

Breast cancer is the most frequently diagnosed type of cancer in women worldwide. Both the development and progression of breast cancer are related to tumour evasion of the immune system through a process called cancer immune-editing, in which regulatory lymphocytes play an important role. The infiltration of Treg cells in patients with breast cancer has been proposed as an independent unfavourable prognostic factor. In the present study, we aimed to evaluate the percentages of the Treg cell populations in the peripheral blood of patients with breast cancer with respect to progesterone receptor expression. Peripheral blood samples were collected from 27 patients with breast cancer treated in the Clinical Department of Breast Cancer and Reconstructive Surgery of the Professor Franciszek Łukaszczyk Oncological Centre, Bydgoszcz. Flow cytometry was used to evaluate the percentage of CD25+/FOXP3+/CD127 (-/low) T cells within CD3+/CD4+ T cells.

The presence of CD25+/FOXP3+/CD127 (-/low) T cells within CD3+/CD4+ T cells was identified in all the examined blood samples. A statistically significantly higher percentage of CD25+/FOXP3+/CD127 (-/low) T cells within CD3+/CD4+ T cells was observed in progesterone receptor (PR)-negative breast cancer patients when compared to PR-positive breast cancer patients.

The observed high percentage of CD25+/FOXP3+/CD127 (-/low) T cells within CD3+/CD4+ T cells in PR (-) breast cancer patients when compared to PR (+) breast cancer patients seems to confirm the unfavourable prognostic significance of these cells in breast cancer patients. This may indicate a rationale for combining standard oncological treatment in breast cancer patients with Treg-depleting therapy.

Key words: breast cancer, Treg lymphocytes, progesterone receptors.

Introduction

Breast cancer is the most frequently diagnosed type of cancer in women and the second leading cause of death from cancer for women worldwide. The prognosis for breast cancer is determined by age, lymph node involvement, tumour grade, nuclear expression of estrogen receptor (ER), progesterone receptor (PR), and membrane expression of human epidermal growth factor receptor 2 (HER2) [1, 2]. The development and progression of the cancer is related to tumour evasion of the immune system through a process called cancer immune-editing consisting of three phases: elimination, equilibrium, and evasion. During the elimination phase, also called immunosurveillance, innate and adaptive immune responses cooperate to destroy the growing tumour cells before they become clinically apparent. In the equilibrium phase rare tumour cell variants that have escaped elimination outgrow. The cancer cells that have acquired resistance to the elimination enter the escape phase. During this phase cancer cells continue to grow and expand in an uncontrolled manner, enabled by several mechanisms including development of a suppressive cancer microenvironment. One of those mechanisms is recruitment of T regulatory cells exerting a regulatory effect on the immune system. At this phase the tumour becomes clinically apparent. Among the tumour-infiltrating lymphocytes (TILs) in breast cancer patients are regulatory T cells (Treg), which are identified by the nuclear factor forkhead box P3 (FOXP3) [3]. FOXP3+ TILs are correlated with a high risk of negative clinicopathological factors, such as ER negativity and high tumour grade [4, 5]. Treg cell infiltration of breast cancer has been considered as an independent negative prognostic factor [6, 7]. However, in a study conducted by West *et al.* with a cohort of 175 women with estrogen-receptor-negative breast cancers, FOXP3+ TILs were demonstrated as an independent positive prognostic factor in ER-negative breast cancer [8]. Tylor *et al.* demonstrated that the recruitment of Tregs to the cancer microenvironment inhibits an effective antitumour immune response, and in patients with claudin-low breast cancer, these tumours were found to be highly enriched with Tregs

[9]. On the other hand, FOXP3+ TILs were also identified as an independent factor for improved survival and progression-free survival in triple-negative breast cancer [10].

In the present study, we aimed to evaluate the percentages of Treg cell populations in the peripheral blood of patients with breast cancer with respect to progesterone-receptor status.

Material and methods

The study included 27 patients who were treated surgically for breast cancer in 2017 in the Clinical Department of Breast Cancer and Reconstructive Surgery of the Łukaszyk Oncological Centre, Bydgoszcz, Poland.

