## PREFACE

The Adaptation and Optimization project at IIASA is largely concerned with the development of algorithmic procedures for stochastic programming problems. In this paper, Professor Georg Pflug of the University of Giessen considers existing methods of controlling the step size in algorithms based on stochastic quasigradient techniques, and presents a new, adaptive step-size rule that leads to more rapid convergence of the associated algorithm.

System and Decision Sciences

## ABSTRACT

For algorithms of the Robbins-Monro type, the best choice (from the asymptotic point of view) for the step-size constants $a_{n}$ is known to be $a / n$. From the practical point of view, however, adaptive step-size rules seem more likely to produce quick convergence. In this paper a new adaptive rule for controlling the step size is presented and its behavior is studied.

# ON THE DETERMINATION OF THE STEP SIZE IN STOCHASTIC QUASIGRADIENT METHODS 

Georg Ch. Pflug

1. INTRODUCTION AND HISTORY OF THE PROBLEM

We consider the problem of unconstrained minimization of a function:

$$
\begin{aligned}
& h(x)=\min ! \\
& x \in \mathbb{R}^{k}
\end{aligned}
$$

by a stochastic quasigradient method. This implies the use of a steepest-descent (gradient) algorithm for which only statistical estimates of the gradients but not their exact values are available. In particular it is assumed that at each point $x$ and for every $\varepsilon>0$ we can observe a vector-valued random variable $Y_{x, \varepsilon}$ such that its expectation $E\left(Y_{X, \varepsilon}\right)$ satisfies

$$
\left|E\left(Y_{X, \varepsilon}\right)-\nabla h(x)\right|<\varepsilon
$$

Sometimes there is even an unbiased estimate $Y_{x}$ of the gradient, i.e.,

$$
E\left(Y_{X}\right)=\nabla h(x)
$$

The unknown minimum point $x_{0}=$ argmin $h$ is estimated by a recursive
sequence $\left\{X_{n}\right\}$ of the form

$$
\begin{equation*}
x_{n+1}=x_{n}-a_{n} y_{n} \tag{1}
\end{equation*}
$$

where $Y_{n}$ is a sequence of stochastic quasigradients, i.e., the conditional expectation of $Y_{n}$ given the history of the approximation process satisfies

$$
\lim _{n \rightarrow 0}\left|E\left(Y_{n} \mid x_{1}, \ldots, X_{n}\right)-\nabla h\left(X_{n}\right)\right|=0
$$

The values $a_{n}$ are the step-size constants and $X_{1}$ is an arbitrary starting value.

Univariate recursions of the form (1) were considered for the first time in a pioneering paper by $H$. Robbins and $S$. Monro in 1951. These authors examine the problem of recursively estimating the root of an unknown regression function $R(\cdot)$. In the minimization case this amounts to assuming that one can obtain an unbiased estimate of $h^{\prime}(\cdot)$. If, however, only an unbiased estimate of $h(\cdot)$ [not of $h^{\prime}(\cdot)$ ] is available, then $h^{\prime}(\cdot)$ has to be approximated by numerical differentiation. The corresponding procedure was developed by J. Kiefer and J. Wolfowitz in 1952.

These two methods were generalized to the multidimensional case by Blum (1954). Sacks (1958) proved the asymptotic normality of the properly normalized process $X_{n}$ in the Robbins-Monro (RM) case. The Kiefer-Wolfowitz (KW) situation is a bit more complicated, since in this case two speeds of approximation influence the asymptotic behavior: the deterministic speed of the approximation of $\nabla \mathrm{h}(\cdot)$ by finite differences and the stochastic convergence rate derived from the Central Limit Theorem. It was shown by Fabian (1967) that the rate of convergence can be increased considerably by using higher-order numerical approximations of the gradient. Fabian (1968) also gave a very general result concerning the asymptotic normality of recursive schemes, including the RM and KW processes.

The asymptotic distribution depends on (i) the local properties of $h(\cdot)$ at the minimum point $x_{0}=\operatorname{argmin} h(\cdot)$ (or, more precisely, on the Hessian $\nabla^{2} h(\theta)$, if this exists); (ii) the covariance
structure of $Y_{x}$; (iii) the step-size constants $a_{n}$; and (iv) the way in which $\nabla h(\cdot)$ is approximated numerically. It is, however, independent of the starting value $\mathrm{X}_{1}$. In particular, there is -from the asymptotic point of view -- a best choice for the constants $a_{n}$, namely

$$
a_{n}=\frac{a}{n}
$$

This choice maximizes the convergence rate. Moreover, in the univariate case there is even an optimal choice of the constant a, namely $a=1 / h^{\prime \prime}\left(x_{0}\right)$, which minimizes the asymptotic variance. However, if only asymptotic convergence is required then the conditions

$$
\begin{equation*}
a_{n} \geq 0 ; \quad \sum a_{n}=\infty ; \quad \sum a_{n}^{2}<\infty \tag{2}
\end{equation*}
$$

are sufficient.
The asymptotic approach is really rather unsatisfactory for practical applications. Due to the fact that the asymptotic distribution of $X_{n}$ is independent of the starting value $X_{1}$, the asymptotically optimal choice of the $a_{n}$ is very bad for finite samples, especially if $\left|X_{1}-x_{0}\right|$ is large. This is illustrated by the following example.
1.1. Example. Let $h(x)=\left|x-x_{0}\right|$. We consider, for simplicity, only the deterministic gradient algorithm

$$
x_{n+1}=x_{n}-\frac{a}{n} \operatorname{sgn}\left(x_{n}-x_{0}\right)
$$

Let $N$ be the first index for which $\left|X_{n}-x_{0}\right| \leq \varepsilon$. Then $N$ depends exponentially on $\left|x_{1}-x_{0}\right|$ ! Thus we pay for a bad choice of starting value by incurring an exponentially increasing number of necessary steps. This disadvantage disappears if we consider only the asymptotic distribution.

