Objectives: To prevent invasive fungal disease (IFD) in adult patients undergoing remission-induction chemotherapy for newly diagnosed acute lymphoblastic leukaemia (ALL).

Patients and methods: In a double-blind multicentre Phase 3 study, patients received prophylactic liposomal amphotericin B (L-AMB) at 5 mg/kg intravenously or placebo twice weekly in a 2:1 random allocation during remission-induction treatment. The primary endpoint was the development of proven or probable IFD. Secondary endpoints included those focused on the safety and tolerability of prophylactic L-AMB.

Results: Three hundred and fifty-five patients from 86 centres in Europe and South America received at least one dose of L-AMB ($n = 237$) or placebo ($n = 118$). Rates of proven and probable IFD assessed independently were 7.9% (18/228) in the L-AMB group and 11.7% (13/111) in the placebo group ($P = 0.24$). Rates of possible IFD were 4.8% (11/228) in the L-AMB and 5.4% (6/111) in the placebo group ($P = 0.82$). The remission-induction phase was a median of 22 days for both groups. Overall mortality was similar between the groups: 7.2% (17/237) for L-AMB and 6.8% (8/118) for placebo ($P = 1.00$). Hypokalaemia and creatinine increase were significantly more frequent with L-AMB.

Conclusions: The IFD rate among adult patients undergoing remission-induction chemotherapy for newly diagnosed ALL was 11.7% in the placebo group, and was not significantly different in patients receiving L-AMB, suggesting that the L-AMB regimen studied is not effective as prophylaxis against IFD. The IFD rate appears higher than previously reported, warranting further investigation. Tolerability of L-AMB was what might be expected. Further studies are needed to determine the optimal antifungal strategy during remission-induction chemotherapy of ALL.

Introduction

Adult patients with acute lymphoblastic leukaemia (ALL) are given intensive multidrug chemotherapy to induce remission based on paediatric protocols of 6–8 weeks duration.¹ During this period, patients are at risk of invasive fungal disease (IFD) due to neutropenia and exposure to high-dose glucocorticosteroids.^{1–3} IFD is challenging to diagnose, particularly in the early stages, when symptoms and signs are absent or non-specific.⁴ Moreover, IFD has considerable impact on morbidity and mortality, and may interrupt or delay chemotherapy, consequently reducing dose intensity and complete and molecular remission rates.^{1,2} Antifungal prophylaxis could potentially contribute to treatment efficacy.^{5,6}

An IFD rate of 6.5% has been reported in a retrospective analysis of adult ALL patients, with aspergillosis and candidiasis predominating.² An IFD rate of 8.8% has been reported in ALL patients with neutropenia,⁷ and a rate of 6.7% has been identified in patients receiving induction chemotherapy for the treatment of ALL.⁸ While prophylaxis with azole antifungals has been developed for other patient groups at similar risk, there is currently no approved standard of care for patients with ALL.^{9,10} The European Working Group for Adult ALL (EWALL) recommends that azole antifungals should be avoided because of drug–drug interactions with vinca alkaloids, a key component of ALL chemotherapy regimens.¹ Liposomal amphotericin B (L-AMB) offers an alternative as it is active against a broad variety of fungi, including *Aspergillus* species, *Candida* species and agents of mucormycosis.^{6,11–13} Support for L-AMB use in treatment comes from studies examining its pharmacokinetics in animal models, healthy volunteers and neutropenic patients at doses between 1 and 7.5 mg/kg/day and knowledge that it has a long terminal elimination half-life.^{14–16} L-AMB is not licensed for prophylaxis, but small prophylaxis studies in neutropenic patients that used different, mostly intermittent, dosing regimens have demonstrated a trend towards a reduced incidence of IFD.^{17–21} However, doses >5 mg/kg were associated with an increased incidence of infusion-related reactions.¹⁸

The medical need for antifungal prophylaxis was identified in close collaboration with EWALL. The AmBiGuard study was designed to determine the efficacy and safety of L-AMB given at 5 mg/kg twice weekly compared with placebo to prevent IFD in adults undergoing remission-induction chemotherapy for newly diagnosed ALL.

