## ABSTRACT

Recently graphene and other 2D materials were suggested as nano additives to enhance the performance of nanolubricants and reducing friction and wear-related failures in moving mechanical parts. Nevertheless, up to our knowledge there are not previous studies on electrochemical exfoliated nanomaterials as lubricant additives. In this work, engine oil-based nanolubricants were developed via two-steps method using two different 2D nanomaterials: a carbon-based nano additive, graphene nanoplatelets (GNP) and a sulphide nanomaterial, molybdenum disulfide ( $\text{MoS}_2$ ) nanoplatelets (MSNP). The influence of these nano additives on the thermophysical properties of the nanolubricants, such as viscosity index, density and wettability, was investigated. The unique features of the electrochemical exfoliated GNP and MSNP allow the formulation of nanolubricant with unusual thermophysical properties. Both the viscosity and density of the nanolubricants decreased by increasing the nanoplatelets loading. The effect of the nano additives loading and temperature on the tribological properties of nanolubricants was investigated using two different test configurations: reciprocating ball-on-plate and rotational ball-on-three-pins. The tribological specimens were analysed by Scanning Electron Microscopy (SEM) and 3D profiler in order to evaluate the wear. The results showed significant improvement in the antifriction and anti-wear properties, for the 2D-materials-based nanolubricants as compared with the engine oil, using different contact conditions. For the reciprocal friction tests, maximum friction and worn area reductions of 20% and 22% were achieved for the concentrations of 0.10 wt% and 0.20 wt% GNP, respectively. Besides, the best anti-wear performance was found for the nanolubricant containing 0.05 wt% MSNP in rotational configuration test, with reductions of 42% and 60% in the scar width and depth, respectively, with respect to the engine oil.

## 1. INTRODUCTION

Saving fuel, emission control and increasing the engine service life are some of the main challenges facing the automotive industry [1]. In 2015, the transportation sector included about 1,600 million vehicles used for transportation of people and freight in sea, land, and air. Road vehicles used 75% of the total energy use in transportation [2, 3]. One of the main causes of greenhouse gases emission and higher fuel consumption is the engine friction. Around 28% of the fuel energy is lost due to direct frictional losses, without taking into account those caused by braking friction [4]. Due to the high pressure and temperature conditions within the combustion engine, the lubricant degrades more rapidly and loses their lubricating properties [5]. Further, by improving the antifriction and anti-wear properties of the lubricants, the lifetime of the moving parts will increase, which in turn would enhance the durability of the engine. Therefore, improving the efficiency of the lubricants would bring tremendous environmental and economic benefits [6].

Friction losses take place in three main parts of the engine; the piston ring-cylinder liner interface, the crankshaft and the valve train [7]. Reducing the wear and friction losses in these engine components is linked to the use of suitable lubricating oils, which contain tailored additive packages. A wide variety of lubricant additives are available to enhance the properties of the engine oil, such as friction modifiers (FMs), which are used mainly to reduce friction losses. This type of additives improves load-carrying capability and are applied mainly on the boundary and mixed lubrication regimes [8].

Recently, nanomaterials have been widely employed as lubricant additives because of their excellent physical and chemical properties. Several researchers have reported that incorporation of nanoparticles into lubricating oil can improve their extreme pressure, anti-wear and friction reduction properties [9-11]. The reduced size of nanoparticles allows them to repair defects of the contact surfaces through different mechanisms, which depend

1  
2  
3 on the morphology and the nature of the nanoparticles, producing subsequently positive  
4  
5 lubrication effects.  
6

7  
8 The rheological behaviour of nanolubricants depends on several characteristics of  
9  
10 the nano additives such as the particle size, morphology and concentration. Thus, control  
11  
12 of the variation on viscosity properties of the nanolubricants is of great interest. In  
13  
14 particular, viscosity reduction leads to lower friction forces between the piston ring and  
15  
16 cylinder liner [12] and achieves a decrease in fuel consumption by 0.2-2.5% [2]. Further,  
17  
18 according to Hamrock and Dowson equation [13], lubricant film thickness depends on  
19  
20 their viscosity. A low lubricant viscosity results in thin oil film, which leads to an increase  
21  
22 in the surface contact and hence, the wear of sliding surfaces [14]. For this reason, nano  
23  
24 additives are more efficient under boundary lubrication (BL) regime forming a tribofilm on  
25  
26 the asperity contact surface. Wettability is another important property to be taken into  
27  
28 consideration due to the influence on the tribological properties of contact surfaces at the  
29  
30 micro and nanoscales [15]. Contact angle, one of wetting properties, plays an important  
31  
32 role in improving tribological properties. Thus, hydrophilic surfaces (static water contact  
33  
34 angle  $< 90^\circ$ ) have high free surface energy and hence, present a higher resistance against  
35  
36 friction and wear [16].  
37  
38  
39  
40  
41

42 All 2D materials, such as graphene nanoplatelets (GNP) and molybdenum disulfide  
43  
44 ( $\text{MoS}_2$ ) nanoplatelets (MSNP) exhibit lamellar morphology, with the atomic or molecular  
45  
46 thick layers connected via weak van der Waals forces. The adjacent layers are readily  
47  
48 exfoliated under a shear force, and lower friction is achieved with sliding movement [17].  
49  
50 For this reason, in this work GNP and MSNP were selected among other kind of  
51  
52 nanomaterials to be analysed as lubricant additives. Different researchers have employed  
53  
54 graphene and other 2D nanomaterials in different base oils to improve friction and wear  
55  
56 reduction. Eswaraiyah et al. [18] have observed an 80 % reduction in friction coefficient for  
57  
58  
59  
60