In practice it is preferable to choose the step length $a_{n}$ such that it depends on the (unknown) distance $\left|X_{n}-x_{0}\right|$. If $\left|x_{n}-x_{0}\right|$ is very large the procedure should make large corrections;
the step length should be decreased only when $\left|x_{n}-x_{0}\right|$ becomes smaller. On the other hand, it is clear that an adaptive choice of the $a_{n}$ entails greater mathematical difficulty since in such a case the $a_{n}$ can no longer be treated as constants, but become random variables $a_{n}=a_{n}\left(x_{1}, \ldots, x_{n}\right)$. We should emphasize the fact that methods based on the adaptive choice of step length $a_{n}$ are quite different from random search techniques. In the adaptive choice approach $a_{n}$ is a function of the (random) history of the process, whereas in random search methods the $a_{n}$ are random variables which are independent of the past, but whose distributional parameters may depend on past events.

A first step toward the use of adaptively chosen step lengths in the RM case can be found in a paper by H. Kesten (1958). He proposed to take any deterministic sequence $\alpha_{n}$ satisfying (2) and set

$$
\begin{aligned}
& a_{1}=a_{1} \\
& a_{n}= \begin{cases}a_{n-1}=\alpha_{m} \quad(\text { say }) & \text { if } \operatorname{sgn} Y_{n-1}=\operatorname{sgn} Y_{n} \\
a_{m+1}\end{cases}
\end{aligned}
$$

Kesten shows that the convergence properties hold in this case, but he was unable to give a mathematical argument to justify his procedure.

A further contribution was made by V. Fabian (1960), who proposes a random linear search after the stochastic gradient has been evaluated. He takes additional random observations of $h\left(X_{n}+j \alpha_{n} Y_{n}\right)$, say $V_{n, j} ; j \geq 1$, and chooses $a_{n}=j \cdot \alpha_{n}$ where $j$ is the largest integer such that $V_{n, 1} \geq V_{n, 2} \geq \cdots \geq V_{n, j}$. With this choice it is also possible to derive the a.s. convergence properties.

A different method of controlling the step size was proposed by Yu. Ermoliev et al. (1981). They assume that an unbiased estimate $Z_{n}$ of the objective function value $h\left(X_{n}\right)$ is available and define (for $k \in \mathbb{N}$ )

$$
E_{n}=\frac{1}{k} \sum_{j=n-k+1}^{n} Z_{j}
$$

Then $a_{n}$ is chosen according to the rule

$$
a_{n+1}= \begin{cases}a_{n} / 2 & \text { if }\left|E_{n-s}-E_{n}\right| \leq \delta \\ a_{n} & \text { otherwise },\end{cases}
$$

where $k$, s and $\delta$ are appropriately chosen constants. This stepsize rule is quite plausible since $a_{n}$ is decreased as soon as it is evident that the mean improvement in the value of the objective function is too small. However, it is also unsatisfactory, for the following reasons:
(i) The procedure cannot distinguish between two different situations: random fluctuations around the minimum point $x_{0}$, and small gradients combined with large variances far away from $x_{0}$. In the second case the procedure will, with high probability, continue to reduce the step size.
(ii) Divergence caused by overshooting will not be detected.
(iii) An additional estimate of the value of the objective function must be provided.

A new method for controlling the step size is proposed in Section 4 of this paper. However, we shall begin by considering some instructive examples.

## 2. EXAMPLES

A graphical representation is often quite useful in describing univariate problems. Assume that $Y_{X}$ is an unbiased estimate of the derivative $h^{\prime}(x)$ of the objective function $h(x)$. Let $\sigma^{2}(x)=$ $\operatorname{Var}\left(Y_{X}\right)$. The following diagram shows a possible behavior of $E\left(Y_{X}\right)=$ $h^{\prime}(x)$ (full line) and the functions $h^{\prime}(x) \pm \sigma(x)$ (dashed lines).

2.1 Example (Univariate quadratic problem). Let the univariate objective function take the form

$$
h(x)=\frac{\alpha}{2}\left(x-x_{0}\right)^{2}
$$

and suppose that the stochastic gradients $Y_{n}$ have expectations $\alpha X_{n}$ and variances $\sigma^{2}$. The situation can be described diagrammatically as follows:

To obtain a better understanding of the influence of the choice of step-size constants $a_{n}$, we shall for the moment take them to be constant, $a_{n} \equiv a$. Then, introducing the error variables $z_{n}=$ $Y_{n}-h^{\prime}\left(X_{n}\right)$, procedure (1) takes the form

$$
x_{n+1}=x_{n}-a \alpha\left(x_{n}-x_{0}\right)+a z_{n}
$$

or, equivalently, with $c=a \alpha$,

$$
\left(x_{n}-x_{0}\right)=\left(x_{1}-x_{0}\right)(1-c)^{n-1}+a_{i=1}^{h-1}(1-c)^{i-1} z_{n-i}
$$

