8
9 **Abstract** The construction industry has already begun the transition to circular economy and
10 intensive research has been conducted over the last decades at laboratory scale to assess the
11 potential use of waste in ceramic applications. However, industrial trials to prove its scale up
12 have been performed to a lesser extent. This work studies the effect of trial scale on the
13 technological and environmental properties of high quality ceramic products incorporating
14 Waelz slag (WS), an industrial by-product from the recovery of electric arc furnace dust
15 (EAFD). To this aim, three groups of ceramics have been produced varying the WS content and
16 the process parameters, moulding water and pressure, at laboratory and industrial scale.
17 Preliminary laboratory scale tests were used to optimize WS content and process conditions
18 using the software GAMS (General Algebraic Modeling System). Optimum ceramic products
19 were processed at both laboratory and industrial scale and tested for their technological and
20 environmental properties. Results from the laboratory and industrial trials were compared to
21 evaluate the scale effect on the ceramic properties. The introduction of WS in clay bricks seems
22 to be easily scaled-up for additions of $WS \leq 10\%$ wt, but higher percentages of WS promotes
23 relevant differences in the properties of the laboratory and industrial bricks.

2 **Introduction**

3 The construction industry has already begun the transition to circular economy and intensive
4 research has been conducted over the last decades at laboratory scale to assess the potential use
5 of waste in ceramic applications. However, industrial trials to prove its scale up have been
6 performed to a lesser extent [1–3]. This research aims to apply the principles of the circular
7 economy by the use of Waelz slag (WS), an industrial by-product from the recovery of electric
8 arc furnace dust (EAFD), in the production of ceramic bricks. WS contains the non-volatile
9 components of the original EAFD, primarily iron (~50-60%) and calcium (~15%) oxides.
10 Contrary to EAFD, WS is classified as a non-hazardous waste according to the European List of
11 Waste (code 10 05 01) [4] due to its lower heavy metal concentration. However, occasionally it
12 could be considered as a potentially hazardous waste and it is disposed of in landfills at
13 increasing economic and environmental costs [5, 6]. An attractive alternative to disposal is its
14 use as alternative material in the construction sector [7]. Ceramic processes, apart from the
15 heterogeneity of raw materials and products requirements, are also considered as good potential
16 receptors for the recycling of wastes due to the different roles that they can play in the ceramic
17 process: fluxing agents, fillers, clay substitutes, body fuels, pore formers and other properties
18 affecting wastes. These roles are directly related to the chemical and mineralogical composition
19 of the materials. On the other hand, the different roles that the wastes may play in the ceramic
20 process, make possible to obtain ceramic products fulfilling the quality requirements
21 established by the recent Construction Products Regulation (CPR)[8]. One of the new key issues
22 of the CPR is the requirement on sustainability, especially the sustainable use of natural
23 resources and the reduction of life-cycle impacts [9–13]. Furthermore, the CPR addresses health
24 and environment aspects of the ceramic products, including the potential release of dangerous
25 substances to soil and water during entire lifecycle useful life and at the end of its life.

26 Previous studies looking for reusing alternatives for WS have provided relevant information
27 about: (i) the sintering behaviour of WS[14]; (ii) the technological and environmental properties
28 of ceramic products containing WS and WS combined with other wastes[15]; (iii) the
29 mathematical models that describe the technological [16] and environmental [17] behaviour of
30 ceramic products containing WS in mixtures with other wastes and, (iv) the acid gas emissions
31 from ceramic processes containing WS and WS mixed with other wastes [17, 18].

32 Results from all these previous investigations demonstrate that the content of WS in the initial
33 mixture and the firing temperature of the ceramic process are key parameters that affect not only
34 the technological properties but also have a strong effect on their environmental performance.
35 High contents of WS in the mixtures produce ceramic products with increased bulk density,
36 open porosity, and flexural strength when compared with the natural clay but, lower water
37 absorption, weight loss and linear firing shrinkage. In general low firing temperature decrease
38 emissions of acid gases [18, 19], and immobilizes most of the heavy metals present in the WS
39 but do not immobilize neither the Cr nor Mo present in the WS, whose leaching becomes
40 controlled by soluble salts formation [17]. However, to the best of our knowledge, the influence
41 of the moulding parameters (water and pressure of moulding) on the final properties of waste-
42 based ceramics has been studied to a lesser extent. The aim of this research is basically to assess
43 the feasibility of recycling WS in the production of facing bricks, a high temperature process,

1 through laboratory testing and validation at industrial trials. The reason to select facing bricks
2 for this study is that the market of bricks focuses mainly to be used in external walls. These
3 bricks require high technological, environmental and aesthetic properties, so they are resistant to
4 the weather, with no significant leaching of heavy metals caused by the rain.

