postulate. The example involves adding a blocker with a weight of 5 to the game $[3; 2, 1, 1]$, and adjusting the quote in such a way that the set of minimal winning coalitions of the joint games equals the union of the sets of minimal winning coalitions in each game. This amounts

to joining the games $[3; 2, 1, 1]$ and $[5; 5]$. Note that the blocker is a dictator in the added game. Since the second game has a single coalition, which is trivially minimal winning, the joint game is complete. The bicameral meet postulate does not hold for representation-compatible indices, because adding the blocker changes the power ratios of the players. This postulate is satisfied by the BZI and the MSRI.

There are many lesser paradoxes and other properties that may distinguish between different indices. One useful property is neutrality in symmetric voting games. In a symmetric weighted voting game, each player commands an equal number of votes. For a power measure to respect neutrality, the power of a voting bloc must equal the sum of individual powers of its members, so that satisfying the bloc postulate does not carry strategic implications. The power vectors for games $[3; 1, 1, 1, 1]$ and $[3; 2, 1, 1]$ in Tables of Appendix A.2 clearly show that representation-compatible indices do not respect neutrality. This property is satisfied by the MSRI.

5 Integral weights and type preservation

A normalization of voting weights is unreasonable if they represent the number of shares of a corporation or the number of members of a political party. In these cases, we require the weights to be integers. This observation has led to the development of a power index based on the minimum sum integer representations, called the MSR index (Freixas and Kaniovski 2014).

Let us return to the weighted game $v = [2; 1, 1, 1]$. We already mentioned that there exist 1176 feasible integer weight vectors with the total weight of 100. The average of all these vectors equals $(\frac{100}{3}, \frac{100}{3}, \frac{100}{3})$, yielding $(\frac{1}{3}, \frac{1}{3}, \frac{1}{3})$ as the average weight distribution, which is not surprising, given the inherent symmetry of the game.

Things get more interesting if we consider the game $v = [3; 2, 1, 1]$. Table 7 lists the number of feasible integer weight vectors for an increasing total weight, as well as the average weight distributions. The distribution appears to converge to $(\frac{11}{18}, \frac{7}{36}, \frac{7}{36})$, which equals the AWI for this game. This convergence can be rigorously established by numerically approximating the integrals in Definition 3.5 over a successively finer equally spaced grid inside the polytope. A similar result holds if an integer-valued quota is taken into account, in which case we obtain the ARI in the limit. The dummy-revealing and type-revealing property is also preserved in the limit.

To obtain power indices based on integer representations, we can minimize the sum of weights instead of taking it to infinity. Unfortunately, the minimum sum representations are not unique for $n \geq 8$ (Kurz 2012). Nevertheless, one can take a convex combination of all such minimum sum representations, which yields, after a normalization, the MSR index recently introduced in Freixas and Kaniovski (2014).⁸ One motivation for minimizing weights is to minimize the cost of political representation by minimizing the number of representatives. Another motivation for minimum sum representation and the MSR index is given in Ansolabehere, Snyder, Strauss and Ting (2005), who argue that many observations on the formation of coalition governments are more consistent with minimal integer-voting weights, rather than power distributions implied by the classical power indices.

The minimum sum integer representations are dummy-revealing, but not type-revealing. Take the two representations $(12, 7, 6, 6, 4, 4, 4, 3, 2)$ and $(12, 7, 6, 6, 4, 4, 4, 2, 3)$, which are minimum sum representations of the same game. Indeed, there exists no integer representation of

⁸Minimizing $q + \sum_{i=1}^n$ instead of $\sum_{i=1}^n$ makes no difference, so there is no need to distinguish the two cost functions.