1  
2  
3 graphene-based engine oil without modifying the nanomaterial surface, using a four-ball  
4  
5 tester. Lin et al. [19] have demonstrated that the addition of graphene platelets, modified  
6  
7 by stearic and oleic acids, improves notably the wear resistance and load-carrying capacity  
8  
9 of lubricating oils. Sulfides nanoparticles ( $\text{MoS}_2$ ,  $\text{WS}_2$ ,  $\text{CuS}$ ) exhibit protective film  
10  
11 mechanism as a result of heat generated for the friction between the mating surfaces [1].  
12  
13 Kogovšek and Kalin [20] have compared the tribological behaviour in boundary  
14  
15 lubrication regime, using a ball-on-disc configuration, of seven different micro and nano  
16  
17 additives in polyalphaolefin (PAO) oil:  $\text{MoS}_2$  nanotubes and platelets (2 and 10  $\mu\text{m}$ ),  $\text{WS}_2$   
18  
19 nanotubes and fullerene-like nanoparticles, graphite platelets and multi-walled carbon  
20  
21 nanotube.  $\text{MoS}_2$  particles (nanotubes and platelets) showed the best friction reduction (55-  
22  
23 60%) as compared to  $\text{WS}_2$  and carbon-based particles. Koshy et al. [21] have investigated  
24  
25 the tribological performance of a vegetable (coconut) oil and of mineral oil (500 N base-  
26  
27 oil) with  $\text{MoS}_2$  nanoparticles (unmodified and surfactant-modified) under boundary film  
28  
29 lubrication regime. The results show that friction and wear reduction increases when  
30  
31 nanolubricants are used at the sliding interface rather than the base lubricant. However, the  
32  
33 majority of the work in the literature used graphene and  $\text{MoS}_2$  nanoparticles with small  
34  
35 lateral size, which increases the edge to plane ratio. While the layers in the nanoplatelets  
36  
37 can move relative to each other upon applying shear stress, the edges are very sharp and  
38  
39 might cause several types of scratches and surface imperfections. In addition, most of the  
40  
41  $\text{MoS}_2$  in the literature have been prepared by hydrothermal processes followed by a heat  
42  
43 treatment step. This kind of materials usually suffers from a high level of amorphous  
44  
45 phases contamination, which is usually harder than crystalline 2D materials and could be a  
46  
47 source of wear on the surface. Furthermore, the nanoparticles additives usually suffer from  
48  
49 agglomeration in many oil-based system and surfactants are added to prevent the particles  
50  
51 from clustering, which might increase the risk of corrosion. It is also important to have a  
52  
53

1  
2  
3 comparative study between graphene and MoS<sub>2</sub> based lubricants at the boundary  
4 conditions to shade more light on the tribofilm formation.  
5  
6

7 In this work, large flakes (2-10 μm lateral size) of multi-layered graphene and  
8 MoS<sub>2</sub> prepared by cathodic electrochemical exfoliation were used as the nano additive to  
9 commercial engine oil (5W-30). The specific preparation of both materials was selected to  
10 avoid sharp edges and, consequently, scratches and surface imperfections obtained with  
11 other procedures. In addition, the residual electrostatic charges on the surface obtained  
12 with this procedure lead to the nanoplatelets did not show any significant agglomeration  
13 without the need of surfactants. The nanolubricant prepared using both types of  
14 nanoplatelets showed considerable enhancement on the anti-wear and friction properties.  
15 The work is focused on investigating the influence of the 2D materials on the tribological  
16 properties (friction and wear) in boundary lubrication regime using different loading of the  
17 nanoplatelets. Tribological tests were performed simulating real engine sliding conditions  
18 and using different contact geometries: ball-on-plate and ball-on-three-pins.

Commercial SAE 5W-30 synthetic oil was used as the base oil to prepare the  
nanolubricants in this work. Table 1 summarises the specifications of this engine oil.

**Table 1.** Properties of neat 5W-30 engine oil.

| Neat 5W-30 oil                           |        |
|--|--------|
| VI                                       | 163.3  |
| $\rho_{298K} / \text{kg m}^{-3}$         | 848.6  |
| $\nu_{303K} / \text{mm}^2 \text{s}^{-1}$ | 112.74 |
| $\nu_{373K} / \text{mm}^2 \text{s}^{-1}$ | 11.83  |

Fourier Transform Infrared (FTIR) spectroscopy was employed to characterise the fresh 5W-30 engine oil sample and to study the formation of chemical bonds between the nano additives and the base oil. Figure 1 shows infrared spectra of the engine oil sample and the nanolubricants with the highest concentration of each nano additive, which was collected in a FTIR spectrometer (VARIAN 670-IR) equipped with a Golden Gate horizontal attenuated total reflectance (ATR) accessory in transmission mode and over the spectral range 4000–400  $\text{cm}^{-1}$ . FTIR spectrum shows in the range between 3000 and 2850  $\text{cm}^{-1}$  typical bands of C-H stretching, in particular at 2920 and 2852  $\text{cm}^{-1}$  which conform to  $-\text{CH}_2$  asymmetrical and symmetrical stretching, respectively. The peak at 1460  $\text{cm}^{-1}$  corresponds to  $-\text{CH}_2$  scissoring. In addition to C-H stretching peaks, methyl groups exhibit C-H bend at  $1375 \pm 10 \text{ cm}^{-1}$  [23]. This peak is clearly seen in Figure 1 at 1377  $\text{cm}^{-1}$ , which confirms the presence of symmetric  $-\text{CH}_3$  bending. The last peak takes place at 721  $\text{cm}^{-1}$  that corresponds at  $-\text{CH}_2$  rocking vibration. This band is observed only in long-chain alkanes (with at least four methylene groups in a row). No new spectral peaks or shifts are found for the nanolubricants compared to the engine base oil, which indicates that no chemical bonds were formed.

