11

12 ABSTRACT

13 The ability of compounds of natural origin (black, white, red, and green tea extracts, phytic acid) 14 to inhibit TMAO-demethylase enzyme was assayed. Black tea and phytic acid exerted the highest 15 inhibiting activities, similar to the already known inhibitor sodium citrate. Hake minces 16 incorporating these three compounds were prepared and stored frozen (150 days, -12 °C). 17 TMAO-demethylase enzyme was partially inhibited (lower enzyme activity, reduction of 18 formaldehyde accumulation). The study of physicochemical properties of the minces (salt-19 soluble proteins, water holding capacity, structural water associated with myofibrils) pointed to 20 evident protein aggregation and loss of functionality when phytic acid was added, whereas black 21 tea and sodium citrate did not have a negative effect. Consequently, the salt-ground mince with 22 phytic acid showed worse viscoelastic properties than the others. In conclusion, black tea 23 polyphenols and sodium citrate can be used as additives to inhibit TMAO-demethylase enzyme 24 during frozen storage of fish minces.

25 Keywords

26 Protein aggregation; formaldehyde; tea extract; gelation; fish muscle

28 1. INTRODUCTION

29 Freezing is extensively used to preserve fish from microbial and enzymatic spoilage during long 30 periods. However, it is well known that fish muscle spoils during frozen storage because of 31 muscle hardening derived from protein aggregation and, depending on the fish species, because 32 of the development of rancid flavors derived from lipid oxidation (Gómez-Estaca, Giménez, 33 Gómez-Guillén, & Montero, 2010; Tejada, Huidobro, & Mohamed, 2003). The main cause of 34 muscle freeze-induced protein aggregation is the progressive dehydration of proteins as ice 35 crystals form and grow, along with the consequent increase in the salt concentration in the liquid 36 phase (Bigelow & Lee, 2007; Cheung, Liceaga, & Li-Chan, 2009), both resulting in the formation 37 of intermolecular cross-links (Bigelow & Lee, 2007). Other factors influencing the loss of muscle 38 protein quality during frozen storage are the accumulation of dimethylamine and formaldehyde 39 derived from the demethylation of trimethylamine oxide (TMAO) catalyzed by the 40 trimethylamine oxide demethylase enzyme, as well as the accumulation of lipid oxidation 41 products (aldehydes), depending on the fish species. The accumulation of formaldehyde is 42 especially important in gadoids, whereas that of lipid oxidation products is of importance in fatty 43 fish (Leelapongwattana, Benjakul, Visessanguan, & Howell, 2005; Saeed & Howell, 2002; Sikorski 44 & Kostuch, 1982; Sotelo, Gallardo, Piñeiro, & Pérez-Martin, 1995).

45 The quality of frozen fish depends on intrinsic factors such as species and season, as well as on 46 technological factors such as handling practices prior to freezing, freezing rate, storage 47 temperature, etc. (Careche, Herrero, Rodríguez-Casado, Del Mazo, & Carmona, 1999). Apart 48 from this, in order to improve quality and shelf life of frozen fish, novel treatments have also 49 been applied. Some of these strategies are based on the addition of antioxidants that retard 50 lipid oxidation; cryoprotective agents such as sorbitol, sucrose, or protein hydrolysates that 51 prevent ice crystal growth and protein dehydration; polyphosphates that improve water-binding 52 capacity and protein solubility; sodium alginate that chelates calcium ions responsible for cross-