Patients were treated in line with the accepted management standard; in all cases, this involved combination treatment. All 27 patients underwent surgical treatment with radiotherapy of the breast. In every case, breast-conserving treatment (BCT) with sentinel lymph node biopsy (SLNB) was applied [11, 12]. Each patient underwent radical surgery. According to current recommendations, this involved removal of the tumour within the limits of healthy tissues (no ink on the tumour) [11, 12], and this was confirmed by the histopathological examination of the state of surgical margins. The SLNB procedure identified the patients without the presence of metastatic lesions in the axillary (cN0 group). The pre-operative assessment of the clinical condition required for this purpose included a physical examination of the patients supplemented by an ultrasound examination of the axilla. The isotope method was used to identify the sentinel lymph node. The surgical procedure was preceded by lymphoscintigraphy using ^{99m}Tc radionuclide with 75–100 MBq activity on the albumin carrier (Nanocol). The isotopic marker was administered intradermally at the margin of the nipple envelope (in the breast quadrant where the primary change was located) approximately 2–3 hours before the surgery. For intraoperative identification of places of increased accumulation of radiotracers in the axillary cavity, and to measure the radiation value of the lymph nodes, a handheld gamma ray detector was used. The lymph node with the highest level of radiation was considered the sinner node sought during the surgical procedure. According to the “10% rule” established by Martin *et al.* [13], lymph nodes displaying elevated radiotracer collection greater than 10% of the radiation value obtained for the sentinel node (nodes of the heart) were also removed.

The patient’s consent was obtained in each case. Additionally, approval for the research program was granted by the Ethical Committee of the Nicolaus Copernicus University Ludwig Rydygier *Collegium Medicum* in Bydgoszcz (KBET/364/B/2015).

All the patients in our study had an invasive ductal breast cancer. From these patients two groups were selected: 19 patients with invasive breast cancer luminal type A: ER (+) PR (+) HER (–), Ki 67 until 15% and eight patients with non-luminal (HER-positive) invasive breast cancer ER (–) PR (–) HER (+), Ki 67 in each case, according to Saint Gallen Consensus 2017. No statistically significant differences in tumour stage, lymph node status, tumour grade,

and HER status were observed between the two groups of patients. The characteristics of the patient groups are presented in Table 1. From each of the patient peripheral blood samples were collected one day before the surgical procedure.

Flow cytometry

The samples for the cytometric evaluation of the Treg cell population in the whole blood of breast cancer patients (luminal A type) were prepared using Becton Dickinson reagents, according to the manufacturer’s instructions. At first, the following antibodies for the detection of surface antigens were added to 100 µl peripheral blood collected on EDTA: 5 µl CD3 APC-Cy7, 20 µl CD4 FITC, 20 µl CD25

Table 1. Characteristics of the patient group

Characteristic	Number of patients (%)
Age	57 years (range: 31–64)
Tumour stage according to TNM 2010	
T1b	9 (33)
T1c	17 (62)
T2	1 (3)
Lymph node status according to TNM 2010	
Without lymph node involvement N0	22 (81)
With lymph node involvement N1	5 (19)
Tumour differentiation grade	
Grade 1	1 (3)
Grade 2	25 (92)
Grade 3	1 (3)
Histopathological assessment	
Carcinoma ductale	27 (100)
After operation margin	
> 1 cm	27 (100)
< 1 cm	0 (0)
Hormonal status	
ER positive	19 (70)
ER negative	8 (30)
PR positive	19 (70)
PR negative	8 (30)
HER status	
HER positive	8 (30)
HER negative	19 (70)
Ki-67 expression	
< 10%	0 (0)
10–15%	19 (70)
> 20%	8 (30)
Type of treatment	
BCT operation	27 (100)
Radiotherapy	27 (100)
Brachytherapy	26 (96)
Chemotherapy	1 (4)

Fig. 1. The percentage of CD25+/FOXP3+/CD127 (-/low) T cells within CD3+/CD4+ T cells in patients with progesterone receptor (PR) (+) and PR (-) breast cancer tumours