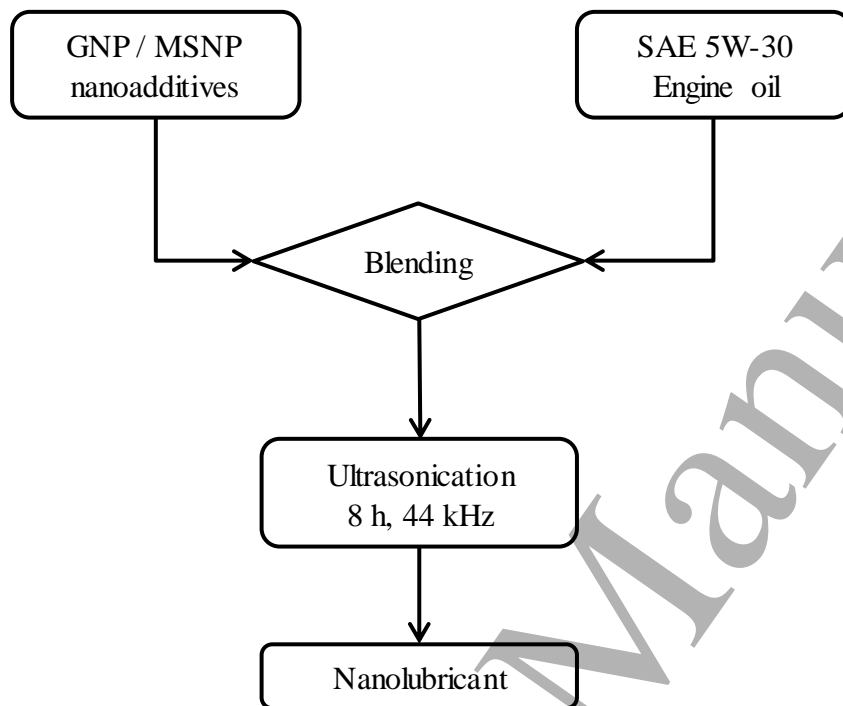

**Figure 1.** FTIR spectrum of engine oil SAE 5W-30 (black line) and nanolubricants with 0.20 wt% of a) GNP (red line) and b) MSNP (blue line).

The FTIR spectrum of the engine oil corresponds to a polyalphaolefin (PAO) [24]. PAOs are mainly used as high-performance functional base fluids in engine lubricants. These synthetic lubricants are classified by their kinematic viscosities at 373.15 K. Therefore; the engine oil 5W-30 can be associated as PAO12 because it has a kinematic viscosity of  $11.83 \text{ mm}^2 \text{ s}^{-1}$  at 373.15 K.

## 2.2. Formulation of nanolubricants

Three different concentrations of both nano additives were prepared by the two-step method: 0.05 wt%, 0.10 wt% and 0.20 wt%. The weight fractions used have been selected with the criterion of cost reduction for a future industrial application. The use of small quantities reduces the manufacturing cost of the nanolubricant. Furthermore, previous works [25, 26] have shown that the use of weight fractions greater causes a decrease in the antifriction and anti-wear capacity of the nanolubricant and reduces its stability. But on the contrary, Gupta et al. [27] have concluded that if the nanoparticle concentration is sufficiently low, the lubrication is ineffective and friction/wear is dominated by base oil. Therefore, there is no concrete evidence on the optimum concentration of nano additives to be used because their effectiveness depends on certain factors, such as their compatibility with base oils, their size and morphology and their dispersion stability. The appropriate

amount of GNP and MSNP was added to 100 mL of the motor oil 5W-30 and was stirred with an ultrasonic bath (Ultrawave U500H) for 8 hours at a 44 kHz frequency to obtain a uniform dispersion. The procedure used for nanolubricants preparation is shown in schematic Figure 2.

**Figure 2.** The procedure used for nanolubricant preparation.

### 2.3. Nanolubricants stability

The stability of the nanolubricants was evaluated by two different methods: visual control and temporal evolution of the refractive index. The first method consists of taking photographs of the nanolubricants over time from the moment they are prepared. The second method is based on measuring the refractive index of the base oil and the nanolubricants and observing how it varies as a function of time. A Mettler Toledo RA-510 M refractometer was used to register the temporal evolution of the refractive index ( $n$ ) at  $T = 296.15$  K operating at the wavelength of the D-line of sodium (589.3 nm). This apparatus works in a range from 1.32 to 1.56 with a resolution of 0.00001. The nanolubricants with

the highest load with each type of nanoparticle have been selected to carry out the stability study, thus ensuring that the stability for lower concentrations will be equal or greater. This method was presented in our previous works [24, 28].

**Figure 3.** Digital images of the just prepared nanolubricants with the highest nanoparticle loading and after 6 months of the preparation.

