ABSTRACT

The myoblast-mediated delivery of angiogenic genes represents a cell-based approach for targeted induction of therapeutic collateralization. Here, we tested the superiority of myoblast-mediated co-delivery of vascular endothelial growth factor-A (VEGF) together with platelet-derived growth factor-BB (PDGF-BB) on transpial collateralization of an indirect encephalomyosynangiosis (EMS) in a model of chronic cerebral ischemia. Mouse myoblasts expressing a reporter gene alone (empty vector; EV), VEGF, PDGF-BB or VEGF and PDGF-BB through a single bi-cistronic vector (VIP) were implanted into the temporalis muscle of an EMS following permanent ipsilateral internal carotid artery occlusion in adult, male C57BL/6N mice. Over 84 days, myoblast engraftment and gene product expression, hemodynamic impairment, transpial collateralization, angiogenesis, pericyte recruitment and post-ischemic neuroprotection were assessed. By day 42, animals that received PDGF-BB in combination with VEGF (VIP) showed superior hemodynamic recovery, EMS collateralization and ischemic protection with improved pericyte recruitment around the parenchymal vessels and EMS collaterals. Also, supplementation of PDGF-BB resulted in a striking astrocytic activation with intrinsic VEGF mobilization in the cortex below the EMS. Our findings suggest that EMS surgery together with myoblast-mediated co-delivery of VEGF/PDGF-BB may have the potential to serve as a novel treatment strategy for augmentation of collateral flow in the chronically hypoperfused brain.

Key words Collateral circulation; Gene therapy; Moyamoya disease; Neurosurgery; Revascularization

INTRODUCTION

Patients with chronic cerebral hemodynamic impairment due to progressive stenosis or occlusion of major cerebral arteries carry a risk of recurrent transient ischemic attacks and cerebral infarction up to 20-30% at 2 years.^{1,2} Direct extra- to intracranial bypass grafting with augmentation of collateral flow was expected to reduce this risk of subsequent ischemic stroke but surprisingly failed to show a benefit compared to best medical management, most likely due to the high procedure-related perioperative stroke rate up to 15% within the first 30 days following surgery.^{1,3} An encephalomyosynangiosis (EMS), represents a simple and safe alternative to direct bypass surgery for treatment of chronic cerebral hemodynamic impairment and describes a technique, where a vascularized pedicle graft of the temporalis muscle is placed in direct contact with the surface of the hypoperfused brain after removal of the bone and dura.^{4,5} However, hemodynamic rescue following the spontaneous formation of transpial extra- to intracranial collaterals between the muscle / brain interface of an EMS is not immediate and appears to be effective only in pediatric patients with Moyamoya vasculopathy and high endogenous pro-angiogenic activity⁶⁻¹⁰ and not in adults with hemodynamic compromise due to arteriosclerotic cerebrovascular disease.^{11,12} Importantly, effective collateralization through an EMS not only requires remodeling and outgrowth of *pre-formed* collateral vessels – arteriogenesis in the classical sense – but also *de novo* growth and maturation of an entirely new vascular network following mechanisms of postnatal vasculo- and angiogenesis, which precede the formation of patent and functional collaterals between the extracranial and intracranial vascular beds.

Here, Vascular Endothelial Growth Factor-A (VEGF) delivered at an appropriate microenvironmental concentration was shown to act as a key regulator of formation and maintenance of the native collateral density in the brain, next to the role of VEGF as a factor to induce capillary arterialization and proliferation of preformed arteriolar-arterial vessel networks.¹³⁻¹⁸ However, VEGF delivery alone may act as a negative regulator of vessel maturation,¹⁹ which is determined by pericyte recruitment mainly controlled by platelet-derived growth factor-BB (PDGF-BB).^{20,21} Against this background, we previously showed that a balanced, myoblast-mediated co-expression of VEGF and PDGF-BB using a single bi-cistronic vector, VIP, appears to provide superior conditions to harness the potency of VEGF for safe and effective induction of therapeutic neovascularization.²²⁻²⁵ Together with an EMS, retrovirally transfected myoblasts

1
2
3 appear to be the ideal drug delivery vehicle for targeted and specific stimulation of collateral
4 vessel growth in chronic cerebral ischemia, based on their capacity to fuse with pre-existing host
5 muscle fibers of the EMS and ensure a highly localized gene product delivery without the need
6
7 for immune suppression or the propensity to proliferate in an uncontrolled manner.^{17,18,23,25-29}
8
9

10
11 To overcome the limitations of VEGF single-factor delivery, we therefore tested the
12 efficacy of a balanced, myoblast-mediated co-expression of both murine VEGF (VEGF₁₆₄) and
13 human PDGF-BB (hPDGF-BB) on collateralization and ischemic protection in a mouse model of
14
15 EMS revascularization and chronic cerebral ischemia.

MATERIAL AND METHODS

Ethics Statement

Experiments were permitted by the local ethics committee on animal research (Landesamt für Gesundheit und Soziales, Berlin, Germany. LAGeSO No. G 0186/16) and in conformity with the German Law for Animal Protection and the National Institute of Health Guidelines for Care and Use of Laboratory Animals. Experiments have been reported following the ARRIVE guidelines.

Cell culture and growth factor secretion

The isolation, cultivation and retroviral infection of primary C57BL/6 mouse myoblasts was performed as previously described.^{23,25,27,30} Briefly, primary myoblasts were transduced with a constitutive LacZ-encoding retrovirus to express the β -galactosidase marker gene (Empty Vector [EV]). In addition, LacZ-encoded myoblasts were further transduced with retroviral vectors expressing murine VEGF₁₆₄ (designated VEGF), hPDGF-BB (designated PDGF), or both at a fixed ratio to each other from a bi-cistronic cassette through the encephalomyocarditis virus Internal Ribosomal Entry Site (IRES) (designated VIP for VEGF-IRES-PDGF) as previously described.²³ A truncated version of CD8a was co-expressed with VEGF₁₆₄ or hPDGF-BB from a similar bi-cistronic construct (VEGF- and PDGF-myoblasts) or from a separate promoter (VIP) as a cell surface marker of transduced cells. Early-passage myoblast clones were randomly isolated using a FacStar cell sorter (Becton Dickinson, San Jose, CA, USA) and single-cell isolation was confirmed visually. All myoblast populations were cultured in 5% CO₂ on collagen coated dishes.

For optimal selection of myoblast populations based on previous functional and morphological results,²³ VEGF₁₆₄ and hPDGF-BB secretion was quantified in cell culture supernatants using specific ELISA kits (R&D Systems, Abingdon, UK) as described previously.^{17,23} Myoblast populations were selected for implantation as follows: monoclonal VEGF myoblasts homogeneously secreting $61.0 \pm 2.9 \text{ ng}/10^6$ cells/day of VEGF₁₆₄, polyclonal PDGF-myoblasts secreting on average $45.7 \pm 2.4 \text{ ng}/10^6$ cells/day of hPDGF-BB and polyclonal VIP-myoblasts secreting an average amount of $58.9 \pm 5.8 \text{ ng}/10^6$ cells/day of VEGF₁₆₄ and $9.7 \pm 0.7 \text{ ng}/10^6$ cells/day of hPDGF-BB at a fixed ratio in each cell.