53 linking; or soy protein isolate that reduces free water available for ice crystallization (Badii & 54 Howell, 2002; Bigelow & Lee, 2007; Cheung, et al., 2009). Another alternative to improve frozen 55 fish quality could be the inhibition of TMAO demethylase enzyme, resulting in the reduction or 56 inhibition of formaldehyde accumulation, consequently retarding protein aggregation and loss 57 of functionality (Leelapongwattana, Benjakul, Visessanguan, & Howell, 2008, 2010). In this 58 regard, several compounds have been assayed in order to inhibit the activity of TMAO 59 demethylase, such as sodium citrate, pyrophosphate, H_2O_2 , or hydrocolloids such as sodium 60 alginate, xanthan gum, or carrageenan (Da Ponte, Roozen, & Pilnik, 1986; Leelapongwattana, et 61 al., 2008, 2010; Parkin & Hultin, 1982). The mechanism of action of many of these additives 62 seems to be related to the chelating effect on ferrous ion, which is located in the active site of 63 the enzyme and is also required for TMAOase activity (Leelapongwattana, et al., 2008). Despite 64 this, the body of literature in this regard is quite scarce, and research on new compounds, 65 especially those of natural origin, could be of great interest. Polyphenols are known to be good 66 metal chelators (Bravo, 1998), so we hypothesize that they could be potential candidates to 67 inhibit TMAO demethylase enzyme, improving fish quality and gelation ability during frozen 68 storage. Tea (Camellia sinensis), a common beverage consumed worldwide, is well known for 69 inducing health benefits because it contains phenolic compounds and derivatives with biological 70 properties against a number of chronic diseases (Sanlier, Gokcen, & Altuğ, 2018). Catechins 71 predominate in the phenolic composition of unfermented tea (green tea) or slightly fermented 72 tea (white tea), while theaflavins and thearubigins (oxidized phenolic species) accumulate during 73 fermentation, reaching a maximum in fully fermented black tea (Wang & Ho, 2009). Besides 74 their radical scavenging capacity, green tea catechins and black tea theaflavins are also 75 recognized for possessing well-established iron-chelating properties (Hatcher, Singh, Torti, & 76 Torti, 2009). Similarly, phytic acid (inositol hexaphosphate), which is ubiquitous in eukaryotic 77 cells, could also be a possible natural candidate to inhibit TMAO demethylase enzyme, owing to 78 its strong iron affinity (Nielsen, Tetens, & Meyer, 2013). To the best of our knowledge, the

inhibiting activity of polyphenols and phytic acid on TMAO demethylase enzyme has not yet
been reported. Therefore the objective of the present work was to study the TMAO demethylase
inhibiting activity of several chelating agents, with special emphasis on those of natural origin
(tea polyphenolic extracts and phytic acid), and their impact on hake mince protein functional
aptitude, including gelation ability, during frozen storage.

84 2. MATERIALS AND METHODS

85 2.1. Materials and reagents

Four hakes (*Merluccius merluccius*), each weighing 3–4 kg, were acquired at a local market in
Madrid 36 h after fishing and immediately transported to ICTAN. TMAO was from Sigma-Aldrich
(Madrid, Spain). Phytic acid and sodium citrate were from Sigma-Aldrich (Madrid, Spain). White,
green, red, and black teas were acquired in a local market.

90 **2.2.** Preparation and partial purification of TMAOase

91 The partially purified enzyme extract was prepared following the method described by Benjakul, 92 Visessanguan, and Tanaka (2004). For this purpose, finely chopped viscera or minced muscle of 93 hake (Merluccius merluccius) were extracted with 3 volumes of chilled 20 mM Tris-acetate buffer 94 (pH 7), containing 0.1 M NaCl and 0.1% Triton X-100, in an Omnimixer-Homogenizer (model 95 17106, OMNI International, Waterbury, USA). The homogenates were centrifuged at 38,500×g 96 at 4 °C for 30 min (Sorvall Combiplus, Dupont, Wilmington, DE, USA), and the supernatants were 97 partially purified by acidification. For this purpose, they were mixed at a 1:1 ratio (v:v) with 0.1 98 M Na-acetate buffer, pH 4.5, centrifuged at 38,500×g at 4 °C for 30 min, and the supernatants 99 were neutralized to pH 7 with NaOH. The neutralized supernatants were centrifuged again 100 (38,500×g, 4 °C, 30 min) to remove undissolved debris. The supernatants obtained were used as 101 crude enzyme extract (partially purified TMAOase) for: (i) enzyme inhibiting experiments, (ii)

addition to the minces (extracts obtained from viscera), and (iii) determination of residual
 TMAOase activity in the minces during frozen storage (extracts obtained from minced muscle).

104 **2.3. Determination of TMAO demethylase activity**

105 The method described by Benjakul, et al. (2004) was used, with slight modifications. To 2.5 mL 106 of assay buffer (24 mM Tris-acetate, 24 mM TMAO, 2.4 mM ascorbate, 0.24 mM FeCl₂, and 0.12 107 M NaCl, pH 7), 0.5 mL of properly diluted partially purified enzyme extract was added. The 108 reaction was performed at 25 °C for 20 min, after which 1 mL of 10% trichloroacetic acid was 109 added to terminate the reaction. The pH of the enzyme reaction was checked (6.8 \pm 0.15) and 110 no significant differences ($p \le 0.05$) were observed among samples. The reaction mixture was 111 centrifuged at 8,000×g for 30 min and the supernatant was subjected to formaldehyde 112 determination. One unit of TMAOase was defined as the activity that released 1 µmol of 113 formaldehyde per minute.