Figure 3 shows digital images of the nanolubricants with a concentration of 0.20 wt% after different periods of preparation. A slight sedimentation is observed in the nanolubricant containing MSNP as nano additive. However, the sedimentation at the bottom of the bottle is negligible with GNP nano additive material. This indicates less stability for the nanolubricant containing MSNP. The temporal evolution of the refractive index can be observed in Figure 4. An overall refractive index variation of 0.008 and 0.003 over 96 h was obtained for 0.20 wt% MSNP and for 0.20 wt% GNP nanolubricants, respectively. The overall variation of the refractive index is smooth ( $\leq 0.003$ ) during the 96 first hours after sonication for GNP-based nanolubricant while this variation (0.003) is reached at 15 hours for the MSNP-based nanolubricant. A better stability for the nanolubricant of 0.20 wt% of GNP is again verified. These results reveal that these nanolubricants are stable during this time interval without using any surfactant.

**Figure 4.** Temporal evolution of the refractive index,  $n$ , at  $T = 296.15$  K for base oil, 5W-30 (broken line), and for nanolubricants at 0.20 wt% GNP (unfilled circle) and 0.20 wt% MSNP (filled circle).

## 2.4. Characterisation of nanolubricants

### 2.4.1. Wettability

The wetting behaviour of the neat engine oil and the nanolubricants was evaluated using a contact angle analyser (Phoenix MT) at ambient temperature ( $\sim 296$  K). Before the contact angle,  $\theta$ , measurements, the surfaces used for the tribological tests (AISI 420 stainless steel plate) were rinsed with ethanol and dried in a stream of hot air. To measure the static contact angle, 1 ml of lubricant sample was dropped on the sample surface using a syringe. At least three measurements of the contact angle were replicated, and the average value of the steady-state value and its standard deviation was calculated. A time period of about 30 s was necessary to reach a stable contact angle value with the lubricants.

#### 2.4.2. Density, viscosity and viscosity index

The thermophysical properties (density, viscosity and viscosity index) of the nanolubricants were determined with a SVM 3000 Anton Paar rotational Stabinger viscometer. This device has been described in detail previously [29]. Density and viscosity were determined over the temperature range from 278.15 to 373.15 K at atmospheric pressure. The temperature of the cell is controlled through an integrated thermostat with cascaded Peltier elements and measured with a Pt100 thermometer. Density cell consists of a glass U-tube, which is excited to produce mechanical resonant vibrations according to DIN 51757 standard. The expanded uncertainties ( $k = 2$ ) are 0.02 K for the temperature,  $T$ ,  $0.0005 \text{ g cm}^{-3}$  for density,  $\rho$ , and 1% in the case of dynamic viscosity,  $\eta$ . This apparatus (SVM 3000) also allows measurement of the viscosity index, VI, according to the ASTM D2270 standard [30].

#### 2.4.3. Tribological tests

The tribological characterisation was performed using two different contact configuration testers: a reciprocating tribometer in a ball-on-plate configuration at the starting temperature of lubricant in the engines (room temperature) and a rotational tribological cell in a ball-on-three-pins configuration at the optimum temperature of the combustion engine (363.15 K). Before and after each tribological test, all specimens were cleaned with hexane and dried with a stream of air for a few seconds.

Reciprocating friction tests were carried out with a CSM Standard tribometer. Chrome steel balls AISI 52100 (diameter: 6 mm; hardness: 803 HV, Young's modulus: 190 to 210 GPa; Poisson's ratio: 0.29; roughness: 32 nm) were run against AISI 420 stainless steel plates ( $40.5 \times 21 \times 5 \text{ mm}^3$ ; hardness: 194 HV, Young's modulus: 190 to 210 GPa; Poisson's ratio: 0.27) with a mirror finish polishing (roughness 10.55 nm). The plates were lubricated with five drops of the neat oil (5W-30) or the nanolubricants. The

setup used in the tests is shown in Figure 5(a). Tests were conducted at room temperature ( $\sim 296$  K) under normal load of 20 N, which correspond to maximum Hertzian contact pressures of 1.8 GPa. At least three replicates were performed for each sample at a stroke length of 10 mm, sliding a total distance of 360 m with an average sliding speed of  $0.064$   $\text{m s}^{-1}$ , so the friction coefficient reported is an average of three measurements. The criterion considered for selecting values was that the difference in the friction coefficient of a test compared to the mean value should be below 15 % [31]. The reciprocating friction tests have been carried out at room temperature to simulate the conditions of an internal combustion engine during start-up.

**Figure 5.** Schematic setup of the contact configurations employed: a) reciprocating ball-on-plate and b) rotating ball-on-three-pins.

Rotational tests of the friction coefficient were performed using an Anton Paar MCR 302 rheometer equipped with a Peltier heated tribology cell T-PTD200 and a Peltier Hood H-PTD200 for precise temperature control [32, 33]. The setup used in the tests was a ball-on-three-pins, as shown in Figure 5(b). A chrome steel ball AISI 52100 (diameter: 12.7 mm) rotates against three 100Cr6 pins (diameter: 6 mm) under an axial force  $F$  of 20 N which is transferred into three normal tribological forces  $F_N$  of 9.43 N (1.1 GPa of maximum Hertzian contact pressure) acting perpendicular to the bottom pins at the contact

1  
2  
3 points. Both material pairings for tribological testing (ball and pins) have the following  
4 specifications: hardness from 62 to 66 Rockwell C; Young's modulus from 190 to 210  
5 GPa; Poisson's ratio of 0.29 and surface roughness of 0.1  $\mu\text{m}$ . To cover the pins 0.5 ml of  
6 the engine oil or of the nanolubricants were introduced in the sample holder. The sample  
7 holder is fitted with a protector to prevent lubricant spillage or leakage during the  
8 experiments. Two replicates were performed for each sample at a sliding distance of 180 m  
9 and a linear speed at the contact points of 0.1  $\text{m s}^{-1}$  (rotational speed 213 rpm). In order to  
10 simulate the actual conditions of an internal combustion engine, an optimum operating  
11 temperature of 363.15 K has been selected for the rotational friction tests [5].