Animals and design

A total number of 292 male C57BL/6N mice (Charles River WIGA GmbH, Sulzfeld, Germany), aged 10-12 weeks were randomized to the following experimental groups:

- *EV*: ICA-O and EMS with implantation of empty vector myoblasts
- *VEGF*: ICA-O and EMS with implantation of VEGF₁₆₄-expressing myoblasts
- *PDGF*: ICA-O and EMS with implantation of hPDGF-BB-expressing myoblasts
- *VIP*: ICA-O and EMS with implantation of VEGF₁₆₄- and hPDGF-BB co-expressing myoblasts

Animals were randomized with the help of an online randomizing tool (<https://www.randomizer.org>). Along the course of the observation period up to 84 days, 44 animals were excluded due to procedure-related mortality (EV n = 12, VEGF n = 13, PDGF n = 11, VIP n = 8). For all procedures, mice were anesthetized with 70 mg/kg ketamine and 16 mg/kg xylazine, and body temperature was maintained at 37°C. Ketamine and xylazine were selected based on our previous model validation³¹ in order to minimize cardiovascular and respiratory effects on cerebral blood flow (CBF) that may occur with volatile anesthetics, opioids or benzodiazepines and hamper reliable assessment of the acetazolamide-specific cerebrovascular reserve capacity (CVRC). Mice were kept in an enriched environment with free access to food and water. Blinding for treatment and data analysis was ensured by coding the myoblasts before implantation. To determine group allocation, un-coding was performed after individual data analysis.

ICA-occlusion, encephalomyosynangiosis and myoblast implantation

The internal carotid artery occlusion (ICA-O) was performed immediately before the EMS procedure at a time point defined as day 0. For ICA-O, the animal was positioned supine and the right-sided ICA was permanently ligated with an 8/0 silk suture. Next, the animal was turned to prone position and a right-sided craniectomy was performed along the superior temporal line to the temporal skull base, extending from the bregma to the lambdoid suture using a diamond-tip micro drill (Proxxon GmbH, Wartberg/Aist, Austria). The dura was completely excised along the margin of the craniectomy. To secure the temporal muscle above the cortical surface after

1
2
3 myoblast implantation (see below), the overlying muscle fascia was sutured to the contralateral
4 aponeurosis and the skin was readapted with 6/0 Nylon as previously described.^{28,29,31} For
5 implantation, cultured EV-, VEGF-, PDGF- and VIP-myoblasts were trypsinized and re-
6 suspended in phosphate-buffered saline with 0.5% bovine serum albumin. Five cell suspensions
7 of 5µL, each containing 5×10^5 myoblasts (equaling a total number of 25×10^5 cells) were implanted
8 into the temporalis muscle using a Hamilton® microsyringe with a 26-gauge needle (Hamilton Co.,
9 Reno, NV, USA) during the EMS procedure on day 0.

19 *Measurement of cerebral hemodynamics using Laser Speckle Imaging*

21 Resting CBF and acetazolamide-specific CVRC of the *affected* (right) hemisphere was
22 determined on days 0, 7, 21, 42 and 84 with non-invasive laser speckle imaging (LSI). After
23 positioning of the laser speckle device (MoorFLPI, Moor Instruments, Devon, England), a five-
24 minute baseline measurement of cortical resting perfusion (CBF-Flux measured in arbitrary
25 perfusion units) was recorded within a 6x4 mm region of interest over the right middle cerebral
26 artery (MCA) territory, which permitted a combined arterial, venous and parenchymal perfusion
27 and blood flow assessment. A 120-second CBF-Flux plateau was calculated as baseline
28 perfusion. Next, 50mg/kg acetazolamide (Diamox, Goldshield Pharmaceuticals Ltd., Surrey,
29 England) was injected intraperitoneally and the acetazolamide-specific cerebrovascular reserve
30 capacity (CVRC) was calculated as the percent perfusion change between the baseline plateau
31 and a 120-second CBF-Flux plateau after a maximum rise in CBF-Flux.^{29,31} (days 0-21: EV n=21,
32 VEGF n=20, PDGF n=22, VIP n=23; day 42: EV n=17, VEGF n=15, PDGF n=17, VIP n=16; day
33 84: EV n=8, VEGF n=8, PDGF n=8, VIP n=9). The normalized resting perfusion at each time point
34 (defined as 100%) and mean CVRC on day 0 was additionally determined in the *unaffected* (left)
35 hemisphere.

53 *Middle cerebral artery occlusion and cortical stroke volume assessment*

55 The percentage of ipsilateral cortical infarction after 60-minute MCA-O and 6-hour reperfusion
56 was assessed through magnetic resonance imaging (MRI) on days 21, 42 and 84. For temporary
57 MCA-occlusion (MCA-O), animals were turned to supine position and the midline neck incision
58
59
60

1
2
3 was reopened. The carotid sheath was carefully dissected and the right ICA was incised distal to
4 the site of the previous ICA-O. Next, a 7/0 silicone-rubber coated monofilament (Doccol
5 monofilament, length 20mm, diameter with coating 0.21 ± 0.01 mm; Doccol cooperation, Sharon,
6 MA, USA) was smoothly inserted up to the level of the ICA/MCA bifurcation. After 60 minutes, the
7 filament was removed and the ICA was permanently ligated proximal to the incision. Six hours
8 later, the volume of the ischemic cortical tissue and of the total cortex ipsilateral to the
9 encephalomyosynangiosis (EMS) was determined in a 7-tesla animal MRI (Bruker Pharmascan
10 70/16 with a 20mm radio frequency volume resonator, Bruker Biospin, Ettlingen, Germany) and
11 analyzed with purpose-designed biomedical imaging software (Analyze 10.0, Biomedical Imaging
12 Resource, Mayo Clinic, Rochester, MN, USA) to determine the percentage of cortical infarction
13 according to signal hyperintensity in serial T2-weighted coronal images.²⁹ Laser Speckle Imaging
14 was used to visualize the cortical perfusion pattern over the affected hemisphere during the 60-
15 minute occlusion. Correlation between the percentage of cortical infarction and CVRC was
16 analyzed to assess the effect of the hemodynamic response following EMS and VIP-myoblast
17 implantation. (day 21: EV n=5, VEGF n=6, PDGF n=6, VIP n=6; day 42: EV n=7, VEGF n=6,
18 PDGF n=7, VIP n=7; day 84: EV n=6, VEGF n=8, PDGF n=5, VIP n=7).