114 **2.4.** Extraction and determination of formaldehyde

Formaldehyde was extracted by steam distillation in the presence of phosphoric acid as described by Rehbein (1987). Formaldehyde determination was performed by means of the Hantzsch reaction as described by Nash (1953).

118 **2.5.** *In vitro* enzyme inhibiting assay

The TMAO-demethylase inhibiting activity of sodium citrate, phytic acid, and various types of tea extracts (white, green, red, and black) was evaluated. Sodium citrate and phytic acid were dissolved in distilled water (5 g/100 mL) by magnetic stirring for 1 h at room temperature. Tea extracts (5 g/100 mL) were prepared by infusion at 90 °C for 15 min in a thermostatic bath and filtration through Whatman No. 1 filter paper. For enzyme inhibiting assays, to 2.5 mL of assay buffer (24 mM Tris-acetate, 24 mM TMAO, 2.4 mM ascorbate, 0.24 mM FeCl₂, and 0.12 M NaCl,

125 pH 7), 0.5 mL of properly diluted partially purified enzyme extract from viscera and 0.12 mL of 126 various dilutions of enzyme inhibiting solutions or extracts were added. The reaction was 127 performed at 25 °C for 20 min, after which 1 mL of 10% trichloroacetic acid was added to 128 terminate the reaction. The reaction mixture was centrifuged at $8,000 \times g$ for 30 min and the 129 supernatant was subjected to formaldehyde determination. As positive control, a sample was 130 prepared following the same procedure but with the addition of 0.12 mL of distilled water 131 instead of enzyme inhibiting solution. Results have been expressed as IC₅₀, which is the 132 concentration of inhibiting agent needed to reduce the initial enzyme activity by 50%. In the 133 case of the tea extracts, IC50 is calculated based on the amount of leaves (w/v) used to prepare 134 the extracts.

135 **2.6. Mince preparation**

136 Hakes were headed, gutted, skinned, filleted, and washed with cold tap water. Chopped muscle 137 was ground with 1.5% NaCl and divided into 1250 g aliquots, which were mixed with partially 138 purified enzyme extract from viscera (1160 units/Kg mince) in a Stephan blender at 2 °C for 1 139 min, in order to magnify the subsequent TMAO activity. Afterwards, the various enzyme 140 inhibitors, cooled to 3 °C, were added to achieve a final concentration of 3.7 g/Kg mince and 141 mixed for 2 min. According to the results of the in vitro inhibiting assay, four different batches 142 were produced: (i) control without enzyme inhibitor (C), (ii) with phytic acid (PA), (iii) with 143 sodium citrate (SC), and (iv) with black tea extract (BT). All batches were vacuum-packed in 250 144 g aliquots in flexible bags (type BB4L, Cryovac, Barcelona, Spain), placed in stainless steel trays, 145 and frozen in a horizontal plate freezer (Sabroe, Aarhus, Denmark) at -40 °C for 2 h. All batches 146 were subsequently stored at -12 °C in order to simulate temperature abuse conditions and allow 147 magnification of the changes in formaldehyde accumulation (Sotelo, Aubourg, Perezmartin, & 148 Gallardo, 1994).

149 2.7. Color determination

For mince color determination, the minces were allowed to thaw and then placed in a glass sample container, and the color coordinates L* [black (0) to white (100)], a* [green (–) to red (+)], and b* [blue (–) to yellow (+)] were obtained with a Konica Minolta CM-3500d spectrophotometer (Konica Minolta Sensing, Inc., Osaka, Japan). Simple transformations were used to convert a* and b* coordinates to C* and h° chromatic parameters. Total color differences (ΔE) from control mince and whiteness index (WI) were calculated as shown below in Eqs. 2 and 3, respectively:

159 where L^* , a^* , and b^* are the values of these parameters for each sample, and L^*_c , a^*_c , and b^*_c are 160 those of the control sample.

161 **2.8.** Protein solubility and water holding capacity

162 Protein solubility was determined as previously described by Gómez-Estaca, et al. (2010) and

163 expressed as g soluble protein/100 g protein present in the muscle. Water holding capacity was

164 determined as described by Gómez-Guillén, Montero, Hurtado, and Borderías (2000) and results

165 expressed as g water retained/100 g water present in the muscle.