APC, 5 μ l CD127 PerCP-Cy5.5, and 5 μ l CD194 PE-Cy7. After a 20-min incubation with mAbs (in the dark at room temperature – RT), the cells were washed with 2 ml of fetal bovine serum (FBS) buffer and centrifuged for 10 min at 250 \times g. The obtained cell pellet was fixed with 2 ml of freshly prepared 1 \times buffer A (for 10 min at RT) and centrifuged for 5 min at 500 \times g. The cells were then washed with 2 ml of FBS buffer (5 min, 500 \times g) and permeabilised with 0.5 ml of freshly prepared buffer C (for 30 min in the dark at RT). After two further washing steps (2 ml FBS; 5 min, 500 \times g), the cells were stained with 20 μ l of anti-human nuclear FOXP3 PE antibody for 30 min in the dark at RT. After two additional washing steps, the cells were suspended in 0.5 ml of FBS buffer and analysed using BD FACS Canto II flow cytometer and BD FACS Diva Software (Becton Dickinson). In each sample, 15,000–25,000 CD3+/CD4+ cells were collected, among which the percentage of Treg lymphocytes was determined, according to the gating strategy described in the additional materials in the article by Santegoets *et al.* [14]. Treg cells were considered to be CD3+/CD4+/CD25+/FOXP3+/CD127 (-/low).

Statistical analysis

The distribution of variables in the study groups of the women was checked with the use of the Shapiro-Wilk test. The statistical significance between the groups was determined by the Kruskal-Wallis test, one-way analysis of variance by ranks. The Mann-Whitney U test was then used as applicable. All statistical analyses were carried out with Statistica 8.0 software (StatSoft Inc., Tulsa, OK, USA). A p -value < 0.05 was considered indicative of statistical significance.

Results

The CD3+/CD4+/CD25+/FOXP3+/CD127 (-/low) T cells were identified in all the examined blood samples derived from the patients with breast cancer after the surgical pro-

cedure. The statistically significantly higher percentage of CD25+/FOXP3+/CD127 (-/low) T cells within CD3+/CD4+ T cells was observed in PR (-) breast cancer patients following surgery when compared to PR (+) breast cancer patients following surgery (Fig. 1).

Discussion

The loss of PR may reflect a change to a more aggressive tumour behaviour [15]. PR is an ER-regulated gene that mediates the effects of progesterone on the development of mammary glands in physiology and is involved in the development of breast cancer. Increased breast cancer incidence is identified in patients after combined estrogen and progesterone hormone replacement therapy compared to estrogen therapy alone [16]. ER-positive/PR-negative metastatic tumours are observed to have a more aggressive course and are associated with a reduced overall survival compared to those preserving PR [17].

In the present study, statistically significantly higher CD25+/FOXP3+/CD127 (-/low) T cells within CD3+/CD4+ T cells were identified in the patients with PR(-) breast cancers compared to those with PR(+) breast cancers. Moreover, in a meta-analysis, Wang *et al.* demonstrated that Treg cell infiltration was more prominent in breast cancer patients with ER (+) and PR (-) tumours. The loss of PR expression is correlated with more aggressive tumour behaviour and a reduced overall patient survival rate [18, 19]. In the presented study the number of the patients with PR-negative tumours is small, which might impair the statistics; however, the general trend in the presence of CD25+/FOXP3+/CD127 (-/low) T cells within the CD3+/CD4+ T cell population in PR (-) invasive breast cancer patients is documented.

Thus, it seems that patients with breast cancer might benefit from the elimination of Treg cells. Dendritic cells have been used in the development of antitumour vaccines because they trigger the antitumour immunity in cancer; however, this response was not sufficient to induce tumour regression. It has been proposed that this is due to the expansion of immunosuppressive cells such as Treg cells. In an experimental study by Ayala *et al.* [18], FOXP3 blockade improved the efficacy of dendritic cell vaccines by inhibiting Treg cells and the direct antitumour effect. It was thus proposed that FOXP3 blockade can neutralise the immunosuppressive tumour microenvironment and switch the antitumour immune response [18].

Conclusions

In conclusion, the subpopulation of regulatory T cells in our study were related with the loss of PR expression, an unfavourable prognostic factor. Our study, together with other reports, therefore seems to confirm a rationale for combining the standard oncological treatment with Treg-depleting therapy.

The authors declare no conflict of interest.