$X_{n}$ is the superposition of a nonrandom drift

$$
x_{0}+(1-c)^{n-1}\left(x_{1}-x_{0}\right)
$$

and the zero-mean stochastic process

$$
a \sum_{i=1}^{n-1}(1-c)^{i-1} z_{n-i}
$$

The above can be approximated by the stationary process

$$
U_{n}=a \sum_{i=1}^{\infty}(1-c)^{i-1} z_{n-i}
$$

$U_{n}$ is an $A R(1)$ process, since it is a stationary solution of the stochastic difference equation

$$
U_{n+1}=U_{n}(1-c)+a Z_{n}
$$

with moments

$$
\begin{aligned}
E\left(U_{n}\right) & =0 \\
\operatorname{Var}\left(U_{n}\right) & =\frac{\sigma^{2} a^{2}}{2 c-c^{2}}
\end{aligned}
$$

$$
\begin{aligned}
& \operatorname{cov}\left(U_{n}, U_{n-s}\right)=\frac{\sigma^{2} a^{2}(1-c)^{s}}{2 c-c^{2}} \\
& \operatorname{corr}\left(U_{n}, U_{n-s}\right)=(1-c)^{s} .
\end{aligned}
$$

Taking a trajectory from this process:

we obtain a typical picture of the process $X_{n}$ by superposition.

Analogously, the gradient process

$$
\begin{aligned}
Y_{n} & =\alpha\left(x_{n}-x_{0}\right)+z_{n} \\
& =\alpha(1-c)^{n-1}\left(x_{1}-x_{0}\right)+c \sum_{i=1}^{n-1}(1-c)^{i-1} z_{n-i}+z_{n}
\end{aligned}
$$

can be approximated by the superposition of a deterministic component

$$
\alpha(1-c)^{n-1}\left(x_{1}-x_{0}\right)
$$

and the zero-mean stationary process

$$
v_{n}=c \sum_{i=1}^{\infty}(1-c)^{i-1} z_{n-i}+z_{n}
$$

$V_{n}$ is an ARMA $(1,1)$ process since

$$
v_{n+1}-(1-c) v_{n}=(2 c-1) z_{n}+z_{n+1}
$$

The moments are

$$
\begin{aligned}
& E\left(V_{n}\right)=0 \\
& \operatorname{Var}\left(V_{n}\right)=\frac{\sigma^{2}}{1-(c / 2)} \\
& \operatorname{Cov}\left(V_{n}, V_{n-s}\right)=\sigma^{2} c(1-c)^{s-1}+(1-c)^{s} \frac{\sigma^{2} c}{2-c} \text { for } s \geq 1
\end{aligned}
$$

Note that if $\sigma^{2}=0$ then $X_{n} \rightarrow x_{0}$ and $Y_{n} \rightarrow 0$ for any $c$ such that $0<c<1$. Hence there is no need for a reduction of the step size in the deterministic situation unless $a \geq \frac{1}{\alpha}$. If, however, $\sigma^{2}>0$, then

$$
\begin{aligned}
& \lim _{n \rightarrow \infty} \operatorname{Var}\left(x_{n}-x_{0}\right)=\frac{\sigma^{2} a^{2}}{2 c-c^{2}} \\
& \lim _{n \rightarrow \infty} \operatorname{Var}\left(Y_{n}\right)=\sigma^{2}+\frac{\sigma^{2} c}{2-c}
\end{aligned}
$$

and the process $X_{n}$ will oscillate around the solution $x_{0}$ unless we reduce the step size. The asymptotic variance decreases as $a \rightarrow 0$, but on the other hand a small value of a results in slow convergence of the deterministic part. What we can learn from this example is that the step size should be reduced if it is evident that the deterministic drift has fallen to zero and the fluctuation of $\mathrm{X}_{\mathrm{n}}$ is due only to the random element (the stationary process $\mathrm{U}_{\mathrm{n}}$ ).
2.2 Example (Multidimensional quadratic problem). Let the objective function be of the form

$$
h(x)=\frac{1}{2} x^{\prime} A x,
$$

where A is a positive definite matrix. Without loss of generality, $x_{0}$ is assumed to be zero. The error variables $Z_{n}$ are independent and identically distributed with expectation 0 and covariance matrix $C$. Again we let the $a_{n}$ remain constant and equal to $a$. The process (1) takes the form

$$
x_{n+1}=(I-a A) x_{n}-a z_{n}
$$

or, equivalently,

$$
x_{n}=(I-a A)^{n-1} x_{1}+a \sum_{i=1}^{n-1}(I-a A)^{i-1} z_{n-i}
$$

Once again, $X_{n}$ can be approximated by the sum of a deterministic drift and the following vector-valued AR(1) process:

$$
U_{n}=a \sum_{i=1}^{\infty}(I-a A)^{i-1} z_{n-i}
$$

This process is well-defined if a is smaller than the inverse of the largest eigenvalue of $A$. The gradient process

$$
Y_{n}=A X_{n}+Z_{n}
$$

can be rewritten as

$$
Y_{n}=A(I-a A)^{n-1} x_{1}+a A \sum_{i=1}^{n-1}(I-a A)^{i-1} z_{n-i}+z_{n} \quad .
$$