166 2.9. Protein aggregate size measurement and ζ-potential

167 An amount of 1 g of muscle was homogenized with cold 0.8 M NaCl for 1 min in an Omnimixer-

168 Homogenizer (model 17106, OMNI International, Waterbury, USA) immersed in an ice/water

169 bath. The homogenates were centrifuged (6,000×g, 2 °C, 15 min) in a Sorvall Evolution RC

170 Centrifuge (Thermo Fisher Scientific Inc., Landsmeer, The Netherlands) and the supernatants

171 were used for analyses. Particle size and ζ -potential of the soluble protein fraction were

172 determined using a Zetasizer Nano ZS (Malvern Instruments Ltd., Worcestershire, UK) at ≤5 °C.

Z-average was measured by dynamic light scattering (DLS), and ζ-potential by laser Doppler
velocimetry through the electrophoretic mobility, provided by the Hückel approximation. All
samples were diluted with 0.2 M phosphate buffer (pH 7.0) to a final concentration of 0.01
mg/mL, and the results were the means of at least 10 replicates.

177 2.10. Low-Field Proton Nuclear Magnetic Resonance (LF-NMR H¹)

178 Relaxometry analysis was carried out according to Sánchez-Alonso, Moreno, and Careche (2014). 179 Portions of mince measuring $1 \times 1 \times 2$ cm and weighing 2 g were placed in NMR tubes (1.8 cm 180 diameter and 18 cm height) and sample temperature was kept at 4 °C using a Thermo Haake 181 C/DC class DC10-K10 refrigerated circulator (Fisher Scientific S.L., Madrid, Spain). Transverse 182 relaxation data (T2) were determined in a Low-Field Nuclear Magnetic Resonance Minispec 183 mq20 analyzer (Bruker Optik GmbH, Germany) with a magnetic field strength of 0.47 T (proton 184 resonance frequency of 20 MHz). Relaxation time distribution was analyzed using the CONTIN 185 regularization algorithm employing the Carr–Purcell–Meiboom–Gill pulse sequence with a τ -186 value of 150 μ s, and 16 scans at 2 s intervals with a total of 3,000 echoes were obtained per 187 sample. At least three replicates were measured per sample.

188 **2.11.** Viscoelastic properties and gelling capacity

The salt-ground muscles were obtained by homogenizing the minces with NaCl for 2 min to a final concentration of 1.5 g/100 g mince, using a domestic homogenizer (Braun, Germany) immersed in an ice/water bath. Batter moisture was adjusted to 80% with the required amount of ice. Viscoelastic properties of the batters (elastic modulus G' and viscous modulus G'') were determined using a Bohlin rheometer (Bohlin Instruments Ltd., model CVO, Worcestershire, UK) with a cone-plate geometry (cone angle 4°, gap=0.15 mm). A dynamic frequency sweep was carried out at 10 °C over the frequency range 0.1–10 Hz (γ =0.005). A dynamic temperature

- 196 sweep was done at 1 Hz by heating from 10 °C to 85 °C at a scan rate of 1 °C/min (γ=0.005). At
- 197 least two replicates per sample were measured.

198 3. RESULTS AND DISCUSSION

3.1. *In vitro* TMAO demethylase inhibiting assay

200 The compound showing the highest enzyme inhibiting activity was phytic acid (95.2 \pm 4.8) 201 ($p \le 0.05$), followed by black tea extract (116.9 ± 5.8) and sodium citrate (114.7 ± 5.7), which 202 showed similar values (p>0.05). The red, white, and green tea extracts were significantly less 203 active than the other compounds studied ($p \le 0.05$), showing IC₅₀ values of 234.1 ± 11.7, 268.1 ± 204 13.4, and 268.9 ± 13.3, respectively. The inhibition exerted by sodium citrate in the present work 205 agrees with previous results obtained by Leelapongwattana, et al. (2008). The authors cited 206 studied the TMAO demethylase inhibiting activity of a number of potentially inhibiting 207 compounds, finding that sodium pyrophosphate, sodium citrate, and sodium alginate showed 208 the highest activities, in decreasing order. The proposed mechanism of action of the three 209 compounds was a chelating or complexing effect on ferrous or ferric ions. To the best of our 210 knowledge, there are no previous reports on the inhibiting activity of phytic acid or polyphenolic 211 extracts on TMAO demethylase enzyme. The mechanism of action of the natural inhibitors used 212 in the present work (tea polyphenols and phytic acid) would most probably also be iron ion 213 chelation (Hatcher et al., 2009; Gupta et al., 2013). Interestingly, among the various tea types 214 tested, there seems to be a positive relationship between the presumably higher oxidation level 215 of polyphenols in black tea and its higher TMAOase inhibiting activity, probably favored by a 216 higher Fe chelating activity (Wang & Ho, 2009).