Patients and methods

The study was conducted at 86 centres in 13 countries in Europe and South America and registered on clinicaltrials.gov (NCT01259713) and EudraCT (2010-019562-91). The study was conducted in accordance with the Declaration of Helsinki. The protocol was approved by the institutional review board of each participating site. Written informed consent was obtained from each patient. An independent data safety monitoring board (DSMB) supervised the study and undertook a planned interim data review for futility when half the subjects had completed the study. An independent data review board (IDRB) performed a blinded review of data from all patients to assess the presence of IFD according to the revised consensus definitions.⁴

Eligibility criteria

Adults ≥ 18 years were eligible provided they were to receive remission-induction chemotherapy for newly diagnosed ALL that was likely to induce

≥ 10 days of neutropenia (absolute neutrophil counts $< 500/\mu\text{L}$), and were able to start the study drug within 5 days of the first dose of chemotherapy. Patients were excluded if there was clinical suspicion of IFD including unexplained fever, evidence of pulmonary infiltrates on imaging or if they had been given antifungal treatment in the previous 30 days. Patients were also excluded if their serum creatinine was > 2 times the upper limit of normal (ULN), liver function tests were $> 5 \times \text{ULN}$ ²² or if there was any severe comorbidity or any hypersensitivity to amphotericin B.

Study drug

The colour and overall appearance of L-AMB and placebo (riboflavin 5' phosphate formulated in soy phosphatidylcholine as liposomes) did not differ. The two drugs were prepared and given in the same manner. Study personnel were blinded to treatment allocation. A blinded member of the pharmacy staff prepared the solutions and provided blind-labelled infusion bags for administration. L-AMB was given at a dose of 5 mg/kg based on the patient's weight at screening and dose adjustment to weight changes was allowed. This dose was selected in order to minimize toxicity. Study drug was infused over 2 h twice weekly (3–4 day interval) during the entire remission-induction phase of chemotherapy. The dosing schedule was chosen on practical grounds.

IFD monitoring and diagnostic-driven antifungal treatment

Patients underwent prospective monitoring for the development of IFD according to defined study algorithms throughout the duration of the study and for the 30 days after stopping the study drug (Figures S1–S3, available as Supplementary data at JAC Online). Serum samples were drawn twice weekly and tested for galactomannan (GM) and 1,3- β -D-glucan (BDG) centrally in Belgium, Argentina or Brazil. The results were reported to the site within 48–72 h. A thoracic CT scan was recommended when the mycological criteria were met for a proven or probable IFD, and the study algorithm was followed according to the result (Figure S2).²³ When no mycological criteria were met,⁴ a work-up was undertaken when patients had unexplained fever (temperature $\geq 38^\circ\text{C}$ for ≥ 72 h) despite antibiotic treatment, relapsing fever, new pulmonary infiltrates on chest X-ray or other potential signs and symptoms of IFD (Figure S3).

Systemically active antifungal agents were not permitted except for patients who developed oropharyngeal candidiasis despite topical measures; they were allowed to receive concomitant oral fluconazole at 100–200 mg for 10 days.

Study treatment was replaced for up to 5 days with an antifungal other than amphotericin B when there were findings suggestive of IFD to allow further diagnostic tests to be done. Treatment was stopped and prophylaxis restarted when these tests proved negative. Protocol-specified criteria to stop prophylaxis and start broad-spectrum antifungals were defined.

Study procedures

All concomitant medications, including chemotherapy and other antimicrobials, were recorded from 30 days before recruitment and until study completion. All adverse events (AEs) were recorded up to 30 days from last dose, regardless of their potential relationship to the study drug. Laboratory assessments (haematology and chemistry) and complete or symptom-directed physical examinations, including vital signs and temperature, were done at scheduled times.

Study treatment ended for the patient when one of the following occurred: (i) diagnosis of a proven or probable IFD; (ii) remission-induction chemotherapy was completed, neutropenia resolved and the patient was well enough to be discharged from hospital; or (iii) consolidation or salvage chemotherapy was started.

Pharmacokinetic sampling

Amphotericin B serum trough concentrations were determined in a subset of patients.