The stochastic part of this process can be approximated by the stationary vector-valued ARMA (1,1) process

$$
\begin{equation*}
V_{n}=a A \sum_{i=1}^{\infty}(I-a A)^{i-1} z_{n-i}+z_{n} \tag{3}
\end{equation*}
$$

which fulfills the difference equation

$$
V_{n+1}-(I-a A) V_{n}=(2 a A-I) z_{n}+z_{n+1}
$$

Clearly (3) determines the covariance structure of the process. Instead of considering the autocovariance matrices $E\left(V_{n} V_{n-s}^{\prime}\right)$ we calculate the following two numbers:

$$
\begin{aligned}
& E\left(\left\|V_{n}\right\|^{2}\right)=\operatorname{tr}\left(C\left(a^{2} A^{2} \sum_{i=0}^{\infty}(I-a A)^{2 i}+I\right)\right) \\
& E\left(V_{n+1}^{\prime} V_{n}\right)=\operatorname{tr}\left(C\left(a^{2} A^{2} \sum_{i=1}^{\infty}(I-a A)^{2 i-1}+a A\right)\right)
\end{aligned}
$$

where $\operatorname{tr}$ (B) denotes the trace of matrix $B$. Use of the formula

$$
\sum_{i=0}^{\infty} B^{i}=(I-B)^{-1}
$$

which is valid for positive definite matrices $B$ with all eigenvalues less than unity, leads to the simplifications

$$
\begin{align*}
& E\left(\left\|V_{n}\right\|^{2}\right)=\operatorname{tr}\left(C\left(I-\frac{a}{2} A\right)^{-1}\right)  \tag{4}\\
& E\left(V_{n+1}^{\prime} V_{n}\right)=\operatorname{tr}\left(C a A\left(2 I-(2 I-a A)^{-1}\right)\right) . \tag{5}
\end{align*}
$$

As in the univariate case, the approximation process $X_{n}$ converges (for fixed a) only if $C=0$, i.e., if the procedure is a deterministic one.
2.3 Example (Nonsmooth univariate case). In this example we consider the objective function $h(x)=\alpha\left|x-x_{0}\right|$ and assume that the error variables $Z_{n}$ are again independent and identically distributed with expectation zero and variance $\sigma^{2}$. Furthermore, we assume that the distribution of the $Z_{n}$ is symmetrical around zero and possesses finite moments of any order. Since $h^{\prime}(x)=$ $\alpha \operatorname{sgn}\left(x-x_{0}\right)$ if $x \neq x_{0}$, the problem may be represented graphically as follows:

Without loss of generality, we can assume that $x_{0}=0$. The stochastic approximation process (1) is then given by

$$
\begin{equation*}
x_{n+1}=x_{n}-a \alpha \operatorname{sgn}\left(x_{n}\right)+a z_{n} \tag{6}
\end{equation*}
$$

To which limiting distribution does this recursion converge, if any? Or, equivalently, what are the stationary distributions of the Markovian process (6)? Let G be the c.d.f. of the variables $Z_{n}$. A stationary distribution $F$ must clearly fulfill

$$
\begin{equation*}
\mathrm{F}=\tilde{\mathrm{F}} * \mathrm{G}, \tag{7}
\end{equation*}
$$

where

$$
\tilde{F}(u)=\left\{\begin{array}{lr}
F(u-c) & u<-c \\
F(u+c)-F(0)+F(u-c) & -c \leq u \leq c \\
F(u+c) & u \geq c
\end{array}\right.
$$

and $\mathrm{c}=\mathrm{a} \alpha$.
This convolution equation is best handled by considering the Fourier transforms. Let X be distributed according to $F$ and let

$$
\begin{aligned}
& \psi_{1}(t)=E\left(e^{i t x} 1_{\{x>0\}}\right) \\
& \psi_{2}(t)=E\left(e^{i t x} 1_{\{x<0\}}\right)
\end{aligned}
$$

Then (7) can be rewritten as

$$
\begin{equation*}
\left(\psi_{1}(t) e^{-i c t}+\psi_{2}(t) e^{i c t}\right) \phi(a t)=\psi_{1}(t)+\psi_{2}(t) \tag{8}
\end{equation*}
$$

where $\phi(\cdot)$ is the characteristic function of the $Z_{n}$. We assume that $\phi(\cdot)$ does not vanish anywhere, i.e., $\mathrm{Z}_{\mathrm{n}}$ is non-lattice. Any solution of (7) must be symmetric, i.e., such that

$$
\begin{aligned}
& \psi_{2}(t)=\psi_{1}(-t) \\
& \psi_{1}(0)=1 / 2
\end{aligned}
$$

The functional equation (8) can then be written as

$$
\begin{align*}
\log \psi_{1}(t)-\log \psi_{1}(-t) & =\log \left(\phi^{-1}(a t)-e^{i c t}\right) \\
& -\log \left(e^{-i c t}-\phi^{-1}(a t)\right) \tag{9}
\end{align*}
$$

Since, from the moment conditions on $Z_{n}$,

$$
\phi(t)=1-\frac{1}{2} t^{2} \sigma^{2}+o\left(t^{2}\right),
$$

taking the derivative of equation (9) at the point 0 leads to

$$
4 \psi_{1}^{\prime}(0)=\frac{-1}{i c}\left(a^{2} \sigma^{2}+c^{2}\right)
$$

Hence $E\left(X 1_{(x>0\}}\right)=\frac{a \sigma^{2}+c^{2}}{4 c}$ and therefore

$$
\begin{equation*}
E(|x|)=\frac{c^{2}+a^{2} \sigma^{2}}{2 c} \tag{10}
\end{equation*}
$$

On taking higher derivatives we see that $E\left(|X|^{k}\right)$ is uniquely determined for odd $k$. (For even $k$ the $k$ th derivative vanishes on both sides.) Let $2 \beta_{k}=E\left(|x|^{2 k+1}\right) ; k \geq 0$. Thus

$$
\int_{0}^{\infty} x^{2 k+1} d F(x)=\beta_{k}
$$

Or, by introducing the distribution function

$$
H(x)=\frac{\int_{0}^{x} u d F(u)}{\beta_{1}}
$$

we obtain

$$
\begin{equation*}
\frac{\beta_{k}}{\beta_{0}}=\int_{0}^{\infty} x^{k} \mathrm{dH}(\sqrt{\mathrm{x}}) \tag{11}
\end{equation*}
$$

We see that $H(\cdot)$ and consequently $F(\cdot)$ is uniquely determined by the sequence $\left\{\beta_{\mathrm{k}}\right\}$ if the corresponding moment problem (11) has a unique solution.