19 20 21 22 23 24 25 26 27 28 29 30 31 32 33 34 35 36 37 *FITC-lectin perfusion for assessment of transpial collaterals*

38 To determine transpial collateralization across the EMS, an *in-vivo* Fluorescein isothiocyanate
39 (FITC)-lectin perfusion was performed via the external carotid artery ipsilateral to the side of the
40 EMS in two groups of animals with and without MCA-O (please see above). The ipsilateral
41 external carotid artery was cannulated with a polyethylene catheter (inner diameter 0.28mm; outer
42 diameter 0.61mm) connected to a micro syringe. The ipsilateral common carotid artery was
43 proximally ligated and a solution of 50 μ l (100 μ g) FITC-lycopersicon esculentum (tomato) lectin
44 (Vector Laboratories Inc., Burlingame, CA, USA) and 200 μ l phosphate-buffered saline was
45 injected. The mice were decapitated within 2 seconds after the injection and whole-head
46 specimens were snap-frozen at minus 80°C. To characterize the positive or negative
47 development of transpial collaterals we defined the *EMS take-rate* parameter: In each section,
48 transpial collateralization was determined positive only after direct visual confirmation of (a)
49 continuous FITC-lectin positive vessels crossing from the muscle into the cortex and (b) a distinct

1
2
3 association of these vessels with the resident vasculature of the cortical region below the EMS.
4
5 The total number of sections with positive transpial collaterals was counted in each animal and
6
7 the individual EMS take-rate was defined positive if collaterals were noted in $\geq 50\%$ of all section
8
9 levels. The overall take-rate was calculated as the percentage of positive versus negative EMS'.
10
11 Further, Correlation between the number of collaterals and CVRC was analyzed to assess the
12
13 effect of transpial collateralization on the hemodynamic response. (day 21: EV n=5, VEGF n=6,
14
15 PDGF n=6, VIP n=6; day 42: EV n=7; VEGF n=7, PDGF n=7, VIP n=7; day 84: EV n=6, VEGF
16
17 n=8, PDGF n=6, VIP n=7).

21 *Immunohistochemistry*

22
23 To assess fusion and reporter gene expression of implanted myoblasts at the muscle / brain
24
25 interface of the EMS, an X-gal stain was performed on day 21 after implantation and is described
26
27 elsewhere in detail.²⁸ Briefly, 60 μ m coronal cryosections of snap-frozen, whole-head specimens
28
29 were fixed with 4% paraformaldehyde, rinsed in phosphate buffered saline and incubated with X-
30
31 gal reaction buffer (diluted 40mg/ml X-gal in dimethylformamide to 1:40 with X-gal dilution buffer)
32
33 for 24 hours. Myoblast fusion and reporter gene expression was identified according to the visual
34
35 confirmation of β -gal positive cells.

36
37 For analysis of transpial collaterals and neuron survival after MCA-O, vessel density and
38
39 pericyte coverage, proliferation and neuronal apoptosis, and astrocyte activation with VEGF or
40
41 phospho-PDGF-R β co-localization, 10 μ m coronal cryosections of snap-frozen, whole-head
42
43 specimens were obtained from the anterior, middle and posterior region of the EMS (Bregma -
44
45 0.5mm, -1.5mm and -2.5mm, respectively). Sections were mounted and visualized under a
46
47 fluorescence-enhanced microscope (Axio Imager 2, Zeiss, Oberkochen, Germany). For analysis
48
49 of pericyte recruitment of transpial collaterals, 20 μ m cryosections were obtained in animals that
50
51 underwent FITC-lectin perfusion without MCA-O and visualized under a laser-scanning
52
53 microscope (LSM710, Zeiss, Oberkochen, Germany). Negative control information was obtained
54
55 by incubating tissue samples with only the corresponding secondary antibodies.

56
57 To determine surviving neurons following MCA-O together with patent transpial
58
59 collaterals, NeuN positive cells per mm² (days 21, 42 and 84) and FITC-lectin positive collaterals
60

1
2
3 per animal (day 42) were counted in the cortical region below and across the muscle / brain
4 interface of the EMS (day 21: EV n=5, VEGF n=6, PDGF n=6, VIP n=6; day 42: EV n=7; VEGF
5 n=7, PDGF n=7, VIP n=7; day 84: EV n=6, VEGF n=8, PDGF n=6, VIP n=7). To assess the
6 morphology of transpial collaterals (EV n=7, VEGF n=7, PDGF n=7, VIP n=7) and the cortical
7 vasculature (EV n=4, VEGF n=4, PDGF n=4, VIP n=4) on day 42, the vessel density and pericyte
8 coverage were evaluated by a combined CD31/Desmin stain. Vessel density within the cortical
9 area below the EMS was calculated as CD31-positive vessels per mm² for vessels below and
10 above 10µm in diameter. Pericyte coverage for the cortical vessels and transpial collaterals was
11 expressed as the percentage of CD31-positive vessels with Desmin co-localization. Neuronal
12 apoptosis on day 42 (EV n=4, VEGF n=4, PDGF n=4, VIP n=4) in the cortical region below the
13 EMS was assessed by a combined TUNEL/NeuN stain. Apoptotic neurons were calculated as
14 cells per mm² (Supplemental Figure I). Astrocyte activation and VEGF or phospho-PDGFR-β co-
15 localization in relationship to the cortical vasculature below the EMS on day 42 (EV n=4, VEGF
16 n=4, PDGF n=4, VIP n=4) were detected by a combined glial fibrillary acidic protein (GFAP) /
17 VEGF or phospho-PDGFR-β / CD31 stain. GFAP / VEGF or phospho-PDGFR-β co-localization
18 was calculated as surface area (µm²) per mm² or pPDGFR-β coverage (%) of the GFAP-positive
19 surface area, respectively.