this game with a weight sum smaller than 36. Both representations are not type-revealing since the equivalence classes of voters are given by $\{1\}$, $\{2, 3\}$, $\{4, 5, 6\}$, and $\{7, 8\}$, while $w_7 \neq w_8$. Implementing one of the two representations may cause some confusion, as one might erroneously think that one of the two voters is more powerful than the other. The unique type-revealing minimum sum representation for this example is given by $[14; 8, 7, 7, 5, 5, 5, 3, 3]$. It has a total weight of 43 instead of 36. Unfortunately, even the type-revealing minimum sum representation can be non-unique if at least $n = 9$ voters are involved, see Kurz (2012). At the very least, one can define a minimum sum representation type-revealing index of a weighted game as a normalization of the convex combination of the corresponding set of type-revealing minimum sum representations. Some uniqueness results for both the minimum sum representation and the type-revealing minimum sum representation exist for special classes of weighted games. Freixas and Kurz (2014) proved that weighted games with up to two equivalence classes of voters admit a unique minimum sum representation. For minimum sum representations, the authors give non-unique examples for four equivalence classes of voters and conjecture a uniqueness result for three equivalence classes of voters.

For the algorithmic aspects of computing minimum sum representations and the MSR index, see Kurz (2012). The gist of this research is that the minimum sum representation can often be computed by solving a small sequence of linear programs. The computation of type-revealing minimum sum representations requires only minor adjustments.

Table 7: Convergence of feasible integer weights for $[3; 2, 1, 1]$.

Total weight	Number of integer representations	Weight distribution
100	1601	(0.608832,0.195584,0.195584)
1000	166001	(0.610888,0.194556,0.194556)
10000	16660001	(0.611089,0.194456,0.194456)
100000	1666600001	(0.611109,0.194446,0.194446)

6 Concluding remarks

The average representations of a weighted voting game can be used to obtain four representation-compatible indices of voting power for this type of voting game. The average representations are computed from weight and representation polytopes defined by the set of winning and losing coalitions of the game. The weight polytope is based on normalized voting weights, whereas the representation polytope also includes the quota.

These average representations come remarkably close to fulfilling the standard criteria for a coherent measure of voting power. They are symmetric, positive, efficient and strongly monotonic. But they do not respect the dummy property that assigns zero power to powerless players. This shortcoming is easily rectified by further restricting the polytopes. The resulting restricted average representations respect the dummy property and are coherent measures of power.

The above modification suggests that we can endow the indices with qualities by tailoring the polytope. Restrictions based on the equivalence classes of voters defined by the Isbell desirability relation lead to another pair of power indices, which ascribe equal power to all members of an equivalence class. These indices are strictly monotonic in voting weight.

The defining property of the indices is representation-compatibility, which ensures proportionality between power and weight. By redistributing weights among the voters, we can redesign

any given weighted voting game in such a way that the distribution of voting weight will also be the distribution of voting power. This allows us to read power directly from the weights, a convenient property that recommends representation-compatible indices as optimal representations for weighted voting games, or optimal designs for voting institutions. The obvious disadvantage is the computational intensity of integrating monomials on highly-dimensional polytopes. Obtaining power distributions in weighted games with many players may require numerical integration based on random sampling.

Reflecting on the place representation-compatible indices may take among the existing measures of power, we believe that proportionality makes them ideal measures of power for voting institutions, in which the votes are distributed to the voter based on their contribution to a fixed purse. In this setting, voting power reflects the extent of a voter's control of the distribution of a fixed purse – the ultimate outcome of voting, measured by that voter's expected share in the purse.⁹ If a voter's expected share of spoils coincides with the voter's contribution to the fixed purse, an equilibrium emerges in which voters will not wish to redistribute votes. This leads to a stable institutional design of vote-for-money institutions, such as a corporation.

A Appendix

A.1 Example [3;2,1,1]

The sets of minimal winning and maximal losing coalitions for the game [3;2,1,1] are, respectively, $\{\{1,2\}, \{1,3\}, \{1,3\}\}$ and $\{\{1\}, \{2,3\}\}$. Since voters 2 and 3 are equivalent, there are two equivalence classes in this game. There are no dummies.