However, the author was unable to solve (10) explicitly even for a normal error distribution. It also seems to be difficult to determine the even moments, especially the variance of the symmetric solution.

Nevertheless, we can still take the first absolute moment as a measure of dispersion. From (10) it can be seen that in this case $X_{n}$ does not converge to zero unless $a \rightarrow 0$ even when $\sigma^{2}=0$. This is the important difference between examples 2.1 and 2.3. The asymptotic dispersion (10) can be viewed as a superposition of a "deterministic part" c/2 and a stochastic part $a^{2} \sigma^{2} / 2 c$.

## 3. DETERMINISTIC STEEPEST-DESCENT METHODS

In this section we study step-size rules for deterministic steepest-descent methods. Let $h(\cdot)$ be a quasiconvex, continuous function defined on $\mathbb{R}^{k}$. This means that the sets

$$
S(x)=\{y \mid h(y) \leq h(x)\}
$$

are closed, convex sets. We assume that $h$ is continuously differentiable for $x \neq x_{0}$ with gradient $7 h(x) \neq 0$ for $x \neq x_{0}$ and that $S\left(x_{0}\right)=\left\{x_{0}\right\}$, i.e., $x_{0}=\operatorname{argmin} h(\cdot)$. An algorithm of the form

$$
\begin{equation*}
x_{n+1}=x_{n}-a_{n} \nabla h\left(x_{n}\right) \tag{12}
\end{equation*}
$$

is known as a steepest-descent algorithm. In mathematical programming the step-size constants $a_{n}$ are usually determined from

$$
\begin{equation*}
h\left(x_{n}-a_{n} \nabla h\left(x_{n}\right)\right)=\inf _{a}\left(x_{n}-a \nabla h\left(x_{n}\right)\right) \tag{13}
\end{equation*}
$$

i.e., they are found by a line search. However, this type of procedure cannot be used in stochastic gradient methods since for these problems only a stochastic estimate of the optimal a would be available. Such an estimate would require additional observations as well as contradicting the basic philosophy of stochastic approximation: Not to waste too much time trying to get a better estimation of the next step when the current point is still a long way from the solution.

Let us therefore concentrate on those step-size rules which depend only on $n$ (the number of the step) and the history $\left(x_{1}, \ldots, x_{n-1}\right)$ of the iteration process, and which do not require any additional evaluation of the objective function.

One important subclass of these rules is formed by sequences $a_{n}$ which depend only on $n$. The corresponding convergence properties are given by the following theorem.
3.1 Theorem. Let the function $h$ be defined as above and suppose that for every $\varepsilon>0$

$$
\begin{aligned}
& \quad \inf _{\left\|x-x_{0}\right\| \geq \varepsilon} \frac{\left\langle x-x_{0}, \nabla h(x)\right\rangle}{\|\nabla h(x)\|^{2}} \geq \eta_{1}(\varepsilon)>0 \\
& \inf _{\left\|x-x_{0}\right\| \geq \varepsilon}\left\langle x-x_{0}, \nabla h(x)\right\rangle \geq \eta_{2}(\varepsilon)>0
\end{aligned}
$$

If

$$
\begin{equation*}
a_{n} \geq 0 ; \quad a_{n} \rightarrow 0 ; \quad \sum a_{n}=\infty \tag{14}
\end{equation*}
$$

then the iteration $\left\{x_{n}\right\}$ given by (12) converges to $x_{0}$.
Proof. Without loss of generality we can assume that $x_{0}=0$. If $\left\|x_{n}\right\| \geq \varepsilon$ then

$$
\begin{aligned}
\left\|x_{n+1}\right\|^{2} & =\left\|x_{n}\right\|^{2}-2 a_{n}\left\langle x_{n}, \nabla h\left(x_{n}\right)\right\rangle+a_{n}^{2}\left\|\nabla h\left(x_{n}\right)\right\|^{2} \\
& \leq\left\|x_{n}\right\|^{2}-2 a_{n} \eta_{2}(\varepsilon)\left(1-\frac{a_{n}}{\eta_{1}(\varepsilon)}\right) .
\end{aligned}
$$

Thus, for large $n,\left\|x_{n}\right\|^{2} \geq \varepsilon$ implies that $\left\|x_{n+1}\right\|^{2} \leq\left\|x_{n}\right\|^{2}-2 a_{n} k$, where $K$ is a constant depending only on $\varepsilon$. If, however, $\left\|x_{n}\right\| \leq \varepsilon$ then, by the continuity of $\nabla \mathrm{h}(\cdot),\left\|\nabla \mathrm{h}\left(\mathrm{x}_{\mathrm{n}}\right)\right\|$ is bounded and hence $\left\|x_{n+1}\right\| \leq 2 \varepsilon$ for large $n$. From $\sum a_{n}=\infty$ we can conclude that $\lim \sup \left\|x_{n}\right\| \leq \varepsilon$. Since $\varepsilon$ was arbitrary the theorem is proven.

Before trying to construct a more adaptive step-size rule we first draw attention to the following lemma.
3.2 Lemma. Let $h$ be convex and twice-differentiable. The function $a \mapsto\langle\nabla h(x), \nabla h(x-a \nabla h(x))\rangle$ is monotonically decreasing and vanishes if and only if a is the solution of (13).