17 *Real-time PCR and Western blot*

18
19 For analysis of exogenous (IRES) gene product transcription and VEGF / hPDGF-BB protein
20 expression in the temporalis muscle and within the muscle / brain interface of the EMS on day
21 42, tissue samples of the temporalis muscle and the interface were harvested and snap-frozen
22 for real-time PCR (rtPCR) and Western blot analysis (EV n=4, VEGF n=4, PDGF n=4, VIP n=4).
23
24
25
26
27

28 For transcription analysis, RNA isolation was performed with Trizol, according to standard
29 Trizol extraction protocol (Invitrogen, Carlsbad, CA, USA). The amount of RNA was quantified
30 using Infinite 200 PRO (TECAN, Männedorf, Switzerland). cDNA was reversely transcribed using
31 QuantiTec Reverse Transcription Kit (Qiagen, Venlo, Netherlands) according to the
32 manufacturer's recommendation. Real-time PCR amplifications were performed in triplicates in a
33 25 μ L reaction volume using the SYBR Premix Ex Taq Kit (Takara Bio Inc., Shiga, Japan) with the
34 indicated primer pairs of IRES-forward: GCTCTCCTCAAGCGTATTCAACA and IRES-reverse:
35 CCCAGATCAGATCCCATACA and a 7900HT Fast rtPCR System or ABI Prism 7000 Sequence
36 Detection System (Applied Biosystems, Foster City, CA, USA). For standardization, GAPDH was
37 used as housekeeping gene (GAPDH-forward: GGCCTTCCGTGTTCCCTACC; GAPDH-reverse:
38 AACCTGGTCCTCAGTGTTACC). All data were analyzed by the relative quantification method
39 ($\Delta\Delta$ Ct). For Western blot, samples harvested from the temporalis muscle or the muscle / brain
40 interface were homogenized with a solution of RIPA buffer and Protease inhibitors (ratio
41 Sample:RIPA = 1:10). For Western blot analysis, the protein concentration of each sample was
42 determined using a Pierce BCA Protein Assay Kit (Thermo Fisher Scientific, Waltham, MA, USA)
43 according to the standard protocol. Samples containing 100 μ g of protein were subjected to 10%
44 polyacrylamide gel electrophoresis in the presence of 0.1% sodium dodecyl sulfate. Protein bands
45 were transferred from the gel to PVDF membranes, which were incubated with a 1:1000 dilution

3 of rabbit polyclonal anti-VEGFA antibody (1µg/ml, Abcam AB46154, Cambridge, UK) or with
4
5 1:100 dilution of rabbit polyclonal anti-platelet-derived growth factor (PDGF) antibody (1µg/ml,
6
7 Abcam AB16829, Cambridge, UK) and membranes were reacted with horseradish peroxidase-
8
9 conjugated donkey anti-rabbit IgG antibody (Jackson ImmunoResearch Laboratories, West
10
11 Grove, PA, USA). Protein bands on membranes were detected by an enhanced
12
13 chemiluminescence method. Quantification of the Western Blot bands was performed after
14
15 normalization of the GAPDH densities. First, images were converted to 8bit grayscale and
16
17 identical threshold intensity settings were applied with the help of image processing and analysis
18
19 software (ImageJ, Ver. 2.0.0-rc-68/1.52g, <https://imagej.nih.gov/ij/>). Next, we determined the
20
21 background-subtracted densities (Integrated Density) of the protein of interest (PI; VEGF or
22
23 PDGF-BB) and the normalizing control (GAPDH) bands. For each PI, we then identified the
24
25 GAPDH band with the highest density (Control, VEGF, PDGF or VIP). In order to obtain a
26
27 normalized GAPDH value, we then divided all GAPDH density values by the highest GAPDH
28
29 density value. To then quantify the density of the PI in each lane based on the normalized GAPDH
30
31 value, each PI density was divided by the normalized GAPDH value in their respective lane.
32
33
34

35 *Statistical analysis*

36
37 Data are presented as mean ± standard deviation (SD) or percentage. All continuous variables
38
39 passed normality and equal variance testing, determined by the Shapiro-Wilks and F-Test and
40
41 parametric testing was performed accordingly. Baseline perfusion and CVRC were compared by
42
43 a two-way ANOVA for repeated measurements with subsequent pair-wise comparison of means
44
45 by Fisher's least projected difference test. Cortical infarct size, NeuN positive cells after MCA-O,
46
47 transpial collaterals, EMS take rate, vessel density, pericyte coverages, neuronal apoptosis and
48
49 GFAP/VEGF or phospho-PDGF-Rβ co-localization were compared by a one-way ANOVA
50
51 procedure with Bonferroni correction for multiple comparisons. Relative quantity ($\Delta\Delta\text{Ct}$) using
52
53 IRES primer in real-time PCR was compared by a non-parametric Kruskal-Wallis test with Dunn's
54
55 post hoc analysis for multiple comparisons. For correlation of "Cortical infarction" versus "CVRC"
56
57 and "Number of collaterals" versus "CVRC", a Spearman correlation analysis was used due to
58
59 failed normality tests. Statistics were performed with GraphPad Prism for Mac (Version 5.0f,
60
GraphPad Software, San Diego, California, USA). Statistical significance was set at $p < 0.05$.

RESULTS

Myoblast engraftment and gene product expression

On day 21, X-gal staining revealed successfully fused hybrid myofibers in all experimental groups (Figure 1A). A bluish extracellular β -gal signal as a sign of local reporter gene expression by non-fused myoblasts without fiber structure was noted particularly after implantation of PDGF myoblasts. In the temporalis muscle, rtPCR using IRES primer on day 42 confirmed the exogenous transcription of VEGF₁₆₄ and/or hPDGF-BB in VEGF-, PDGF- and VIP-myoblasts, respectively, with the highest transcription rate noted in PDGF myoblasts. An increased amount of total VEGF and/or hPDGF-BB in the temporalis muscle following implantation of VEGF-, PDGF- or VIP myoblasts was confirmed by Western blot (Figure 1B).

Hemodynamic rescue following VEGF₁₆₄ and hPDGF-BB co-delivery

Laser Speckle Images of typical resting perfusion and cortical blood flow responses to acetazolamide on day 42 are illustrated in Figure 2 and expressed as percentage compared to contralateral (resting perfusion) or overall percentage (CVRC). First, we analyzed resting (baseline) perfusion between treatment groups. On day 0 following ICA-O with EMS and myoblast implantation, resting perfusion over the affected hemisphere was reduced >20% and comparable between groups. Although none of the groups reached resting perfusion levels of the contralateral hemisphere, animals treated with VIP myoblasts showed signs of a sustained perfusion increase over time (Figure 2A and 2B, upper panel). We then focused on the cortical perfusion response after acetazolamide challenge: Compared to the hemodynamic response over the unaffected hemisphere on day 0, CVRC over the affected hemisphere on day 0 was reduced >50% and comparable between groups. Over time, spontaneous hemodynamic rescue occurred in all groups with the earliest and most pronounced CVRC recovery in VIP-treated animals, followed by animals treated with VEGF-myoblasts (Figure 2A and 2B, lower panel).