5 This paper introduces an experimental investigation at laboratory scale using extreme firing
6 conditions to study the effect of various substitution rates of WS at different moulding
7 conditions (pressure and moulding water) on the technological properties of the ceramic
8 products. An optimization step to select the best moulding conditions and the optimal WS
9 content in the mixture was also conducted. A second lab-scale trial simulating the industrial
10 firing cycle, as well as an industrial trial were performed using the selected products. The
11 technological, chemical and environmental behaviour of these products were assessed and the
12 feasibility of the scale up of the process was evaluated by comparison of results obtained in the
13 lab and industrial scale trials.

14 **Materials and methods**

15 **Materials**

16 The clay employed in this work was supplied by the industrial brickwork *Cerámicas de*
17 *Cabezón* located in Cantabria (Spain). The WS, commercialised as Ferrosita®, was supplied by
18 Befesa Zinc Aser, Abengoa Group, from its Electric Arc Furnace Dust recycling plant (Erandio,
19 Basque Country, Spain). The raw materials were characterized in terms of chemical
20 composition. The particle size of the raw materials (clay and WS) was set below 500µm, in
21 order to avoid the encapsulation of the WS into the ceramic matrix.

22 The chemical composition of the raw materials (clay and WS) was determined at Activations
23 Laboratories (Canada). Content in major oxides (Al₂O₃, CaO, Fe₂O₃, K₂O, MgO, MnO, Na₂O)
24 were determined by fusion-inductively coupled plasma (FUS-ICP; Thermo Jarrel-Ash ENVIRO
25 II equipment). The contents in Cd, Cu, Mo, Ni, Pb, and Zn were determined using total
26 digestion and ICP (Perkin Elmer SCIEX ELAN 6000). Contents of As and Cr and Cl were
27 determined by non-destructive instrumental neutron activation analysis (INAA). Content in Ba
28 was measured by means of INAA/FUS-ICP while ion selective electrode (ISE) was used in the
29 case of F (Fluorine automatic analyzer from Mandel Scientific). The total content of S was
30 analysed by combustion and infrared detection (IR) (Eltra CS-800 infrared cell).

32 **Ceramic processing**

33 The methodology used in this work is shown in Figure 1. Three different experiments were
34 carried out in this research:

35 - A first group (A) from a preliminary laboratory trial under extreme firing conditions where the
36 WS content was varied from 0 to 50%, the values of the moulding water content were 3, 6 and
37 9% and the values of the pressure used at moulding stage were 50, 100 and 200 bars. Mixtures
38 were homogenised and pressed using a hydraulic press (Nanetti, Mignon SS/EA). This first
39 group (A) of pressed specimens with cylindrical shape (40 mm diameter and 14 mm thickness)
40 were dried in a muffle furnace at 100°C during 24 hours and then fired up to 1000°C with a
41 firing rate of 6°C/min and a dwell time of 60 minutes, as described in Cheeseman et al., [20];

1 - In a second laboratory trial, group B) selected mixtures (with WS contents down to 20%)
2 where pressed using a hydraulic press (Nanetti, Mignon SS/EA) at optimum moulding
3 conditions, 6% of moulding water content and a pressure of 100 bars. Pressed specimens
4 (second group) with cylindrical shape (40 mm diameter and 14 mm thickness) were dried in a
5 muffle furnace at 100°C during 24 hours. Once dried, those pieces were fired simulating
6 industrial firing cycles in a laboratory electric furnace up to 1020°C with a firing rate of
7 1.4°C/min and a dwell time of 210 minutes;

8 - Mixtures for industrial proof, group C) were prepared by mixing the selected mixtures
9 containing clay and WS (up to 20%) with higher quantity of moulding water (16-20%
10 depending on the WS content) in order to achieve the desired plasticity values ($1.4 \pm 0.1 \text{ kg/cm}^2$)
11 that requires the extrusion moulding method. Subsequently, the mixtures were extruded using a
12 pilot scale extruder (Verdés, 050-C) to produce specimens with rectangular shape,
13 (150mm*30mm*20mm). Extruded samples (third group) were dried in an industrial drying
14 room at 100°C for 24 hours and then fired using an industrial brick kiln up to 1020°C at a firing
15 g rate of 1.4°C/min and a dwell time of 210 minutes (commercial firing cycle employed for the
16 manufacturing of facing bricks).