Proof. The assertions follow easily from simple calculus. The situation can be illustrated by the following figure.

Since $\langle\nabla h(x), \nabla h(x-a \nabla h(x)\rangle<0$ implies that a is larger than the optimal a given by (12), we are led to the following heuristic step-size rule:

$$
a_{n+1}=\left\{\begin{array}{llll}
a_{n} & \text { if } & \left\langle\nabla h\left(x_{n}\right), \nabla h\left(x_{n+1}\right)\right\rangle>0  \tag{15}\\
a_{n} / 2 & \text { if } & \left\langle\nabla h\left(x_{n}\right), \nabla h\left(x_{n+1}\right)\right\rangle \leq 0
\end{array}\right.
$$

The decrease by a factor of $1 / 2$ is somewhat arbitrary; any factor $q(0<q<1)$ could be taken.

With this rule we can state and prove a convergence theorem.
3.3 Theorem. Let $h$ be defined as in Theorem 3.1. In addition, we assume that it is inf-compact (i.e., the sets $S(x)$ are compact) and $\|\nabla h(x)\| \leq K\left\|x-x_{0}\right\|$. The iteration

$$
x_{n+1}=x_{n}-a_{n} \nabla h\left(x_{n}\right)
$$

where $a_{n}$ is given by (15), converges to $x_{0}$ for every starting value $\left(x_{1}, a_{1}>0\right)$.

Proof. We show first that, for $a>0,\langle\nabla h(x), \nabla h(x-a \nabla h(x))\rangle>0$ implies that $h(x)>h(x-a \nabla h(x))$. By virtue of the quasiconvexity of $h$

$$
S(x) \subseteq\{y \mid\langle y-x, \nabla h(x)\rangle \leq 0\}
$$

Let $z=x-a \nabla h(x)$. Suppose that $h(z) \geq h(x)$, i.e., $x \in S(z)$. Then $0 \geq\langle z-x, \nabla h(z)\rangle=-a\langle\nabla h(x), \nabla h(z)\rangle>0$ and the theorem is proven by contradiction.

Now consider the sequence $a_{n}$. If $\left\{a_{n}<\infty\right.$ then $x_{n}$ converges. Let the limit be $y$. If $\|\nabla h(y)\|>0$ then $\langle\nabla h(x), \nabla h(x-a \nabla h(x))\rangle>0$ for small a in a neighborhood of $y$. Thus $y$ can be the limit only if $y=x_{0}$. If $a_{n} \rightarrow 0$ but $\sum a_{n}=\infty$ then $x_{n}$ converges to $x_{0}$ by Theorem 3.1. If $a_{n}$ does not converge to zero, then there is an index $N \in \mathbb{N}$ such that $a_{n} \equiv a$ for $n \geq N$ and $\left\langle\nabla h\left(x_{n}\right), \nabla h\left(x_{n+1}\right)\right\rangle>0$. Hence $h\left(x_{n}\right)$ is decreasing for $n \geq N$. The sequence $\left\{x_{n}\right\}$ has a cluster point $y$ since $h$ is inf-compact. Let $z=y-a \nabla h(y)$. Then, by continuity, $h(z)=h(y)$ and $\langle\nabla h(z), \nabla h(x)\rangle \geq 0$. This implies that either $x=z$ or $\nabla h(x)=0$, but in any case $x=x_{0}$.

We finish this section by looking at two examples.
3.4 Example. Let $h(x)=\|x\|$. Then $\nabla h(x)=\frac{x}{\|x\|}$ if $x \neq 0$. Since $\frac{\langle x, \nabla h(x)\rangle}{\|\nabla h(x)\|^{2}}=\|x\|$ and $\langle x, \nabla h(x)\rangle=\|x\|$ the assumptions of Theorems 3.1 and 3.3 are satisfied. The recursion (12) then takes
the form

$$
x_{n+1}=x_{n}\left(1-\frac{a_{n}}{\pi x_{n} \pi}\right)
$$

Or, writing $\mathrm{x}_{\mathrm{n}}=\mathrm{v}_{\mathrm{n}} \mathrm{x}_{1}$,

$$
v_{n+1}=v_{n}-\frac{a_{n}}{\left\|x_{1}\right\|} \operatorname{sgn}\left(x_{n}\right)
$$

If $\left\{a_{n}\right\}$ satisfies (14) and $a_{n+1} \leq a_{n} \leq 2 a_{n+1}$ then

$$
\left\|x_{n}\right\|=c\left(a_{n}\right)
$$

If $\left\{a_{n}\right\}$ is determined by (15) then

$$
\left\|x_{n}\right\|=o\left(2^{-n}\right)
$$

and we see that (15) is much better than (14) in this case.
3.5 Example. Let $h(x)=\frac{1}{2} x^{\prime} A x$, where $A$ is a positive definite matrix. Then $\nabla \mathrm{h}(\mathrm{x})=\mathrm{Ax}$ and

$$
\frac{\langle x, \nabla h(x)\rangle}{\|\nabla h(x)\|^{2}}=\frac{x^{\prime} A x}{x^{\prime} A^{2} x} \geq \frac{m}{M^{2}}
$$

where $M$ and $m$ are the largest and smallest eigenvalues of $A$, respectively. Similarly,

$$
\langle x, \nabla h(x)\rangle=x^{\prime} A x \geq m\|x\|^{2}
$$

and thus the assumptions of Theorems 3.1 and 3.3 are satisfied. Choosing the constants $a_{n}$ according to (14) leads to

$$
x_{n}=\Pi\left(I-a_{n} A\right) x_{1}
$$

This implies

$$
\left.\left\|x_{n+1}\right\|=o \prod_{j=1}^{n}\left(1-a_{j} m\right)\right)
$$