Cortical stroke and regional perfusion following MCA-O

At day 42, animals treated with VIP myoblasts had a 30-35% reduction of cortical infarction compared to animals treated with PDGF or EV myoblasts. At day 84, this benefit for VIP-

1
2
3 compared to EV-treated animals was sustained, corresponding to a 38% reduction of cortical T2
4 signal hyperintensity. Laser Speckle Imaging confirmed sustained cortical perfusion during the
5 MCA-occlusion period in VIP-treated animals compared to animals that only received EV
6 myoblasts. A significant negative correlation was found between the percentage of cortical
7 infarction and the degree of hemodynamic impairment (*p = 0.016; r = -0.59) (Figure 3).
8

10
11
12
13
14

15 *Neuroprotection after MCA-O and transpial collateralization*

16
17 Following proximal stroke through MCA-O at day 21, 42 and 84, VIP-treated animals had a
18 significantly higher number of surviving neurons in the cortical region below the EMS than animals
19 treated with EV myoblasts alone (Figure 4A and 4B). On day 42, positive spontaneous transpial
20 collateralization was detected in all groups with an 85% increase in patent extra- to intracranial
21 collaterals and the highest EMS take-rate in VIP-treated animals compared to animals that
22 received EV myoblasts (Figure 4C). The functional hemodynamic relevance of this improved
23 collateralization is suggested by a significant correlation of the number of collaterals to the CVRC
24 (**p=0.0076; r = 0.29), next to the 20% greater relative CVRC difference in animals with 10 or
25 more collaterals (Figure 4D).

36
37
38

39 *Vessel density, pericyte recruitment and neuronal apoptosis*

40 At day 42, treatment with VIP and PDGF myoblasts resulted in a significant 50% increase in the
41 density of cortical vessels >10µm compared to animals that only received EV myoblasts, which
42 was paralleled by a 13-15% increase in pericyte coverage of vessels <10µm, indicating an
43 increased microvascular maturation (Figure 5A and 5B). Regarding the morphology of transpial
44 collaterals, however, only VIP-treated animals consistently showed a dense mural Desmin
45 coverage of the FITC-positive extra- to intracranial collaterals crossing from the muscle into the
46 brain (Figure 5C and 5D). Further, TUNEL staining on day 42 revealed an 85% reduction of
47 apoptotic neurons following treatment with VIP compared to EV myoblasts (Supplemental Figure

I).

PDGF-BB dependent astrocyte activation with intrinsic VEGF mobilization

In addition to its role in stimulating vessel growth and maturation, VEGF and PDGF-BB are important neurotrophic factors that have the potential to enhance the neurogenic capacity in the brain through astrocytic activation, which is morphologically characterized by hypertrophy of astrocytic somata, processes and prominent expression of GFAP.³²⁻³⁴ Also, VEGF and its receptors are expressed in astrocytes themselves and the level of intrinsic VEGF is upregulated upon astrocytic activation.³⁵ As a last step, we therefore investigated direct effects of local growth factor supplementation on astrocytes below the EMS. Here, GFAP immunofluorescence suggested an increased astrocytic activation in the cortical region below the EMS after PDGF- and VIP-myoblast implantation. Particularly in animals that received a balanced co-delivery of hPDGF-BB and VEGF₁₆₄, activated astrocytes were in direct contact with CD31-positive parenchymal vessels and showed significant VEGF co-localization, possibly due to increased intrinsic VEGF mobilization upon astrocytic activation (Figure 6A and 6B). X-gal staining, rtPCR and Western blot analysis confirmed positive reporter gene expression, gene product transcription and increased VEGF and/or hPDGF-BB levels at the muscle / brain interface of the EMS on day 42 (Figure 6C and 6D). Next to increased astrocytic activation, we found a marked elevation of phospho-PDGF-R β signal intensity in the cortical region of the EMS together with a significantly higher co-localization of phospho-PDGF-R β and the GFAP-positive surface area (Figure 7).

DISCUSSION

In the present model of chronic cerebral ischemia and EMS, co-delivery of VEGF and PDGF-BB led to superior EMS collateralization and hemodynamic rescue with increased ischemic protection compared to delivery of VEGF or PDGF-BB alone. Improved vascular maturity was a key factor associated with these beneficial effects. Further, our findings suggest that PDGF-BB-mediated astrocytic activation might serve as a secondary neuroprotective mechanism independent from therapeutic collateralization.

Growth factor expression and myoblast engraftment

VEGF is a critical mediator of cerebral collateral development and maintenance in the adult mouse brain.^{13,14,16,29} However, VEGF-induced neovascularization requires increased levels of VEGF to achieve beneficial effects, yet high VEGF expression levels readily lead to a loss of safety. In the present study, VEGF₁₆₄ alone was delivered at its most optimal microenvironmental dose by a monoclonal myoblast population homogeneously expressing the most therapeutic amount of VEGF₁₆₄, as determined previously.^{17,18} In comparison, co-delivery of VEGF₁₆₄ and hPDGF-BB at a fixed ratio was enacted without any kind of dose control. This co-expression through the VIP construct previously enabled robust VEGF delivery and further expanded the functional efficacy of VEGF alone.²⁵ Regarding engraftment, we were able to confirm stable fusion and gene product expression of all implanted myoblast populations within the temporalis muscle of the EMS. The different transcription levels that we observed within the muscle and at the muscle / brain interface are likely associated with the fact that PDGF and VIP myoblasts tend to engraft better than the remaining myoblast populations due to the trophic effects of hPDGF-BB on the myoblasts themselves. Interestingly, in some cases PDGF myoblasts resulted in local tumor development within the temporalis muscle, as indicated in Figure 1A. Most likely, this is caused by excessive hPDGF-BB expression by some of the myoblasts in the polyclonal population due to random differences in copy number and genomic integration sites of the retroviral vector. The blush β -gal signal instead of a fiber structure indicates that such tumors are not formed exclusively by the myoblasts, which actually encounter an unfavorable environment for differentiation and remain as single cells.

Hemodynamic rescue, transpial collateralization and ischemic neuroprotection

In clinical practice, the degree of cerebrovascular reactivity remains the most important parameter to assess the patients' risk of hemodynamic ischemic stroke, because non-ischemic cerebral hypoperfusion is typically characterized by a normal or at best only mild reduction of baseline (resting) perfusion.² Therefore, we first addressed whether VEGF₁₆₄ and hPDGF-BB co-expression at the muscle/brain interface of an EMS translated into improved cerebral hemodynamics. In this regard, only VIP-treated animals experienced nearly complete hemodynamic rescue, whereas the CVRC in animals treated with EV, VEGF or PDGF myoblasts alone remained 30-15% below the CVRC response of the non-occluded hemisphere. The time line of this hemodynamic rescue was in line with our present and previous results regarding the time points of myoblast host integration, collateral outgrowth and vascular remodeling.^{17,18,23,29} Importantly, the improved hemodynamics following VIP treatment were not accompanied by an overshooting CVRC response or perfusion increase, which is essential to avoid critical postoperative hyperperfusion in hemodynamically compromised patients undergoing surgical revascularization.³⁶