Efficacy and safety endpoints

The primary efficacy endpoint was the development of proven or probable IFD during remission-induction chemotherapy, measured as the proportion of patients who met this endpoint as assessed by the IDRDB. Secondary endpoints included: the proportion in complete remission at last follow-up (e.g. 30 days after end of study treatment); the time to diagnosis of proven or probable IFD; the proportion that required antifungal treatment according to protocol guidance; the proportion of patients who developed pulmonary infiltrates; the proportion of patients with proven IFD and probable IFD;⁴ and the number of deaths due to IFD as assessed by the IDRDB. Additionally, the development of AEs and abnormal clinical laboratory results were examined.

Randomization, sample size and statistical methods

Patients who met the eligibility criteria were randomized, using an interactive voice or web response system, to receive either 5 mg/kg L-AMB or matched placebo twice weekly. Randomization was done centrally and stratified by geographical region: Europe versus South America using permuted blocks (Table S1).

The intended sample size ($n = 354$) was based on having 81% power to detect a 75% relative reduction in IFD in the L-AMB group, assuming a rate of IFD of 10% in the placebo group using a Cochran–Mantel–Haenszel (CMH) test with a 0.05 two-sided significance level and 2:1 allocation. The assumed IFD rate of 10% for the placebo group is in line with previously reported prophylaxis studies in other patient populations at high risk of IFD.^{10,24,25} A 0.05 two-sided test was chosen because the interim boundaries were based around a two-sided test. We selected 2:1 randomization of L-AMB to placebo rather than 1:1 randomization due to ethical considerations and its potential to provide more comprehensive safety data for the L-AMB group.

The primary efficacy analysis used the ITT population, i.e. all subjects who were randomly allocated to study treatment, who received at least one dose of study drug and met the major eligibility criteria (newly diagnosed with ALL and had not received systemically active antifungals within the previous 30 days). An ITT analysis excluding patients who were never neutropenic was done as was a *post hoc* per-protocol analysis set excluding patients receiving antifungals not permitted by the protocol. The safety analysis population included all patients who received at least one dose of the randomly allocated study drug.

All statistical tests were performed at the 0.05 level (unless otherwise stated) without consideration for multiplicity. The CMH test was used for the primary analysis after adjusting for region.

A planned interim analysis for futility was undertaken when 50% of patients had completed the study, so α for the primary analysis was adjusted by 0.0003.

Categorical secondary efficacy endpoints including the proportion of patients diagnosed with proven or probable IFD were analysed using a non-stratum-adjusted relative risk reduction. The time to diagnosis of proven or probable IFD and the duration of remission-induction chemotherapy were analysed using Kaplan–Meier estimates and the log rank test, after stratifying by region. A P value of <0.05 was considered statistically significant.

Results

From April 2011 to November 2013, 391 patients were screened and 360 were enrolled. Five patients were not treated and 16 failed

to meet the entry criteria, i.e. 15 received protocol-prohibited systemic antifungal treatment in the 30 days prior to first dose of study drug and 1 did not have ALL. Hence, 339 patients were included in the efficacy analysis. The safety analysis comprised 355 patients who received at least one dose of study drug (Figure 1), of whom 237 were randomly allocated to receive L-AMB and 118 to receive placebo.

Demographic and baseline characteristics were similar across the treatment groups (Table 1). The median age was 46 (IQR 30–58) years. Commonly used constituents of chemotherapy for remission induction included cytarabine, cyclophosphamide, vincristine and anthracyclines, particularly daunorubicin and idarubicin. Systemic glucocorticosteroids were part of the chemotherapy in the majority of patients [L-AMB 90.4% (206/228), placebo 91.0% (101/111)]. Over 90% of subjects received twice-weekly infusions of study drug as specified in the protocol.

Efficacy analyses

Rates of proven/probable IFD as assessed by the IDRDB (primary endpoint) were 7.9% (18/228) in the L-AMB and 11.7% (13/111) in the placebo group ($P = 0.24$), suggesting that L-AMB is not effective as prophylaxis against IFD in these patients. The remission-induction phase was a median of 22 days for both groups. Additionally, rates of possible IFD were 4.8% (11/228) in the L-AMB and 5.4% (6/111) in the placebo group ($P = 0.82$) (Table 2, Table S2).

The IFD incidence rates for patients who were neutropenic for ≥ 10 days ($n = 258$) were 6.9% in the L-AMB group versus 13.1% in the placebo group ($P = 0.10$) (Table 2; Table S3).