Choosing, for instance, $a_{j}=a / j$ we obtain

$$
\left\|x_{n}\right\|=o\left(n^{-a m}\right)
$$

For this example, rule (15) can be written as

$$
a_{n+1}= \begin{cases}a_{n} & \text { if } x_{n}^{\prime} A^{2} x_{n}-a_{n} x_{n}^{\prime} A^{3} x_{n}>0 \\ a_{n} / 2 & \text { otherwise } .\end{cases}
$$

It is evident that the constants $a_{n}$ can never fall below $m^{2} / 2 M^{3}$. Thus, if the objective function is quadratic then the constants determined by rule (15) do not converge to zero and the rate of convergence of the iteration is at least

$$
\left\|x_{n}\right\|=0\left(\left(1-\frac{m^{3}}{2 m^{3}}\right)^{n}\right)
$$

Again, rule (15) is superior to (14).
4. A STOCHASTIC STEP-SIZE RULE

A stochastic version of rule (15) is presented in this section. We once again consider the approximation process (1)

$$
x_{n+1}=x_{n}-a_{n} y_{n}
$$

where

$$
E\left(Y_{n} \mid X_{1}, \ldots, X_{n}\right)=\nabla h\left(X_{n}\right)
$$

It would be possible to approximate $\left(\nabla \mathrm{h}\left(\mathrm{X}_{\mathrm{n}}\right), \nabla \mathrm{h}\left(\mathrm{X}_{\mathrm{n}+1}\right)\right.$ ) by $\mathrm{Y}_{\mathrm{n}}^{\prime} \mathrm{Y}_{\mathrm{n}+1}$. However, it would be incorrect to compare this quantity with zero; we should rather look at the expectation of this value for the stationary distribution of (1). Since this distribution depends on $h(\cdot)$ we have to make some additional assumptions.

We assume that $h(\cdot)$ is quadratic, i.e., $h(x)=\frac{1}{2} x^{\prime} A x$, since this is the most important case, and also that the covariance
matrix $C$ of the stochastic gradients $Y_{n}$ is independent of $X_{n}$.
By (5) the expectation of $Y_{n} Y_{n+1}$ under the stationary distribution is

$$
E\left(V_{n+1}^{\prime} V_{n}\right)=\operatorname{tr}\left(C a A\left(2 I-(2 I-a A)^{-1}\right)\right)
$$

To simplify the rule we replace $a A\left(2 I-(2 I-a A)^{-1}\right)=$ $a A\left(2 I-\frac{1}{2} \sum_{i=0}^{\infty}(a A)^{i}\right)$ by $\frac{3}{2} a A$, neglecting terms of higher order in $A$.

The quantity $\operatorname{tr}(a C A)$ can be estimated by taking a random direction $D_{n}$ at $X_{n}$ and estimating the gradient at $X_{n}+a D_{n}$. To be more explicit, let $Y_{n}^{1}$ and $Y_{n}^{2}$ be two independent estimates of $\nabla h\left(X_{n}\right)$. Let $D_{n}=\frac{1}{2}\left(Y_{n}^{1}-Y_{n}^{2}\right)$. Then $E\left(D_{n} \mid X_{1}, \ldots, X_{n}\right)=0$ and $\operatorname{Cov}\left(D_{n}\right)=\frac{1}{2} C$. Let $\tilde{x}_{n+1}=X_{n}+a D_{n}$ and $\tilde{Y}_{n+1}$ be an estimate of $\nabla h\left(\tilde{x}_{n+1}\right)$, i.e., $\tilde{\mathrm{Y}}_{\mathrm{n}+1}=A \tilde{\mathrm{x}}_{\mathrm{n}+1}+\tilde{\mathrm{z}}_{\mathrm{n}+1}$. Then

$$
\begin{aligned}
E\left(D_{n}^{\prime} \tilde{Y}_{n+1}\right) & =E\left(D_{n}^{\prime}\left(A\left(X_{n}+a D_{n}\right)+\tilde{Z}_{n+1}\right)\right) \\
& =a E\left(D_{n}^{\prime} A D_{n}\right)=\frac{a}{2} \operatorname{tr}(A C)
\end{aligned}
$$

A more parsimonious use of the random variables can be achieved by setting $Y_{n}=\frac{1}{2}\left(Y_{n}^{1}+Y_{n}^{2}\right)$, which has the advantage of reducing the covariance matrix by a factor of $1 / 2$. The step-size reduction is then based on the comparison

$$
\frac{1}{k} \sum_{n=1}^{k} Y_{n+1}^{\prime} Y_{n}<\frac{3}{2} E\left(D_{n}^{\prime} \tilde{Y}_{n+1}\right)
$$

This method is summarized in algorithm 4.1. The notation $Y_{n}:=$ $Y\left(X_{n}\right)$ is used to indicate an independent function call of the gradient estimate. In particular, $Y^{1}:=Y\left(X_{n}\right) ; Y^{2}:=Y\left(X_{n}\right)$ does not mean that $Y^{1}=Y^{2}$.