217 **3.2.** Physicochemical changes of hake minces with enzyme inhibitors during frozen storage

Among the various inhibitors studied, black tea, phytic acid, and sodium citrate were selectedto be included in the hake minces. The optical properties of the minces are shown in Table 1.

Sodium citrate did not produce any change in optical properties (p>0.05) as compared to the control batch. In contrast, significant changes (p≤0.05) were observed with the other enzyme inhibitors, which were especially evident in the batch with black tea, resulting in decreased lightness, higher chromaticity, and a change in hue angle toward the blue region. These variations are clearly reflected in the total color difference and also resulted in a decrease in the whiteness index (Table 1).

226 The results of TMAO demethylase activity of hake minces with enzyme inhibitors during frozen 227 storage are shown in Figure 1A. All samples showed a similar trend during storage, i.e., an 228 increase in activity during the first month followed by a decrease as storage continued. 229 Leelapongwattana, et al. (2008) also reported this trend when studying the TMAO demethylase 230 activity of minced lizardfish muscle with the addition of enzyme inhibitors during frozen storage. 231 According to those authors, this effect may be the result of the disruption of cell membranes at 232 the beginning of frozen storage induced by ice crystals, followed by a decrease in activities, 233 possibly because of denaturation of TMAO demethylase and lower extraction efficacy resulting 234 from cold-induced protein aggregation during frozen storage. The batches with phytic acid and 235 black tea generally showed lower values than the control batch during storage ($p \le 0.05$), pointing 236 to a small degree of enzyme inhibition. In contrast, the batch with sodium citrate showed higher 237 enzyme activity than the control ($p \le 0.05$). This result was unexpected, as it does not agree with 238 the in vitro inhibiting results. A possible explanation may be an improvement in enzyme 239 extraction due to cell disruption and muscle protein denaturation in the presence of this salt.

The accumulation of formaldehyde, which could be an indirect measure of the TMAO demethylase activity, is shown in Figure 1B. From the first month of storage onwards, the formaldehyde content in the samples with enzyme inhibitors showed a tendency towards lower values than in the control batch, although differences were not always significant ($p \le 0.05$), suggesting a reduction in enzyme activity. The batch in which the lowest formaldehyde

245 accumulation was observed was the one with phytic acid (PA), followed by black tea (BT) and 246 sodium citrate (SC). These results seem to confirm that the apparent increase in enzyme activity 247 observed in the SC batch (Figure 2) might be due to an improvement in enzyme extraction, as 248 discussed, rather than a real increase in enzymatic activity in the mince. Leelapongwattana, et 249 al. (2008) studied the TMAO demethylase inhibitory effect of sodium alginate, pyrophosphate, 250 and mixtures of them added to minced lizardfish, finding a reduction both in enzyme activity 251 and in formaldehyde accumulation. However, the inhibitory effect observed by those authors 252 was higher than that found in the present work. The differences must be attributed to the 253 different fish species, freshness, enzyme inhibitors assayed, storage temperature, sample 254 preparation, etc.

255 The results of salt-soluble protein and water holding capacity (WHC) of hake minces containing 256 the various TMAOase inhibitors during frozen storage are depicted in Figures 1C and 1D, 257 respectively. Initially, muscle protein solubility was around 74% in the control batch. It 258 decreased sharply to 43% during the first 15 days of storage, and then decreased further to 33% 259 by the end of the storage period. A similar biphasic pattern of fish myofibrillar protein 260 denaturation during frozen storage has been reported previously (Jiang & Wu, 2018). The early 261 sharp decrease was attributed to a pronounced change in muscle protein conformation and 262 aggregation due to strong water recrystallization at the relatively high storage temperature used 263 (-12°C). This temperature of abuse was selected in order to maximize the accumulation of 264 formaldehyde, as its formation is directly related to frozen storage temperature (Sotelo, et al., 265 1994). Sodium citrate and, more intensely, phytic acid reduced protein solubility significantly 266 $(p \le 0.05)$ at day 15 as compared to the control batch and the batch with black tea extract. No 267 significant differences were observed during the subsequent storage period, in which all batches 268 exhibited rather low salt-soluble protein. The water holding capacity decreased with storage 269 time in all batches ($p \le 0.05$). Unlike the protein solubility, a pronounced drop in WHC during the 270 first 15 days was not observed, probably because the initial protein quality was not ideal, and the muscle might have exuded weakly bonded water before and during the mince preparation.
Phytic acid reduced WHC greatly from day 15 onwards, in contrast to sodium citrate and black
tea extract, which showed values close to the control batch.