Subgroup analyses of the primary endpoint showed that the proportion of patients with proven or probable IFD was consistently lower in the L-AMB group than in the placebo group (Figure S4). Time to diagnosis of IFD was not significantly different between the two study groups ($P = 0.33$) (Figure 2).

Chest CT scans were done for 82 (36.0%) patients in the L-AMB group and 51 (45.9%) patients in the placebo group. Antifungal treatment was given during remission-induction chemotherapy to 16.2% (37/228) patients in the L-AMB group and 21.6% (24/111) in the placebo group ($P = 0.22$). These treatments were considered protocol violations in eight patients in each group.

Overall mortality was similar between the groups, being 7.2% (17/237) in the L-AMB group and 6.8% (8/118) in the placebo group ($P = 1.00$) (Figure S5). Two deaths in the L-AMB group were attributed to IFD by the IDRDB (probable invasive pulmonary aspergillosis and proven candidaemia), but none in the placebo group.

Most patients in each group were neutropenic ($<500/\mu\text{L}$) during remission-induction chemotherapy (L-AMB 90.8%; placebo 92.8%), and 76.3% and 75.7% were neutropenic for ≥ 10 days. Median duration of neutropenia $<500/\mu\text{L}$ was 18 days for both groups (IQR L-AMB 13.0–26.0, placebo 11.0–25.0 days). The absolute neutrophil count nadir was $<100/\mu\text{L}$ in 167 (73.2%) patients in the L-AMB group and 82 (73.9%) patients in the placebo group.

There was no significant difference in the median duration of neutropenia.

Complete remission rates were lower in the L-AMB group [72.8% (166/228)] than in the placebo group [79.3% (88/111)], although not significantly so ($P = 0.20$).

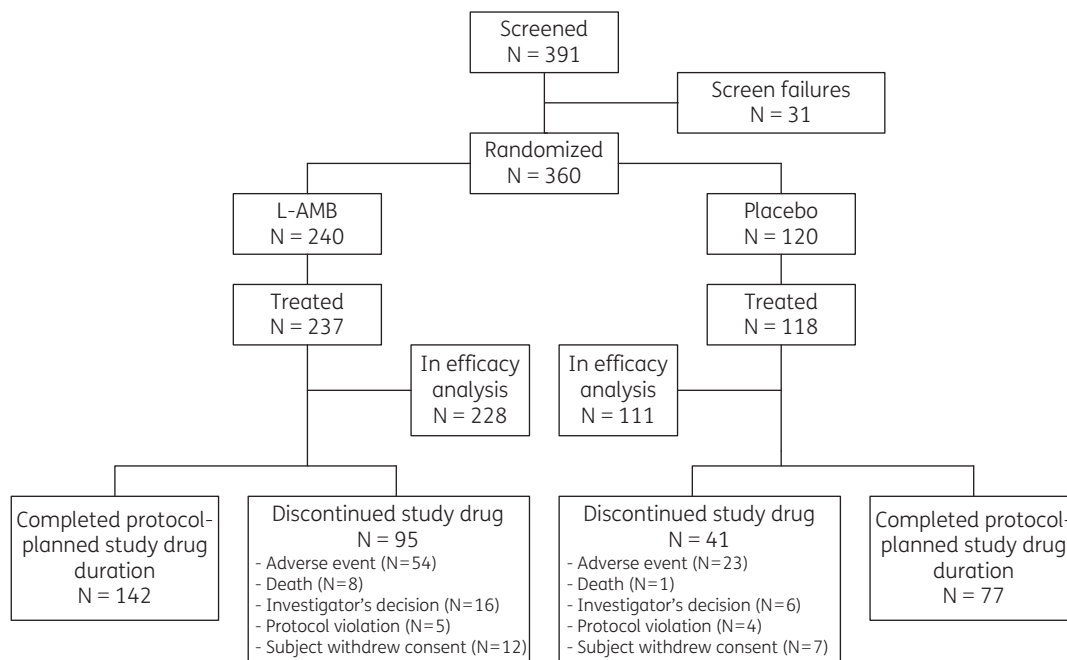

Figure 1. CONSORT flow diagram. Of 360 subjects randomized, 5 were never dosed, and 16 (9 L-AMB, 7 placebo) were excluded from the efficacy analysis, 1 due to misdiagnosis (AML) and 15 due to protocol-prohibited antifungal treatment either concomitant with or within the previous 30 days.