### 4.1 Algorithm

Step 1. Choose starting values $\mathrm{X}_{1}$, a
Step 2. Set $\mathrm{n}:=0 ; \mathrm{N}:=0$. Go to Step 4

Step 3. Set $\mathrm{n}:=\mathrm{n}+1$

$$
\begin{aligned}
& \text { Observe } Y_{n}^{1}=Y\left(X_{n}\right) ; Y_{n}^{2}=Y\left(X_{n}\right) \\
& \text { Set } Y_{n}:=\frac{1}{2}\left(Y_{n}^{1}+Y_{n}^{2}\right) \\
& D_{n}:=\frac{1}{2}\left(Y_{n}^{1}-Y_{n}^{2}\right) \\
& X_{n+1}:=X_{n}-a Y_{n} \\
& \tilde{X}_{n+1}:=X_{n}-a D_{n} \\
& \tilde{Y}_{n+1}:=Y\left(\tilde{X}_{n+1}\right) \\
& \delta_{n}:=D_{n}^{\prime} \tilde{Y}_{n+1}
\end{aligned}
$$

Step 4. Perform Step 3 twice

Step 5. If
$\frac{1}{n-N} \sum_{k=N}^{n-1} Y_{k+1}^{\prime} Y_{k} \leq \frac{3}{2} \frac{1}{n-N+1} \sum_{k=N}^{n} \delta_{k}$
then set $a:=a / 2 ; N:=n$; stop, if $a \leq \varepsilon ;$ perform
Step 3 twice and return to Step 5
Otherwise perform Step 3 once and then return to Step 5

It is important to notice that if the procedure is deterministic $D_{n}=0$ and $\delta_{n}=0$. Therefore algorithm 4.1 is very close to rule (15) except that the algorithm uses the arithmetic mean of the inner products $Y_{k+1} Y_{k}$.

In order to reduce this difference we could use a variant of the algorithm which employs a sequential t-test instead of a simple comparison of mean values. * This algorithm is presented below in more formal notation, which omits iteration indices.

### 4.2 Algorithm

Step 1. Choose starting values X, a
Step 2. Set $n:=0 ; k:=1 ; \gamma=0 ; \eta=1$
*For the theory of sequential tests see Govindarajulu (1975).

Step 3. Set $\mathrm{n}:=\mathrm{n}+1$; $\mathrm{k}:=\mathrm{k}+1$

$$
\text { Observe } Y^{1}:=Y(X) ; Y^{2}:=Y(X)
$$

$$
\text { Set } \begin{aligned}
V & :=Y \\
Y & :=\frac{1}{2}\left(Y^{1}+Y^{2}\right) \\
D & :=\frac{1}{2}\left(Y^{1}-Y^{2}\right) \\
X & :=X-a Y \\
\tilde{X} & :=X-a D \\
\tilde{Y} & :=Y(\tilde{X}) \\
\delta & :=\left(\frac{n-1}{n}\right) \delta+\left(\frac{1}{n}\right) \cdot D^{\prime} \tilde{Y} \\
\gamma & := \begin{cases}\left(\frac{k-2}{k-1}\right) \gamma+\frac{1}{k-1} Y^{\prime} V & \text { if } k \neq 1 \\
Y & \text { if } k=1\end{cases} \\
n & := \begin{cases}\left(\frac{k-2}{k-1}\right) \eta+\frac{1}{k-1}\left(Y^{\prime} v\right)^{2} & \text { if } k \neq 1 \\
n & \text { if } \quad k=1\end{cases}
\end{aligned}
$$

If
$\gamma \leq \frac{3}{2} \delta-\frac{t}{k}\left(\eta-\gamma^{2}\right)$
then set $\mathrm{a}:=\mathrm{a} / 2 ; \mathrm{k}:=0 ; \delta:=\delta / 2$;
stop if $a \leq \varepsilon ;$ go to Step 3
If $\quad\left|\gamma-\frac{3}{2} \delta\right|<\frac{t}{k}\left(n-\gamma^{2}\right)$
then go to Step 3

If
$\gamma \geq \frac{3}{2} \delta+\frac{t}{k}\left(n-\gamma^{2}\right)$
then set $k:=0 ; n:=0 ;$ go to Step 3

The constant $t$ represents the upper $\alpha$-fractile of a standard normal distribution and should be set to a value between 1 and 3 . It is shown below that this algorithm results in a convergent iteration process.
4.3 Theorem. Let $h(x)=\frac{1}{2} x^{\prime} A x$ and let the covariance matrix of the gradient estimations $Y_{n}$ be constant. Then the recursive sequence (1) with step sizes given by algorithm 4.1 or 4.2 converges a.s. to zero.

Proof. We must consider two different cases. If $a_{n} \rightarrow a>0$ then the distribution of the $Y_{n}$ approaches the stationary distribution. Hence, by ergodicity,

$$
\begin{aligned}
& \frac{1}{n} \sum Y_{k+1}^{\prime} Y_{k} \rightarrow E\left(Y_{n+1}^{\prime} Y_{n}\right) \\
&=\operatorname{tr}\left(\operatorname{CaA}\left(2 I-(2 I-a A)^{-1}\right)\right) \\
&<\frac{3}{2} \operatorname{tr}(a C A)=E\left(D_{n}^{\prime} \tilde{Y}_{n+1}\right)
\end{aligned}
$$

Hence, with probability 1, there must be an index $N$ such that $a_{N}$ has to be reduced. Hence $a \underset{n}{ } \rightarrow 0$ is impossible.

If $a_{n} \rightarrow 0$ then $\frac{1}{n} \sum Y_{k+1}^{\prime} Y_{k} \rightarrow 0$ and hence $E\left(Y_{k+1}^{\prime} Y_{k}\right)=0$. This however implies that $X_{n} \rightarrow 0$.