17 **Properties of the ceramic products**

18 The technological properties of the fired specimens were assessed according to standard
19 procedures. Linear firing shrinkage (LFS) was measured with a precision calliper, water
20 absorption (WA), as specified by UNE 67027, open porosity (OP) by mercury intrusion
21 porosimetry using a Micromeritics AutoPore IV 9500 porosimeter, weight loss during firing
22 (WL) as specified by UNE 772-13, bulk density (BD) was calculated from the weight/volumen
23 ratio as specified by UNE-EN 772-13:2001 and 3-point flexural strength (MOR) as specified by
24 UNE-EN 843-1.

25 Firstly, the technological properties of the first group A) were assessed, then the WS content
26 and the moulding parameters (water content and pressure of moulding) were optimized using
27 the software GAMS (General Algebraic Modeling System). Optimum mixtures that produce
28 ceramic products with suitable technological properties were selected for further experiments at
29 laboratory, group B), and industrial scale, group C).

30 The environmental properties assessed were the release of potentially toxic species during their
31 use and leaching of heavy metals after disposal in landfill sites. The environmental behaviour of
32 the fired specimen during its useful life was assessed using the diffusion leaching test NEN
33 7345 [21] on monolithic materials takes 64 days. During this time the concentrations of the
34 studied pollutants in the leachant were measured at specified times. The cumulative emission
35 values at the end of the test per unit mass over 64 days (E_{64}) in mg/m^2 were calculated and these
36 values were compared with the threshold limits established by the Dutch Building Materials
37 Decree [22]. The environmental behaviour of the fired specimen at the end of life was assessed
38 using compliance leaching tests simulating open (EN12457-1) and closed landfill (EN12457-2)
39 conditions on granulated materials milled to below 4 mm to promote contact and leaching of
40 trace elements. Compliance leaching tests were performed using deionized water with
41 liquid/solid ratios $L/S=2$ and $L/S=10$, respectively and 24 h stirring [23]. At the end of the test,
42 samples were filtered and the leachates analysed. The pH was measured and pollutants
43 concentrations in the leachates were determined and compared with the regulatory threshold

1 limits established for close and open landfill conditions [24]. In three leaching tests,
2 concentration values for Ba, Cd, Cr, Cu, Mo, Ni and Zn were determined using ICP Emission
3 Spectrometry (Perkin Elmer Plasma 400), concentration of As, Hg, Pb, Sb and Se by Atomic
4 Absorption (Perkin Elmer 1100B) and concentration values of F⁻, Cl⁻ and SO₄⁼ were
5 determined by Ion Chromatography (Dionex DX 120).

6 **Results and discussion**

7 **Characterization of raw materials**

8 Table 1 shows the major oxide composition of the raw materials (clay and WS) and the total
9 content of main elements. The clay consisted primarily of silica (SiO₂) (63.6%) and alumina
10 (Al₂O₃) (17.2%) and lower amounts of iron oxide (expressed as Fe₂O₃) (6.1%) and potassium
11 oxide (K₂O) (3.1%), as well as traces (<1.0%) of other oxides like MgO, TiO₂, Na₂O and CaO.
12 The content in sulphur of the clay is 0.196%, while the content in metals (Ba, Zn, Cr, Ni, Pb,
13 Cu, As, Mo and Cd) was found in percentage below 0.1%.

14 On the contrary, WS consists mainly of Iron oxide (expressed as Fe₂O₃)(52.7%) and CaO
15 (20%), which can act as fluxing agents during firing, favouring the development of a liquid
16 phase and lowering the sintering temperature [14]. WS present lower concentration of (SiO₂)
17 (8.97%) and alumina (Al₂O₃) (2.91%) and higher concentrations of manganese oxide (MnO)
18 (5.08%), magnesium oxide (MgO) (3.11%) when compared with the clay. Other oxides, such as
19 Na₂O, K₂O, TiO₂ and P₂O₅ were detected at concentrations below 1.0%. The content in zinc
20 (Zn) (>1%), sulphur (S) (0.71%), lead (Pb) (>0.5%), copper (Cu) (0.41%) and chromium (Cr)
21 (0.38%) were found above 0.1%, while the content in Ba, Ni, Mo, As and Cd were reported
22 below 0.1%.