The main goal of an EMS is the reduction of subsequent ischemic events through improvement of collateral flow at the level of the leptomeningeal vasculature, which is a major determinant in the severity of stroke.³⁷ Therefore, we next tested whether our hemodynamic findings also translated into improved collateralization and regional ischemic protection: Indeed, only treatment with VIP myoblasts resulted in a significant and sustained 38% reduction of cortical infarct volume after proximal MCA-O, together with a significantly greater number of patent transpial collaterals. For the first time, we were also able to show a direct link between the size of cortical infarction, the degree of transpial collateralization and the degree of hemodynamic CVRC impairment, which correlated not only with the percentage of cortical infarction but also with the number of transpial collaterals. The reason for focusing on cortical instead of subcortical infarction is the variable degree of native basal and leptomeningeal collateralization in C57BL/6 mice, which results in highly variable subcortical stroke volumes after MCA filament occlusion.^{38,39} In the setting of chronic cerebral ischemia, we were able to confirm our previous findings that an experimental EMS mainly provides ischemic protection in the cortical territories surrounding the newly formed transpial collaterals.²⁹ Since the proportional volume of the cerebral cortex is much

1
2
3 smaller than that of the subcortical region, however, additional analysis of the subcortical stroke
4 volume in our model would mask the protective effect of the EMS. On the other hand, a distal
5 MCA-O model with only a localized focal cortical stroke was not feasible due to the adhesive
6 EMS, which limits access to the leptomeningeal cerebral vasculature without injuring the transpial
7 collaterals. This relationship between improved EMS collateralization and greater ischemic
8 protection is verified by the sustained cortical perfusion across the EMS during MCA-O and in
9 line with our observed neuroprotection under myoblast-mediated co-delivery of VEGF₁₆₄ and
10 hPDGF-BB.

21 *Vascular maturation and pericyte recruitment*

22
23 While VEGF is the crucial factor to promote endothelial cell growth, PDGF-BB is essential for
24 stabilization of blood vessels by recruiting pericytes for regulation of vessel diameters and blood
25 flow.^{20,21} However, VEGF may also act as a negative regulator of pericyte function and vessel
26 maturation,¹⁹ which is suggested by the fact that VEGF₁₆₄ alone failed to sustain pericyte
27 recruitment around parenchymal microvessels or transpial collaterals. In comparison, treatment
28 with VEGF₁₆₄ and hPDGF-BB co-expressing VIP myoblasts not only resulted in improved
29 hemodynamic rescue, transpial collateralization and ischemic protection, but also in a higher pro-
30 angiogenic activity with significantly improved pericyte recruitment as a sign of greater vascular
31 maturation. Remarkably, this increased pericyte recruitment was also noted around the newly
32 formed transpial EMS collaterals and paralleled by an activation of PDGF receptor beta (PDGF-
33 R β) (Supplemental Figure II), which may have relevant clinical implications, because autopsy
34 reports in patients that underwent an EMS demonstrated that the transpial EMS collaterals appear
35 to have a fragile structure with a thin and sparse media composed mainly of smooth muscle actins
36 without a mature perivascular network.⁴⁰ Also, we cannot exclude that an increased microvascular
37 smooth muscle cell coverage and subcortical capillary arterialization, where remodeled capillaries
38 function as collaterals to hypoperfused tissue, may have contributed to the hemodynamic rescue
39 and ischemic protection that we noted.^{13,14,31,41}

Direct effect and limitations of localized hPDGF-BB delivery

The sporadic tumor formation following implantation of polyclonal PDGF myoblasts requires a discussion of safety implications and their possible solutions: As stated, hPDGF-BB production by polyclonal PDGF myoblasts was almost 5-fold higher than that of VIP myoblasts, which explains why tumors were not observed in the VIP-treated animals. Further, our work provides proof-of-principle of the superiority of the combination delivery over VEGF delivery alone, even if VEGF is delivered in its most optimal, homogeneous dose by the monoclonal population employed here. However, refinements need to be enacted for therapeutic application, such as rapid FACS purification to exclude cells expressing excessive PDGF-BB doses, which can easily be performed based on the intensity of the CD8 marker, as described previously.⁴² The sporadic tumor formation following hPDGF-BB supplementation also explains another surprising observation: In contrast to what might have been expected, we noted a similar hemodynamic recovery following hPDGF-BB supplementation and supplementation of VEGF₁₆₄ alone, which could be due to the high amount of VEGF protein also in hPDGF-BB treated groups. This anomalous amount of VEGF protein in tissue treated with PDGF myoblasts is most likely endogenous and upregulated due to tumor formation with ensuing hypoxia, which functionally causes the tissue treated with PDGF myoblasts to behave like tissue under VEGF conditions. Nevertheless, co-delivery of VEGF₁₆₄ and hPDGF-BB in VIP myoblasts still remained superior, because the expression of both factors is balanced and coordinated through the bi-cistronic VIP vector in every cell, whereas in hPDGF-BB-induced tumors, both factors are expressed heterogeneously throughout the tissue. Although we did not find significant differences of the endogenous VEGF₁₆₄ expression within the temporalis muscle, transcription of endogenous VEGF₁₆₄ at the muscle/brain interface was significantly upregulated in VIP animals as sign of the increased pro-angiogenic activity in this group. Interestingly, we also noted a trend towards a higher endogenous VEGF₁₆₄ transcription in animals that received hPDGF-BB alone, which is in line with our hypothesis of tumor-ensuing hypoxia as a cause for the increased VEGF₁₆₄ protein levels in these animals (Supplemental Figure III).

Interestingly, myoblast mediated growth factor supplementation also resulted in an increased activation of astrocytes and co-localization of VEGF within astrocytes / astrocytic processes and endothelial cells in the cortical parenchyma below the EMS (Figure 6 and

1
2
3 Supplemental Figure IV). The significantly increased PDGF-R β expression on reactive astrocytes
4 particularly in PDGF-treated animals (Figure 7) suggests that the observed astrocytic activation
5 appears to be a direct effect following PDGF-BB delivery, which is in line with our reporter-gene
6 expression analysis and molecular findings at the muscle / brain interface of the EMS but also
7 with previous results, demonstrating a PDGF-BB-dependent astrocytic activation and pro-
8 inflammatory response with monocyte recruitment via induction of monocyte chemoattractant
9 protein 1 (MCP-1) and downstream activation of nuclear factor κ B (NF κ B).^{17,18,23,29} Possibly, this
10 astrocytic activation could be a second reason for favorable hemodynamic recovery, because
11 activation of NF κ B with stabilization of hypoxia-inducible factor (HIF)-1 α expression has been
12 identified as a key pathway for capillary arterIALIZATION and maturation of a new arterial collateral
13 network following shear-stress induced endothelial activation of collateral outgrowth.¹⁶ Further,
14 astrocytic activation could also have contributed to direct neuroprotection by reduction of reactive
15 oxidant species and activation of antioxidant mechanisms within activated astrocytes⁴³ next to an
16 increased intrinsic VEGF mobilization, which was shown to directly contribute to structural
17 neuroprotection with improved functional recovery following acute ischemic stroke.^{44,45} Apart from
18 extracellular secretion, the pattern and shape of VEGF localization in GFAP- and CD31-negative
19 areas could be an expression of nuclear and perinuclear VEGF accumulation in neuronal or peri-
20 arteriole smooth muscle cells following the increase of HIF-1 α expression as an adaptive change
21 underlying a low oxygen environment in chronic hypoxia.^{46,47}