#### 23 2.4.4. *Wear and roughness determination*

24  
25  
26 The wear produced on the discs after the tribological test was determined with a  
27 non-contact 3D Optical Profiler Sensofar S Neox working in confocal mode and with a  
28 magnification objective of 10X for the lower specimens (plates and pins). For upper  
29 specimens (balls), focus variation mode with a magnification objective of 20X was used.  
30 In the reciprocating friction tests (three replicates for sample), the counter-pairs selected to  
31 determine the wear produced were those with a COF closer to average. Profiles of the wear  
32 tracks produced in the lower specimens (plates and pins) due to the friction tests for the  
33 studied nanolubricants and 5W-30 engine oil were obtained using a SensoMap software.  
34 From the profile of the wear scars, wear track width (WTW), wear track depth (WTD), and  
35 cross-section area of each worn scar were analysed in three different zones in order to  
36 obtain representative average values. For the upper specimens (balls) the profile of the  
37 wear tracks could not be determined rigorously due to the spherical shape of the counter-  
38 pairs. For this reason, it was only possible to determine the WTW for the balls.  
39 Furthermore, this equipment was also employed to determine the roughness surface,  $R_a$ ,  
40 inside the worn scars; according to with the ISO 4287 standard and applying a Gaussian

### 15 **3. RESULTS AND DISCUSSION**

#### 16 *3.1. Thermophysical Characterisation*

17  
18  
19 Wettability behaviour of the neat engine oil and of the nanolubricants with a  
20  
21 concentration of 0.10 wt% of GNP or of MSNP was determined on the surface of the  
22  
23 stainless steel plates (AISI 420). Average static contact angle,  $\theta$ , values obtained with  
24  
25 Phoenix MT analyser and their corresponding standard deviations,  $\sigma$ , are presented in  
26  
27 Table 2. SAE 5W-30 showed excellent wetting behaviour on AISI 420 stainless steel  
28  
29 surfaces with a contact angle of 18.8°. This value is coherent with those obtained for PAO4  
30  
31 and PAO9 by Kalin et al. [34]. The static contact angle increases by 42.5% and 50.5% with  
32  
33 respect to the neat engine oil when 0.10 wt% of GNP or of MSNP are added, respectively.  
34  
35 The wettability of a surface increases as the contact angle formed by the sample deposited  
36  
37 on is lower. Improved wetting provokes sliding at the solid-liquid interface, and therefore  
38  
39 this fact is even more relevant in tribological applications in boundary lubrication regimes  
40  
41 because of the direct contact between the surfaces. GNP and MSNP are intrinsically mildly  
42  
43 hydrophilic, but 2D materials are susceptible to spontaneous hydrocarbon contamination,  
44  
45 which reduce the surface energy and exhibit their traditionally reported hydrophobicity  
46  
47 [35]. The hydrophobic acquired behaviour of graphene and molybdenum disulfide [36]  
48  
49 may be one of the causes of increased contact angle when this nano additive is added to the  
50  
51 neat oil.

**Table 2.** Steady-state average values of contact angles,  $\theta$ , and their standard deviation,  $\sigma$ , values on AISI 420 stainless steel plates wetted with the neat oil and two nanolubricants.

| Sample                        | $\theta/^\circ$ | $\sigma/^\circ$ |
|-------------------------------|-----------------|-----------------|
| Neat 5W-30 oil                | 18.8            | 0.4             |
| 99.9 wt% 5W-30 + 0.1 wt% GNP  | 26.8            | 0.7             |
| 99.9 wt% 5W-30 + 0.1 wt% MSNP | 28.3            | 2.1             |

Experimental density and kinematic viscosity measurements for the engine oil and for the six nanolubricants formulated with different nanoplatelets loading were conducted using a rotational Stabinger viscometer and are collected in Table S1 and Table S2 of the supplementary information. The density of nanolubricants is lower than the density of the neat oil over all the temperature range, except for the highest graphene loading (0.20 wt%). These results are different from those previously published for other nanolubricants [37, 38], where the density of the nanolubricants increases with the nano additives loading due to the agglomeration of the nanoparticles. In the current work, the nanoplatelets were produced by the cathodic exfoliation processes, and the produced particles are likely to have some static charge residues on the surface [39, 40]. These static charges cause repulsive interactions between the nanoplatelets, which reduce their tendency to agglomerate [41].