Table 1. Patient baseline characteristics

| Characteristic | L-AMB (N = 237) | Placebo (N = 118) | P value ^a |
|---|---------------------|---------------------|----------------------|
| Age (years), median (IQR) | 45 (32–57) | 47 (28–60) | 0.82 |
| Male, n (%) | 139 (59) | 60 (51) | 0.16 |
| White, n (%) | 211 (89) | 100 (85) | 0.25 |
| Weight (kg), median (IQR) | 74.0 (66.0–84.0) | 74.7 (62.3–87.9) | 0.92 |
| Height (cm), median (IQR) | 170.0 (164.0–178.0) | 170.0 (164.0–179.0) | 0.94 |
| BMI (kg/m ²), median (IQR) | 25.2 (22.7–28.7) | 25.0 (22.0–28.7) | 0.76 |
| Baseline ANC (cells/ μ L), median (IQR) | 820 (270–1880) | 560 (210–1610) | 0.27 |
| Patient ANC distribution, n (%) | | | |
| <200 cells/ μ L | 49 (21.2) | 26 (22.8) | |
| 200 to < 500 cells/ μ L | 34 (14.7) | 28 (24.6) | |
| 500 to < 1500 cells/ μ L | 79 (34.2) | 26 (22.8) | |
| \geq 1500 cells/ μ L | 69 (29.9) | 34 (29.8) | |
| Median days between start of remission induction and first dose of study drug (IQR) | 3 (2–4) | 3 (2–4) | 0.55 |

ANC, absolute neutrophil count.

^aCochran–Mantel–Haenszel test for categorical variables and Wilcoxon rank-sum test for continuous variables.

Post hoc efficacy analysis on patients without major protocol deviations

For this analysis, a total of 44 patients in the L-AMB group and 21 in the placebo group were excluded from the ITT analysis set because of at least one protocol deviation that could have influenced the primary endpoint. This included 41 patients who received systemic antifungals in violation of the protocol (24 L-AMB versus 17 placebo), 2 patients in the L-AMB group with baseline IFD and 28 patients who had not been given regimens expected to induce \geq 10 days of neutropenia (21 L-AMB versus 7 placebo). IFD rates in

the remaining 274 patients were 7.6% (14/184) in the L-AMB group and 14.4% (13/90) in the placebo group ($P = 0.07$).

Pharmacokinetic analyses

A total of 175 trough pharmacokinetic samples were collected from 27 patients given L-AMB between 1.4 and 6.4 days after the previous dose of study drug. Mean \pm SD trough serum concentration of free amphotericin B ranged from 0.89 ± 0.59 to 1.58 ± 1.55 μ g/mL.

Table 2. Invasive fungal disease rates

| Patient population | L-AMB | Placebo | P value ^a |

LLN, lower limit of normal; ULN, upper limit of normal.

^aFisher's exact test.

^bTreatment emergent is defined as started on or after first dose and up to 30 days after last dose of study drug.

discontinuation of study drug were similar in the two groups, most commonly because of an AE, the investigator's discretion or withdrawal of consent. Most patients had at least one AE and a similar proportion of patients in each group had AEs of grade 3 or higher.^{16,20} Most patients in each group had AEs considered by the investigator to be related to ALL or to chemotherapy. A similar proportion of patients in each group had AEs considered to be related to IFD or AEs that resulted in premature discontinuation of the study drug. More patients in the L-AMB group had an AE that resulted in interruption of treatment with the study drug (20.3% versus 7.6%; $P = 0.002$), and experienced serious AEs (Table S4) considered related to study drug by the investigator (8.4% versus 1.7%; $P = 0.02$). Statistically significantly more patients were affected by hypokalaemia and elevated creatinine in the L-AMB group (Table 3).

Discussion

This large, randomized, double-blind, placebo-controlled study, using a pre-specified diagnostic algorithm, showed that almost 1 in 11 patients receiving remission-induction chemotherapy for ALL developed a probable or proven IFD. This is almost twice the rate reported in a retrospective cohort study² and is of the same order of magnitude as reported for patients receiving remission-induction therapy for AML without mould-directed antifungal

prophylaxis.¹⁰ The observed incidence in this study is also towards the upper end of IFD rates reported in other retrospective case collections in patients with ALL of between 6.5% and 8.8%.^{2,7,8} It is therefore important to consider the potential factors behind this possibly high observed incidence, which resulted from a prospective trial with a well-designed diagnostic algorithm.