22 23 24 25 26 27 28 29 30 31 32 33 34 35 36 37 38 39 40 41 42 *Study design limitations*

43
44 The use of only young, healthy, male animals requires explanation, because in preclinical stroke
45 research internal and external validity must be reduced by limiting bias and including aged, co-
46 morbid animals of both sexes. However, our present study was an exploratory proof-of-concept
47 investigation with focus on a novel approach for therapeutic cerebral collateralization in a model
48 of cerebral hypoperfusion, which we previously established in male C57BL/6N mice.³¹
49 Importantly, the degree of chronic cerebral ischemia above the threshold of ischemic stroke in
50 mice is largely influenced by the native cerebral collateral vasculature, which underlies a high
51 developmental variability and influences the degree of hemodynamic impairment.^{31,38} Further,
52 differences in molecular mechanisms of ischemic cell death and stroke outcome have been
53
54
55
56
57
58
59
60

1
2
3 observed in males and females. This difference is usually assigned to the estrus cycle in female
4 mice, because estrogen has been shown to protect the brain in numerous models of experimental
5 brain injury. For the purpose of standardization, we therefore deliberately matched age, sex, and
6 genetic background of our animals according to our previously established model^{29,31} and
7 designed our experiments according to the initial Stroke Therapy Academic Industry Roundtable
8 (STAIR) recommendations, where such exploratory studies are recommended to be performed
9 in young, healthy animals without vascular disease or vascular risk factors.⁴⁸ Thus, to what extent
10 the present approach would be beneficial if one of the driving risk factors for stroke and stroke
11 outcomes were present still needs to be determined.

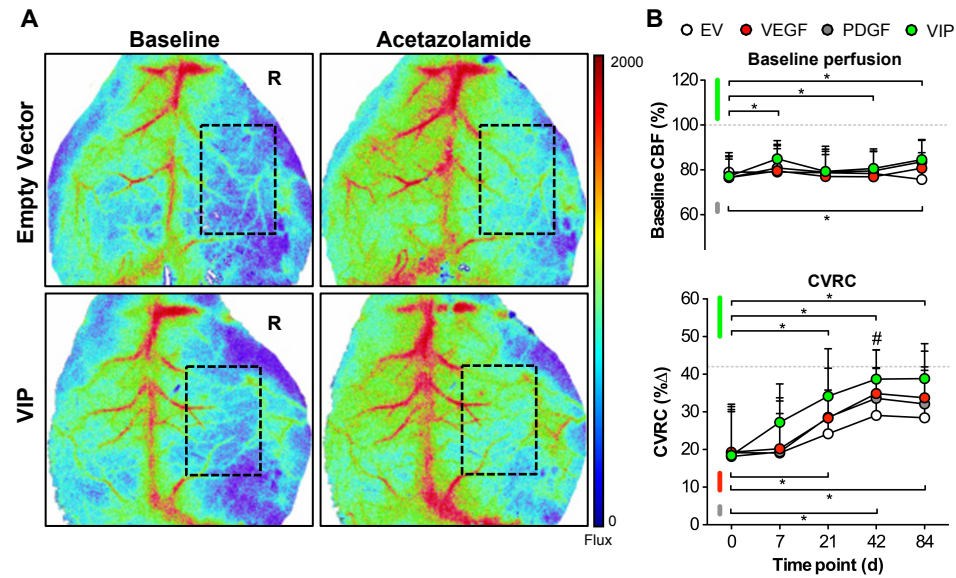

Figure 1

Myoblast engraftment and gene-product expression

(A) Immunohistochemical X-gal staining confirms stable engraftment of EV, VEGF, PDGF and VIP myoblasts on day 21 after implantation into the temporalis muscle. The asterisk within the area of blush reporter gene expression exemplifies a local tumor formation after implantation of myoblasts expressing hPDGF-BB alone. Bar = 200 μ m; m = muscle, c = cortex; dashed line = muscle / brain interface. (B) Real-time PCR using IRES primer and Western blot confirm exogenous gene product transcription and protein expression within the temporalis muscle on day 42 after myoblast implantation; * $p < 0.05$. The panels on the right show the normalized integrated densities [corresponding to the](#) Western Blot bands for VEGF and PDGF-BB.

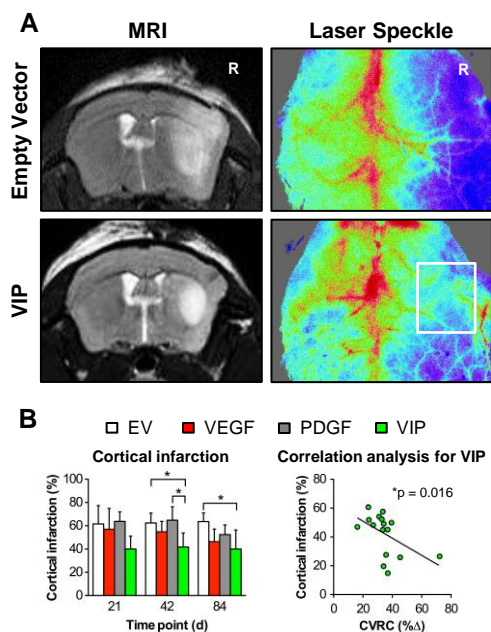

Figure 2

Hemodynamic rescue following VEGF164 and hPDGF-BB co-delivery

(A) Real-time laser speckle images of cortical perfusion before (left) and after (right) acetazolamide showing the improved hemodynamic response in VIP-treated animals on day 42. The dashed rectangle shows the area of perfusion assessment. R = right. (B) Line graphs illustrating the mean resting (baseline) perfusion (CBF-Flux; upper panel) and mean cerebrovascular reserve capacity (CVRC expressed as the percent change in CBF-Flux; lower panel) in animals treated with EV, VEGF, PDGF or VIP myoblasts over the 84-day monitoring period. Although baseline perfusion (upper panel) remained stable during the monitoring period, statistical differences compared to day 0 were found on days 7, 21 and 84 in VIP-treated animals and on day 84 in animals that received PDGF myoblasts (* $p < 0.05$ versus day 0 for VIP and PDGF). Regarding hemodynamic recovery, however, VIP resulted in superior hemodynamic rescue compared to day 0 beginning at day 21 (* $p < 0.05$), next to significant CVRC improvement on day 42 compared to empty vector (EV) myoblasts (# $p < 0.05$ for VIP versus EV). To a lesser extent, hemodynamic rescue compared to day 0 was also noted in VEGF and PDGF-treated animals (* $p < 0.05$ compared to day 0 for VEGF and PDGF). The dashed horizontal lines illustrate the normalized resting perfusion (100%) and mean CVRC (42%) of the non-occluded hemispheres on day 0.