The kinematic viscosity measurements showed similar behaviour to that of the density, with lower values recorded for the oil (5W-30) doped with GNP and MSNP. Several publications [38, 42, 43] reported the increase of the viscosity of the oil with increasing the loading of the nanoparticles, which was attributed to the increasing tendency of the nanoparticles to agglomerate at high loading. This agglomeration leads to an increase in the internal shear stress in nanolubricant, and thus increases the viscosity. In the present work, the well-dispersed GNP and MSNP keep a layer of the oil on the surface, and consequently between the neighbours' flakes. Therefore, the oil works as a localised

1  
2  
3 lubricant that facilitates the sliding of the neighbours flakes on each other upon applying  
4  
5 any shear force. In addition, the weak van der Waals forces between the layers in the GNP  
6  
7 and MSNP can be easily broken by the shear stress, which also lead to the layers sliding on  
8  
9 each other and lowering the viscosity. Ali et al. [44] have observed similar behaviour of  
10  
11 the kinematic viscosity of another 5W-30 engine oil doped with  $\text{Al}_2\text{O}_3$ ,  $\text{TiO}_2$  and  
12  
13  $\text{Al}_2\text{O}_3/\text{TiO}_2$  nanoparticles at the temperatures of 313.15 K and 373.15 K. These authors  
14  
15 attributed the slight decrease of the viscosity with respect to neat engine oil to the  
16  
17 nanoparticles located between the oil layers promote the relative movement between the  
18  
19 lubricant layers [9]. Nanolubricant of SAE 20 W50 engine oil doped with multi-walled  
20  
21 carbon nanotubes at 0.1 wt% showed similar behaviour [45]. The MSNP nanolubricant  
22  
23 shows deeper viscosity variation than the GNP nanolubricant at same particle mass  
24  
25 fractions. This phenomenon can be explained by the rougher surface and the zigzag  
26  
27 morphology of the surface of the  $\text{MoS}_2$  2D crystal. The kinematic viscosity of the engine  
28  
29 oil and of the nanolubricants decreased with increasing the temperature, at moderated  
30  
31 temperature. Some diversion was observed for the lubricants with high graphene loading,  
32  
33 where the viscosity increased above 343.15 K.

**Figure 6.** Viscosity index, VI, for all the nanolubricants based on 5W-30 engine oil.

The viscosity index, VI, of the GNP and MSNP-doped 5W-30 nanolubricants is plotted in Figure 6. The results show that VI increased by 6.4% for the 0.05 wt% GNP loading, and decreased for the higher loading by 0.7% and 0.4% for the 0.10 wt% and 0.20 wt% loading respectively, as compared with the neat engine oil. Whereas, for the MSNP nanolubricants at 0.05 wt%, 0.10 wt% and 0.20 wt% the VI increases by 5.9%, 5.8% and 6.3%, respectively. For GNP at 0.1 wt% a deep dip in the VI can be observed. Similar phenomenon has been observed in our previous work with PAO6/GNP nanolubricant, also at 0.1 wt% GNP loading [24]. This fact may be because VI is determined from the kinematic viscosities,  $\nu$ , at 313.15 K and 373.15 K. At the higher temperature the  $\nu$  values are quite close: 11.99 and 11.74 mm<sup>2</sup> s<sup>-1</sup> respectively for 0.05 wt% and 0.10 wt%, whereas at 313.15 K the  $\nu$  values are quite different: 68.74 and 71.01 mm<sup>2</sup> s<sup>-1</sup> respectively for 0.05 wt% and 0.10 wt%. The increase in the viscosity index means that the lubricant viscosity is less sensitive to temperature, resulting in lower frictional and pumping losses and therefore

providing better resistance to lubricant film thinning and fuel efficiency in an automotive engine [46].

**Figure 7.** Coefficient of friction (COF) and cross-section area of wear scars on plates surfaces for engine oil and six different nanolubricants at room temperature.

### 3.2. Tribological Characterisation

In order to evaluate the tribological performance of the engine oil doped with GNP and MSNP, the frictional behaviour was studied using a CSM Standard tribometer. The measured COF of nanolubricants with different GNP and MSNP loading is shown in Figure 7. Lubrication regime was determined through Eq. 1 (supplementary information) for reciprocating configuration obtaining an  $\lambda$  value of 0.7 at the operating conditions, which corresponds to boundary lubrication regime. Figure 7 shows that the addition of both GNP and MSNP has a positive antifriction effect. The nanolubricant with 0.10 wt% GNP shows a higher reduction in friction under a load of 20 N and boundary conditions, reaching an improvement up 20% when compared with neat commercial engine oil.

1  
2  
3 The friction coefficient as a function of the sliding distance measured at 20 N and at  
4  
5 363.15 K in rotational frictional tests is shown in Figure S1 (supplementary information).  
6  
7 These contact configuration tests were also carried out in boundary lubrication regime,  
8  
9 with an  $\lambda$  value of 0.06. There is a noticeable improvement in the COF of the engine oil  
10  
11 when doped with nano additives. The friction coefficients of the lubricants fluctuated  
12  
13 during the first 50 m of the test. It can be seen that there is a slight initial decrease in COF  
14  
15 followed by a gradual increase to a stable value after large sliding distance. This  
16  
17 phenomenon is more pronounced for the nanolubricant with 0.10 wt% of MSNP, which is  
18  
19 also the dispersion that shows the better antifriction behaviour with respect to the neat  
20  
21 commercial engine oil (5.9% of average COF reduction) in these tests. The decline of the  
22  
23 COF is probably due to the high surface energy of MoS<sub>2</sub> nanoplatelets that can easily  
24  
25 interact and form an abrasion-resistant protective film at the contact interfaces [41]. By  
26  
27 comparing different loading of GNP nanoparticles (Figure S1), it can be concluded that  
28  
29 tribological performance is negatively influenced by increasing the concentration of GNP  
30  
31 above 0.05 wt%. The better tribological performance of the low GNP loading is due to the  
32  
33 slightly enhanced dispersibility of graphene nanoplatelets in the base oil, which enhances  
34  
35 the strength of tribofilm [47]. Furthermore, this behaviour agrees with the results of the  
36  
37 viscosity index for GNP-based nanolubricants, in which an increase in VI was observed  
38  
39 only for the lowest GNP concentration. This increase confers greater viscous stability  
40  
41 against temperature variations and hence, allows the nanoparticles to develop a more  
42  
43 effective lubrication mechanism. In general, MoS<sub>2</sub> nanoplatelets show more pronounced  
44  
45 friction reduction comparing with GNP due to shearing of the nanoparticles forming a low  
46  
47 friction tribofilm.