274 In order to obtain deeper knowledge about the quality of the myofibrillar proteins during frozen 275 storage, the evolution of the size and net charge of soluble aggregates was monitored (Bao, 276 Boeren, & Ertbjerg, 2018; Chihi, Mession, Sok, & Saurel, 2016) and shown in Figure 2. Figure 2A 277 shows the changes that occurred in the C batch during frozen storage, whereas Figures 2B, 2C, 278 2D, and 2E show the changes at days 15, 30, 90, and 150, respectively, depending on the enzyme 279 inhibitor added. At day 0 of storage, the soluble fraction of the C batch consisted mainly of 280 protein aggregates peaking around 700 nm, although fractions of lower (\approx 130 nm) and higher 281 (\approx 5.5 µm) average size were also observed, the latter coinciding with the detection limit of the 282 equipment. After 15 days of storage, a noticeable decrease in intensity of the main population 283 (\approx 700 nm) was concomitant with an increase in 5.5 μ m particles, both events denoting protein 284 rearrangement into larger microaggregates that were still present in the soluble protein fraction. 285 As storage continued, the mean particle size of the main soluble aggregates showed a 286 progressive downward tendency, reaching a value near 250 nm at day 150 of storage; at the 287 same time, the intensity of the largest aggregates also tended to decrease with time (Figure 2A). 288 Although there is no specific literature on the effect of frozen storage of fish on the size of 289 soluble aggregates, the results obtained here are consistent with progressive protein 290 aggregation, with disruption of the original protein aggregates and formation of larger particles 291 that tended to leave the soluble fraction as frozen storage continued. Vate and Benjakul (2016) 292 reported an average particle size of 513 nm in heated natural actomyosin solution from sardine, 293 which upon addition of protein cross-linkers increased to 645 nm as a result of protein 294 aggregation. However, comparisons with the present work are difficult because the above-295 mentioned natural actomyosin was previously heated and changes in particle size distribution 296 were not shown.

297 With regard to the effect of the various enzyme inhibitors, phytic acid was the one that induced 298 the greatest changes, at day 15 causing a marked reduction in the average size of soluble 299 aggregates as compared to the other samples. This was due not only to a shift of the most 300 abundant protein aggregates to a smaller size, but also to a reduction in the amount of larger 301 soluble microaggregates, which presumably went into the insoluble protein fraction (Figure 2B). 302 At the same day of storage, the most abundant protein fraction in SC also shifted toward a lower 303 particle size and the abundance of the 5.5 μ m population decreased, as compared to the control 304 and BT batches (Figure 2B). All these events suggested considerable protein insolubilization at 305 the early stage of storage in both PA and SC batches, in agreement with the protein solubility 306 results (Figure 1C). During storage, the average size of the aggregates in the three batches 307 treated with enzyme inhibitors showed a downward tendency, as described for the control, and 308 at day 150 of storage only minor differences were observed between them and the control batch, 309 as observed before for protein solubility (Figure 1C).

310 The effect of frozen storage on the net charge of the soluble protein aggregates from the various 311 minces is shown in Figure 2F. All samples presented an electronegative ζ -potential, attributed 312 to the abundance of acidic amino acids in the fish muscle, which are largely deprotonated at 313 neutral pH. The ζ-potential of the control batch at day 0 was slightly lower than that reported 314 previously in salt-ground hake muscle (-20.8 mV) (Marín-Peñalver, Alemán, Montero, & Gómez-315 Guillén, 2018), but slightly higher than in heated natural actomyosin from sardine (-13.0 mV) 316 (Vate & Benjakul, 2016). These differences could be related to different protein aggregation 317 status. Furthermore, coinciding with increasing protein aggregation, the protein net charge 318 tended to decrease ($p \le 0.05$) in all batches during storage, and PA was the batch that exhibited 319 the lowest ζ-potential. According to Vate and Benjakul (2016), aggregation of protein molecules 320 had an impact on the surface charge of the aggregates by masking the charged amino acids, 321 which remain inside the protein complexes.