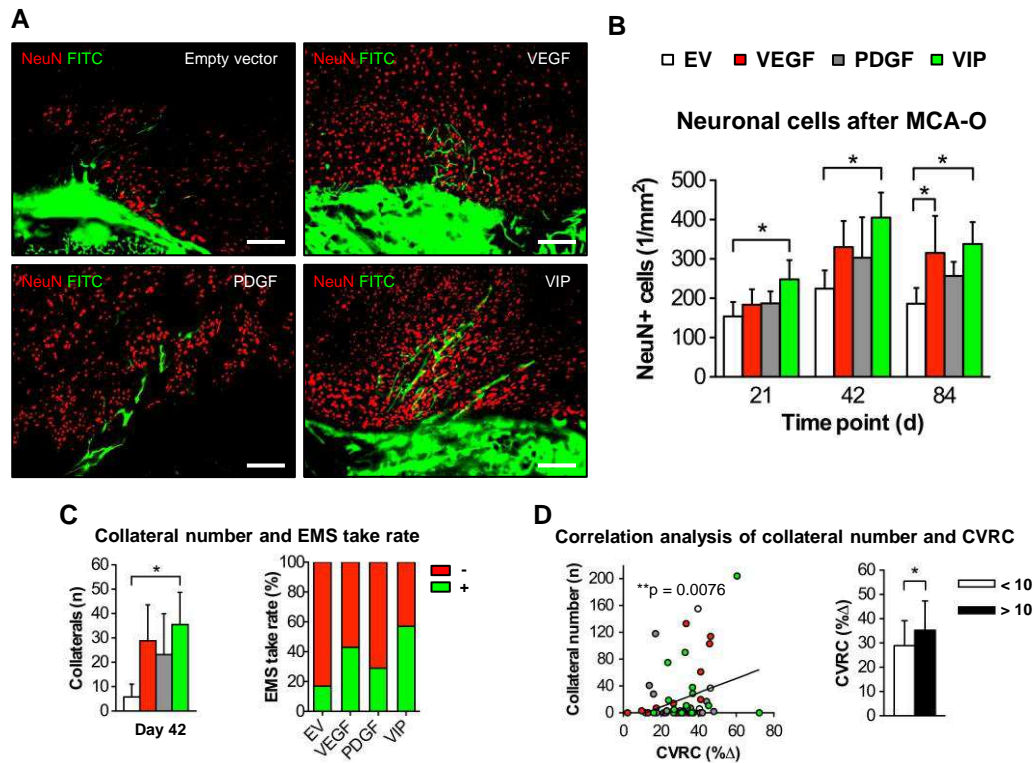

Figure 3

Cortical stroke and regional perfusion following MCA-O

(A) T2-weighted MR (left) and Laser Speckle (right) images illustrate differences in T2 signal hyperintensity (defined as infarction) and perfusion after ipsilateral MCA-O on day 42 in animals treated with EV (upper panels) and VIP (lower panels) myoblasts. R = right. (B) Bar graph illustrating the percentage of cortical infarction (* $p < 0.05$) determined in MR imaging and correlation analysis confirming the significant association between the size of the infarction and the degree of hemodynamic impairment in VIP-treated animals (* $p = 0.016$; $r = -0.59$).

Figure 4

Neuroprotection after MCA-O and transpial collateralization

(A) Photomicrographs of the muscle / brain interface after MCA-O and FITC-lectin perfusion on day 42 illustrate the higher number of surviving neuronal cells post stroke together with the increased EMS collateralization measured as the number of transpial collaterals in VIP-treated animals. Bar = 100 μ m. (B) Bar graph illustrating the number of NeuN positive cells in the cortical region below the EMS (*p<0.05) and (C) showing the corresponding number of transpial collaterals (left) and the EMS take-rate (right) determined by FITC-lectin perfusion through the external carotid artery feeding the EMS after ipsilateral MCA-O; *p<0.05. (D) Correlation analysis between the degree of hemodynamic impairment and the number of transpial collaterals on day 42 (**p=0.0076; r = 0.29). The bar graph illustrates the CVRC depending on the number of collaterals; *p<0.05.

Figure 5

Vessel density and pericyte recruitment

(A) Photomicrographs of the cortical region below the EMS on day 42 show the increased CD31-positive signal and CD31 / Desmin co-localization following EMS and implantation of VIP myoblasts. Bar = 100µm. (B) Bar graphs of the microvascular density (1/mm²) and vascular pericyte coverage (%) in vessels < 10µm (upper graphs) and > 10µm (right); *p<0.05. (C) High-power magnification photomicrographs of the muscle/brain interface obtained with confocal imaging in animals that underwent FITC-lectin perfusion for visualization of transpial collaterals in combination with CD31 / Desmin staining illustrate the increased pericyte recruitment around patent transpial collaterals as a distinct peri-collateral Desmin-positive signal in animals that received VIP. The dashed rectangle illustrates the area of detail enlargement. Bar = 100µm. (D) Bar graph quantifying the pericyte coverage of transpial collaterals; *p<0.05.

Figure 6

Astrocyte activation and intrinsic VEGF mobilization

(A) Photomicrographs of the cortical region below the EMS and of an untreated hemisphere on day 42 show increased GFAP-positive astrocytic activation in animals receiving PDGF or VIP myoblasts with GFAP / VEGF co-localization (arrows) as a sign of intrinsic VEGF mobilization in VIP-treated animals. The dashed rectangle identifies the area of detail enlargement on the right. Bar = 100 μm . (B) Bar graph quantifying the area (μm^2) of GFAP / VEGF co-localization per mm^2 ; * $p < 0.05$. (C) Reporter gene expression at the muscle / brain interface (arrows) and (D) real-time PCR using IRES primer and Western blot confirm exogenous gene product transcription and protein expression at the muscle / brain interface on day 42 after myoblast implantation; * $p < 0.05$. m = muscle; c = cortex.

Figure 7

Figure 7**Figure 7: Phospho-PDGF-R β / GFAP co-localization in the cortical region below the EMS**

(A) Photomicrographs of the cortical region below the EMS on day 42 show an increased GFAP-positive signal in animals receiving VEGF, PDGF or VIP myoblasts together with marked phospho-PDGF-R β expression. Bar = 100 μ m. (B) High-power magnification showing astrocytic GFAP / phospho-PDGF-R β co-localization. Bar = 50 μ m. (C) Quantification of the percent phospho-PDGF-R β -coverage of the GFAP-positive surface area; *p<0.05.