### 3.3. Wear surface characterisation

The wear of the ball surfaces and wear tracks on the plates and pins of the samples after tribological testing have been studied using optical profiling to assess the wear properties of GNP and MSNP nanolubricants. For each specific loading of the nanolubricant, three sets of data have been taken for the measurement of WTW, WTD and cross-section area and the average of three readings are gathered in Table 3 and Table 4.

**Table 3.** Mean values of the width, WTW, depth, WTD, cross-section area and roughness,  $R_a$ , of the wear track and their respective standard deviations,  $\sigma$ , for the six nanolubricants and SAE 5W-30 oil obtained for both specimens with CSM Standard tribometer at room temperature.

1  
2  
3 For the reciprocating friction tests, the results show a reduction of wear area of  
4  
5 19%, and 22% for the 0.10 wt% and 0.20 wt% of GNP, respectively. The reduction in the  
6  
7 wear area was 13% for the 0.20 wt% MSNP formulated oils. However, an increase of the  
8  
9 wear has been recorded for the lower mass fractions of GNP and of MSNP (Figure 7). As  
10  
11 for the wear produced on the chrome steel balls, the results are consistent with those  
12  
13 obtained on the counter-pairs. A reduction in the wear track width is observed for the  
14  
15 nanolubricants with the highest nanoparticle concentrations with both nano additive, as can  
16  
17 be seen from Figure 8, there are reductions of 7% and 2% for 0.20 wt% of GNP and of  
18  
19 MSNP were obtained, respectively. In order to identify the different mechanisms that take  
20  
21 place during sliding wear, the worn plate was observed under a scanning electron  
22  
23 microscope. Figure 9 shows optical and SEM images and wear morphology of the wear  
24  
25 tracks for the stainless steel plates lubricated with neat oil (5W-30) and with  
26  
27 nanolubricants.

**Figure 8.** Optical images with the WTW of the wear scars on the chrome steel balls for the engine oil and the six different nanolubricants for the reciprocating friction tests.

**Figure 9.** Optical and SEM images and wear and roughness map of the wear scars on the stainless steel plates for the engine oil and the best anti-wear nanolubricant concentration of each nano additive.

The oil doped with high GNP and MSNP loading showed the best anti-wear properties. Plastic deformation is evidenced in all the worn surfaces, with a deep well-defined scar. The furrows on the wear surface lubricated only with the engine oil is rougher and deeper, and larger number of furrow can be observed. These grooves are parallel to the ball sliding direction and the growth of subsurface grooves that cause the final detachment, which is a typical feature of abrasion wear. These furrows are smoother in the wear track of the specimens when the nanoplatelets were used as additives. The improvement in the

1  
2  
3 antifriction properties of the lubricant after doping can be attributed to the multifunctional  
4  
5 role of the nano additives. First, the 2D nature of the GNP and MSNP allow them to enter  
6  
7 the frictional contact area, and the relative motion of the surfaces causes the nanoparticle to  
8  
9 shear and adsorb some of the friction force. Second, the planar nature of GNP and MSNP  
10  
11 allow them to be adsorbed readily on the surfaces and form protective friction films at the  
12  
13 beginning of the loading. This protective film breaks with the contentious loading, and the  
14  
15 big flakes fracture into smaller lateral diameter flakes that can easily be transferred with  
16  
17 the lubricant flow. This transfer film provides farther protection by preventing, or  
18  
19 minimising, the direct contact between two sliding surfaces. Furthermore, GNP and MSNP  
20  
21 can mitigate any roughness present on the surface by filling the concave area and cover the  
22  
23 roughness peaks, thereby help to form a uniform oil film and enhance the lubricity. It  
24  
25 should be noted here that the 3D images show deeper and wider groves when the oil is  
26  
27 doped with MSNP than with graphene. Due to the higher surface energy of graphene,  
28  
29 graphene adsorbed onto the surface of the friction pair easier than MSNP, and hence it  
30  
31 forms a more homogeneous physical protective film.  
32  
33  
34  
35  
36

37 For the nanolubricant with 0.20 wt% MSNP, it is possible to detect some wear  
38  
39 debris on the wear scar. Wear debris is typical of abrasive wear, which often occurs  
40  
41 between soft surfaces and hard asperities. Furthermore, the roughness of the surface was  
42  
43 also determined for the specimens lubricated with the doped and undoped oil (table 3). The  
44  
45 value of  $R_a$  in the wear scars is lower for the nanolubricants with 0.10 wt%, 0.20 wt% of  
46  
47 GNP and for 0.20 wt% of MSNP with respect to undoped 5W-30 engine oil. This  
48  
49 reduction in the roughness is in agreement with anti-wear behaviour results. The roughness  
50  
51 reduction of the lubricating surface can be explained by nanoparticle-assisted abrasion,  
52  
53 which is known as the polishing effect. The detection of the debris on the surface when the  
54  
55 MSNP was used provides evidence for the polishing phenomenon. However, the increment  
56  
57  
58  
59  
60

1  
2  
3 of the  $R_a$  in the nanolubricants with low concentrations (0.05 wt% of GNP and MSNP) is  
4 probably because of the lack of sufficient amounts of nano additives to produce an  
5 effective polishing. This fact explains the detrimental effect observed in the wear analysis  
6  
7  
8  
9  
10 for nanolubricants concentrations with low nanoparticles loading.