322 LF-NMR H¹ has been used as a tool to evaluate deeper changes in structural water associated 323 with morphological changes in protein (Sánchez-Alonso, et al., 2014). Figure 3 shows the 324 transversal proton relaxation time curves in the 10–1000 ms range of the various hake minces 325 during frozen storage. At day 0 of storage, the control sample showed a main T₂₁ relaxation band, 326 indicative of water located predominantly in the intra-myofibrillar space (Figure 3A). This finding 327 would be compatible with muscle that has been frozen in adequate conditions (fast freezing) 328 and stored during a short period of time (Sánchez-Alonso, Martinez, Sánchez-Valencia, & 329 Careche, 2012; Sánchez-Alonso, et al., 2014). During storage, the T_{21} band gradually lost 330 amplitude and shifted toward lower relaxation times, which indicates a decrease in the spacing 331 between the myofibrils; at the same time, a slower relaxation component (T_{22}) appeared, 332 corresponding to extra-myofibrillar water, resulting from freeze-induced morphological changes 333 in protein (Sánchez-Alonso, et al., 2012). These changes were indicative of protein denaturation 334 and were consistent with the loss of protein solubility and water holding capacity during frozen 335 storage. In the samples with enzyme inhibitors (Figure 3 B–E), again, from day 15 onward, phytic 336 acid induced the greatest changes in structural water, showing an intense migration of water 337 protons the intra- to extra-myofibrillar space, in agreement with the strong protein aggregation. 338 As with the control batch, the T₂₂ component showed a noticeable tendency to increase in all 339 batches during the storage period. After 90 days, the BT batch was apparently the least affected, 340 but at the end of storage no great differences were found among the various batches.

341 3.3. Gel forming capacity of hake minces with added enzyme inhibitors during frozen storage

In order to determine the effect of the various additives on the viscoelastic properties of the salt-ground muscle, as a previous and necessary step for protein gelation a frequency sweep test was carried out initially (in the control mince without additives at day 0) and at days 15 and 150 of frozen storage (Figure 4). The elastic modulus G' was greater than the viscous modulus G" throughout the whole frequency range in all the samples tested, denoting a typically

347 predominant solid-like behavior, regardless of the additive or the storage period. All mechanical 348 spectra in terms of G' fitted the power law model very well ($R^2 \ge 0.99$). The n' exponent values of 349 the corresponding equations are also shown in Fig. 4. According to Campo and Tovar (2008), the 350 smaller the value of n', the greater the matrix stability. Within the first 15 days of storage, the n' 351 value in the control batch (without inhibitors) increased from 0.134 to 0.149, but it registered 352 the lowest value as compared to the minces with added inhibitors, indicating that at the early 353 stage of storage this was the most stable batter. In contrast, the PA batch presented the highest 354 degree of matrix instability (n' = 0.233), which coincided with the considerable early protein 355 aggregation described in section 3.2. At the end of storage, G' and G" values increased 356 considerably in all batches, but much more intensely in PA, in agreement with its more intense 357 protein aggregation and lower matrix stability. No great differences in the viscoelastic behavior 358 of the respective salt-ground batters were observed in SC and BT batches at the end of the 359 storage period, and it was very similar to that of the control batch (without additives).

360 The thermal gelation profile of the salt-ground muscle without and with inhibitors during frozen 361 storage is shown in Figure 5. Figure 5A shows the changes in G' as a function of the heating 362 temperature of the control batch (without inhibitors) during the whole storage period. During 363 the first 15 days of storage the control batch presented a sharp increase in G' between 30 and 364 39 °C, indicating a strong setting phenomenon (Figure 5A). This peak is largely attributed to the 365 result of endogenous muscle transglutaminase activity that leads to the formation of ε -(γ -366 glutamyl)-lysine covalent bonds (Lanier, Yongsawatdigul, & Carvajal-Rondanelli, 2013). After 367 that, the pronounced drop in G' to \approx 47 °C could be ascribed to the activity of indigenous 368 proteolytic enzymes causing a breakdown in the preformed protein network, constituting the 369 so-called modori phenomenon (Ueki, Wan, & Watabe, 2016). This phenomenon has been also 370 attributed to the destruction of alpha-helix and unwinding of coiled-coil structure of myosin rod 371 (Fukushima, Satoh, Nakaya, Ishizaki, & Watabe, 2003). From 47 °C upwards the progressive rise 372 in G' indicated continuous thermal aggregation of muscle proteins. Similar viscoelastic behavior 373 of salt-ground hake mince upon heating from 5 to 80 °C has been reported previously (Marín-374 Peñalver, et al., 2018). Interestingly, at days 0 and 15 the maximum values of G' registered at 375 the end of the heating ramp did not exceed those of the setting peak, probably because of strong 376 residual proteolytic activity. In contrast, after the first month of storage both setting and modori 377 phenomena clearly tended to be less pronounced or even disappeared at the end of 150 days. 378 This effect could be related to the loss of enzyme activities during frozen storage. Furthermore, 379 values of G' in the thermal profiles tended to be higher with storage time, and the onset of 380 thermal aggregation also showed a slight down-shift, both effects being compatible with 381 progressive freeze-induced muscle protein aggregation and protease inactivation. After 150 382 days of storage, the pronounced increase in the G' values from the onset of the heating ramp 383 indicated that the protein was highly aggregated, but it did not lose its thermal aggregation 384 ability.