Neutropenia and prolonged treatment with glucocorticosteroids are considered host factors that may contribute to the high incidence of IFD observed.⁴ Another factor may be the inclusion of non-culture-based methods in our diagnostic strategy, which may have led to a higher number of cases of IFD being identified. In any event, the high incidence observed clearly warrants further investigation and consideration of appropriate preventative measures, including antifungal prophylaxis.

Our study failed to show that twice-weekly dosing of L-AMB 5 mg/kg significantly reduced the IFD rate, which is difficult to explain since L-AMB is effective in treating IFD.^{11–13} The dose used was chosen to minimize toxicity but may not have been high enough to be effective, representing a major limitation of the study. However, despite the low dose (half the standard treatment dose of 3 mg/kg/day), the number of withdrawals due to AEs and the number of serious AEs were both much higher with L-AMB than with placebo. The dosing interval was chosen on practical grounds and may have been too long, although pharmacokinetic analysis showed that L-AMB trough concentrations were

adequate.^{26,27} Better understanding of the pharmacokinetics of L-AMB is therefore necessary to identify the most appropriate dosage for prophylaxis.

Other factors to consider include the point that the 10% estimate of the IFD rate for the placebo group was exceeded, but expecting a 75% reduction in IFD incidence in the sample size calculation may have been too optimistic.^{10,24,25} Attrition of statistical power due to protocol deviations may provide a further explanation.

Some patients were included although they received regimens that did not induce severe neutropenia, and others received systemic antifungal agents in violation of the protocol despite detailed management algorithms for suspected IFD that may have impacted the assessment of the primary endpoint. This early antifungal treatment may have caused false negativity of the diagnostic-driven strategy applied. *Post hoc* analyses of the group of patients without substantial protocol deviations showed that the difference between treatment groups was more pronounced, though this did not reach statistical significance. The lack of neutropenia in subjects was not explained by the use of growth factors.

Complete remission rates were lower than expected, but this is likely to be due to evaluation of subjects before the end of induction/beginning of consolidation and to some subjects being lost to follow-up (Figure 1).

Mortality was very similar in both treatment groups (7.2% versus 6.8%), and deaths in the placebo group were not attributed to IFD by the investigators. The diagnostic-driven strategy may pick up IFD earlier at a more effectively treatable stage. Because the trial did not reveal a difference in overall mortality or in mortality attributable to IFD, a diagnostic-driven treatment approach may be a more suitable strategy in this specific patient population. While prophylaxis is beneficial for patients receiving remission-induction chemotherapy for AML,¹⁰ heightened clinical awareness combined with intensive microbiological screening may be appropriate for those undergoing similar treatment for ALL.

L-AMB was not effective in preventing IFD in patients receiving remission-induction chemotherapy for ALL. Tolerability of L-AMB was what might be expected but further studies are clearly needed to determine whether a change in dosing might have yielded better results. Nonetheless, the rate of IFD found in this study was higher than that reported in previous studies; however, whether prophylaxis is the best antifungal strategy during remission-induction chemotherapy of ALL, or whether the use of a diagnostic-driven approach combining intensive clinical and microbiological screening to detect IFD at an early stage would be more appropriate, remains to be seen. Finally, even though L-AMB given as prophylaxis did not prove effective in our study, this should not deter others from exploring this subject further, given the high incidence of IFD in this patient population.

Acknowledgements

We extend our thanks to the participating patients, the investigators and their support staff. We also acknowledge the contribution of the Data Safety Monitoring Board (DSMB; A. Pagliuca, A. J. Ullmann, C. Viscoli and D. Wang), and the continuous reliable support of S. Abella MD, R. Hargreaves, E. Harvey, S. Sanchez and C. Simcock.

The Steering Committee members were S. Agrawal, O. A. Cornely, J. P. Donnelly and N. Goekbuget (Chair). The Independent Data Review Board members were C. Cordonnier, C. P. Heussel and C. O. Morrissey.

The results were presented in part at the 56th ASH Annual Meeting, 6–9 December 2014, San Francisco, CA, USA (*Blood* 2014; **24**: 3646).