Using Lemma 3.2, we obtain the following constraints:

$$\begin{aligned} w_1 + w_2 > w_1 &\iff w_2 > 0; \\ w_1 + w_3 > w_1 &\iff w_3 > 0; \\ w_1 + w_2 > w_2 + w_3 &\iff w_1 > w_3; \\ w_1 + w_3 > w_2 + w_3 &\iff w_1 > w_2. \end{aligned}$$

In addition, $w_1, w_2, w_3 \geq 0$ and $w_1 + w_2 + w_3 = 1$. Eliminating w_3 and removing the redundant constraints yields the following inequalities: $w_2 > 0$, $w_2 < 1 - w_1$, $w_2 > 1 - 2w_1$, $w_2 < w_1$. Since $1 - 2w_1 < w_1$ and $1 - w_1 > 0$, we have $w_1 \in (\frac{1}{3}, 1)$. For $w_1 \in (\frac{1}{3}, \frac{1}{2})$, we have $w_2 \in (1 - 2w_1, w_1)$. For $w_1 \in [\frac{1}{2}, 1)$, we have $w_2 \in (0, 1 - w_1)$. The polytope is thus given by

$$\mathbb{V}^d(v) = \{(w_1, w_2) \in \mathbb{R}_{\geq 0}^2 \mid w_2 \geq 0, w_2 \leq 1 - w_1, w_2 \geq 1 - 2w_1, w_2 \leq w_1\}.$$

Since there are no dummies in this game, the dummy-revealing polytope $\mathbb{V}^d(v)$ coincides with its non-revealing counterpart $\mathbb{V}(v)$.

For voter 1, we have

$$\iint_{\mathbb{V}^d} w_1 \, d w_1 \, d w_2 = \int_{\frac{1}{3}}^{\frac{1}{2}} d w_2 \int_{1-2w_2}^{w_2} w_1 \, d w_1 + \int_{\frac{1}{2}}^1 d w_2 \int_0^{1-w_2} w_1 \, d w_1 = \frac{1}{54} + \frac{1}{12} = \frac{11}{108}.$$

For voter 2, we obtain

$$\iint_{\mathbb{V}^d} w_2 \, d w_1 \, d w_2 = \int_{\frac{1}{3}}^{\frac{1}{2}} d w_1 \int_{1-2w_1}^{w_1} w_2 \, d w_2 + \int_{\frac{1}{2}}^1 d w_1 \int_0^{1-w_1} w_2 \, d w_2 = \frac{1}{48} + \frac{5}{432} = \frac{7}{216}.$$

The total volume of the polytope is given by

$$\iint_{\mathbb{V}^d} d w_1 \, d w_2 = \int_{\frac{1}{3}}^{\frac{1}{2}} d w_1 \int_{1-2w_1}^{w_1} d w_2 + \int_{\frac{1}{2}}^1 d w_1 \int_0^{1-w_1} d w_2 = \frac{1}{8} + \frac{1}{24} = \frac{1}{6},$$

This yields the following vector of average (normalized) feasible weights $(\frac{11}{18}, \frac{7}{36}, \frac{7}{36})$.

The polytope for the average representation defined by Lemma 3.3 is given by

$$\mathbb{R}^d(v) = \{(q, w_1, w_2) \in \mathbb{R}_{\geq 0}^3 \mid w_1 + w_2 \geq q, w_1 \leq q, 1 - w_1 \leq q, 1 - w_2 \geq q\}.$$