11  
12 The average wear track width, WTW, produced by rotational friction test at 363.15  
13 K on the chrome steel pins was represented in Figure S2 (supplementary information). The  
14 doped oils showed excellent anti-wear behaviour for all concentrations tested. The best  
15 anti-wear performance was observed for the nanolubricant containing 0.05 wt% of MSNP  
16 with a corresponding WTW reduction of 42 %. The optical images of the wear scars on the  
17 chrome steel balls and on the pins for the engine oil and nanolubricants are shown in  
18 Figure S3 (supplementary information). The reduction in the width of the wear pattern has  
19 been greater on the pins than on the balls. For instance, for the 0.20 wt% GNP/5W-30 the  
20 WTW reduction was of 38 % and 7% for the pin and the ball, respectively. This is a  
21 surprising result, considering the hardness of balls is higher than that of the pins. However,  
22 the planner morphology of the 2D materials, GNP and MSNP, allows them to attached  
23 better on the flat surface of the pins, unlike the curved ball. To gain more insights on the  
24 wear mechanism, roughness surface analysis was carried out to analyse the worn surface of  
25 the lubricated pins during the rotational friction tests. The results (Table 4) show a  
26 decrease in  $Ra$  when GNP and MSNP are used as additives compared to that obtained with  
27 undoped engine oil. An apparent polishing effect produced by the nanoparticles is again  
28 confirmed. The wear mechanism of 2D nanostructures materials additives helps to form a  
29 tribofilm and to sand the existing asperities on the contact surfaces, due to the exfoliation  
30 occurs between the adjacent layers under the applied shear stress [1]. Therefore, it can be  
31 concluded that the deposition of nanoparticles on the worn surface can decrease the  
32 shearing stress, and hence reduce friction and wear. The results of the unique tribological

#### 10 **4. CONCLUSIONS**

11  
12 This work focuses on the thermophysical and tribological behaviour of doping  
13  
14 engine lubricants with electrochemically exfoliated graphene and molybdenum disulfide  
15  
16 nanoplatelets. The effect of the electrochemically exfoliated GNP and MSNP on the  
17  
18 wettability of the engine base oil showed a decrease but without compromising its  
19  
20 tribological performance. Moreover, unlike most reported nanolubricants, the GNP and  
21  
22 MSNP doped oil showed decreases in kinematic viscosity and density due to the lack of  
23  
24 aggregation of the nanoparticles. Further, for most formulated nanolubricants, a significant  
25  
26 increase in the viscosity index was obtained. The antifriction behaviour for both nano  
27  
28 additives obtained from a novel method was revealed for all the concentrations studied  
29  
30 compared to the neat engine oil for both contact configurations. A maximum reduction of  
31  
32 20% was reached for the concentration of 0.10 wt% GNP/5W-30 in the reciprocating  
33  
34 configuration tests. Besides, the addition of GNP and of MSNP in the 5W-30 engine oil  
35  
36 showed excellent anti-wear properties, in particular for the ball-on-three-pins  
37  
38 configuration. The rotational frictional tests lead to a decrease in the worn scar width of 38  
39  
40 and 42% for 0.20 wt% GNP/5W-30 and for 0.05 wt% MSNP/5W-30, respectively,  
41  
42 compared to the neat oil. This excellent tribological behaviour in the boundary lubrication  
43  
44 regime can be explained by two different nanoparticle mechanism detected during surface  
45  
46 analyses when nano additives at an optimum concentration level are added to the base oil:  
47  
48 film formation and polishing effect. Therefore, 2D nanomaterials obtained from a novel  
49  
50 method were proposed as lubricant additives, which can help in the development of new  
51  
52 lubrication systems with an excellent tribological performance for industrial applications.

1  
2  
3 Finally, authors would like to note as future work the interest in studying the  
4 coefficient of friction variation and anti-wear mechanism of these nano additives in mixed  
5 lubrication regime in order to complete the tribological characterisation, because the  
6 lubrication mechanisms of the nano additives mentioned above take place especially under  
7 mixed and boundary lubrication. To this aim, it would be very advantageous to increase the  
8 stability of the nano additives studied in the base lubricant. One of the most effective ways  
9 to improve the nanolubricant stability is to use some dispersant, such as oleylamine or  
10 ascorbic acid.

#### **ACKNOWLEDGMENTS**

Authors thank to Dr. Alfredo Amigo (from Department of Applied Physics, University of Santiago de Compostela) for the useful assistance with the contact angle analyser and for kindly allowing the use of the refractometer. This work was supported by both the Spanish Ministry of Economy and Competitiveness (MINECO) and the ERDF programme through ENE2017-86425- C2-2-R project, and by the Xunta de Galicia (AEMAT ED431E 2018/08 and GRC ED431C 2016/001). These funders also financed the acquisition of the 3D Optical Profile (UNST15-DE-3156). Dr. María J. G. Guimarey acknowledges a postdoctoral fellowship from the Xunta de Galicia (Spain).