385 This pronounced effect of initial protein aggregation on rheological behavior during heating was 386 also observed in the PA batch in the early stage of frozen storage (Figure 5B), where setting and 387 modori were not clearly evidenced. In contrast to the SC and BT batches, the initially high degree 388 of protein aggregation induced by phytic acid at day 15 also resulted in a greater increase in G' 389 as a result of thermal aggregation. However, this effect was considerably reduced after 30 days 390 (Figure 5C), so by the end of the storage period this batch had almost completely lost its thermal 391 gelation ability. The early reduction in protein solubility and WHC induced by the interaction of 392 phytic acid with the muscle proteins and the noticeable decrease in water binding properties of 393 this batch during the entire storage period led to a final collapse of the protein network upon 394 heating. In contrast, the evolution of the gelation profile in the presence of sodium citrate or 395 black tea was quite similar to that of the control batch during 150 days of storage.

396 **4. CONCLUSION**

397

398 The ability of sodium citrate, tea polyphenolic extracts, and phytic acid to inhibit the activity of 399 TMAO-demethylase enzyme was evidenced in vitro and subsequent evaluated in vivo during 400 frozen storage of hake mince (-12 °C/150 days). Results from enzyme activity and formaldehyde 401 accumulation during frozen storage evidenced a discrete inhibition, which was more intense for 402 phytic acid and black tea polyphenolic extract. The study of the salt-soluble proteins (total 403 amount, net charge, and size of aggregates), water holding capacity, and structural water 404 associated with myofibrils pointed to evident protein aggregation and loss of functionality when 405 phytic acid was added to the hake minces, whereas black tea polyphenols and sodium citrate 406 did not have a negative effect. This resulted in a worsening of the viscoelastic properties of the 407 salt-ground muscle for the mince with added phytic acid, whereas the other additives had a 408 negligible effect. All the salt-ground minces were able to form thermally induced gels, but by the 409 end of the storage period the mince with added phytic acid had almost lost this property, owing 410 to extensive protein aggregation. Sodium citrate and black tea polyphenols can be used to inhibit 411 TMAO-demethylase enzyme during frozen storage of fish minces, but they showed a limited 412 capacity to protect the functional aptitude of the hake mince protein. However, as black tea 413 polyphenols could provide fish restructured products with interesting health properties, the use 414 of black tea as a potential bioactive agent should not be disregarded. Under the experimental 415 conditions used, a clear relationship between formaldehyde-mediated protein aggregation 416 inhibition during frozen storage and protein thermal aggregation ability could not be stablished. 417 This could be due to a combined effect of (i) the boosting of protein aggregation at the storage 418 temperature selected (-12 °C) and the muscle processing type (mincing), and (ii) the discrete 419 formaldehyde inhibition observed in vitro. Further studies at lower storage temperatures would 420 be necessary to fully understand the effect of TMAO-demethylase inhibitors on protein quality 421 of fish muscle.

Highlights

- 1. Tea extracts, phytic acid PA, sodium citrate SC inhibit TMAO-demethylase in vitro
- 2. Black tea extract BTE inhibits TMAO-d more intensely than red, white and green ones
- 3. BTE, PA and SC partially inhibit TMAO-d in hake mince during frozen storage
- 4. PA aggregates hake proteins and impairs protein functionality and gelation
- 5. BTE and SC do not affect hake protein functionality and gelation

Table 1. Optical properties of the various minces developed: Lightness (L*), hue angle (h°), chromaticity (C*), total color difference (ΔE), and whiteness index (WI). C: control without inhibitors; SC: with sodium citrate; PA: with phytic acid; BT: with black tea.