We have,

$$\begin{aligned}
\iint_{\mathbb{R}^d} w_1 \, d w_1 \, d w_2 \, d q &= \int_{\frac{1}{2}}^{\frac{2}{3}} d q \int_{1-q}^q w_1 \, d w_1 \int_{q-w_1}^{1-q} d w_2 + \int_{\frac{2}{3}}^1 d q \int_{2q-1}^q w_1 \, d w_1 \int_{q-w_1}^{1-q} d w_2 \\
&= \frac{31}{7776} + \frac{1}{243} = \frac{7}{864} \\
\iint_{\mathbb{R}^d} w_2 \, d w_1 \, d w_2 \, d q &= \int_{\frac{1}{2}}^{\frac{2}{3}} d q \int_{1-q}^q d w_1 \int_{q-w_1}^{1-q} w_2 \, d w_2 + \int_{\frac{2}{3}}^1 d q \int_{2q-1}^q d w_1 \int_{q-w_1}^{1-q} w_2 \, d w_2 \\
&= \frac{29}{15552} + \frac{1}{972} = \frac{5}{1728}, \\
\iint_{\mathbb{R}^d} d w_1 \, d w_2 \, d q &= \int_{\frac{1}{2}}^{\frac{2}{3}} d q \int_{1-q}^q d w_1 \int_{q-w_1}^{1-q} d w_2 + \int_{\frac{2}{3}}^1 d q \int_{2q-1}^q d w_1 \int_{q-w_1}^{1-q} d w_2 \\
&= \frac{5}{648} + \frac{1}{162} = \frac{1}{72},
\end{aligned}$$

so that the average representation is given by $(\frac{7}{12}, \frac{5}{24}, \frac{5}{24})$.

The type-revealing power indices require all voters belonging to the same equivalence class to be equally powerful. This assumption is likely to reduce the dimension of the problem, as the number of equivalence classes is typically smaller than the number of voters. We now move from individual voting weights to weights aggregated by equivalence classes, as if voters belonging to the same class form a voting bloc with weight being equal to the sum of weights of its members.

The game has two classes: class A comprises voter 1, whereas voters 2 and 3 form class B. Let w_a be the voting weight of class A, which equals the weight of the first voter $w_a = w_1$. The AWTI polytope degenerates to an interval

$$\mathbf{V}^t(v) = \{w_a \in \mathbb{R}_{\geq 0} \mid 3w_a \geq 1, w_a \leq 1\}.$$

We have,

$$\int_{\mathbf{V}^t} w_a \, d w_a = \int_{\frac{1}{3}}^1 w_a \, d w_a = \frac{4}{9} \quad \text{and} \quad \int_{\mathbf{V}^t} d w_a = \int_{\frac{1}{3}}^1 d w_a = \frac{2}{3}.$$

The voting power of class A according to AWTI equals $\frac{2}{3}$, which is the power of the first voter. The power of class B equals $\frac{1}{3}$. Since all voters comprising a class share its power equally, the AWTI power vector for the voters reads $(\frac{2}{3}, \frac{1}{6}, \frac{1}{6})$.

We now turn to the final index. The ARTI polytope is given by

$$\mathbf{R}^t(v) = \{(q, w_a) \in \mathbb{R}_{\geq 0}^2 \mid 3w_a \geq 1, 2q \leq 1 + w_a, q \geq 1 - w_a, q \geq w_a\},$$

where w_a is the voting weight of class A. We have,

$$\begin{aligned}
\iint_{\mathbf{R}^t} w_a \, d w_a \, d q &= \int_{\frac{1}{3}}^{\frac{1}{2}} w_a \, d w_a \int_{1-w_a}^{\frac{1+w_a}{2}} d q + \int_{\frac{1}{2}}^1 w_a \, d w_a \int_{w_a}^{\frac{1+w_a}{2}} d q = \frac{1}{108} + \frac{1}{24} = \frac{11}{216}, \\
\iint_{\mathbf{R}^t} d w_a \, d q &= \int_{\frac{1}{3}}^{\frac{1}{2}} d w_a \int_{1-w_a}^{\frac{1+w_a}{2}} d q + \int_{\frac{1}{2}}^1 d w_a \int_{w_a}^{\frac{1+w_a}{2}} d q = \frac{1}{48} + \frac{1}{16} = \frac{1}{12}.
\end{aligned}$$

The power distribution according to the ARTI is $(\frac{11}{18}, \frac{7}{36}, \frac{7}{36})$.