23 On the other hand, the analysis of crystalline phases, has been carried out in previous studies
24 using XRD [14], was qualitative, the intensity of the peaks provided an approximate idea of the
25 contribution of each of the phases in the material. The phase with the greatest contribution is
26 wustite (FeO), followed by calcium silicate (Ca₂SiO₄) and the combined oxide of iron and
27 calcium (Fe₂O₃ (CaO)₂). Other phases in a minor proportion are magnetite (Fe₃O₄) and calcium
28 oxide (CaO).

29 The loss on ignition (LOI) is associated with the presence of clay minerals, hydroxides, organic
30 matter and volatile components. It can be an important parameter to be considered during
31 ceramic processing, with implications in the development of OP, LFS and MOR [16]. The LOI
32 of the clay (6%) corresponds primarily to the loss of crystallisation water and organic matter.
33 The negative LOI value of WS, which amounted up to ~3.7% of the original mass, indicates a
34 weight gain during firing. This could be attributed to the iron oxidation during the thermal
35 treatment, mainly present in the WS as wustite (FeO) to produce magnetite (Fe₃O₄) [14, 15].

36

37 **Preliminary laboratory trial (group A)**

38 The effect of process parameters on the ceramic properties was studied. Figure 2 shows the
39 dependence of the ceramic properties (weight loss, bulk density and linear firing shrinkage) of
40 the first group of fired products (group A) obtained in a preliminary lab-trial at extreme
41 conditions on three process parameters: WS content, water content and moulding pressure.

1 In general, the moulding pressure does not show a significant influence in any of the properties
2 of the ceramic products. On the contrary, weight loss (WL) and linear firing shrinkage (LFS)
3 increase with the water content and decrease with the introduction of WS. It is observed that
4 ceramic products with WS content above 30% suffer negative LFS or expansion. These results
5 are attributed to (i) the presence of inert compounds that do not react during firing which does
6 not contribute to the sintering mechanisms, mainly by a viscous type flux vitrification [25] and,
7 (ii) the oxidation of the crystalline phase wustite (FeO) contained in the WS into magnetite
8 (Fe₃O₄) during the firing process [14]. The unit cell size of crystalline magnetite (Fe₃O₄) is
9 approximately double that of iron oxide (FeO). Consequently, the volume of the unit cell in
10 magnetite (Fe₃O₄) is nearly eight times larger than that in wustite (FeO).

11 The Bulk density (BD) of the ceramic products decreases with the water content and it increases
12 with the WS content. This is attributed to the higher density of the WS mainly due to its high
13 iron content (52,7 %). The water absorption (WA) of the ceramic products increases with
14 moulding water content which contributes to higher WL increasing the OP of the products and
15 thus the WA. On the contrary, the evolution of WA is mainly to increase until WS 20% and
16 then decreases with the content of WS. It is due to WS is constituted of hematite, Fe₂O₃, a
17 refractory material that difficult the sintering mechanisms and thus increasing the open porosity
18 which has a direct effect on the WA. However, when the content of WS is higher the LFS of the
19 material is negative, reducing the porosity, increasing the density of the material and reducing
20 the WA [26].

21 The next step was the optimization of process parameters using software GAMS. The
22 mathematical expressions that relates the physical properties and WS and water content have
23 been obtained by the software TableCurve 3D (Systat software Inc, 2010). The properties BD,
24 LFS and WL can be easily described through linear polynomial equations (with r²> 0.9) that
25 show the correlation between each property (P) and the WS and moulding water (W) contents.
26 On the contrary, more complex mathematical models are needed in the case of WA. The
27 polynomial coefficients (a-g) of these equations (models) are shown in Table 2. The more
28 complex behaviour of WA was also observed in previous works [16] where more complex
29 equations were needed to model and predict its behaviour as a function of the raw materials
30 content [27].

31
$$P = a + b * WS + c * W \quad eq.1$$

32
$$P = a + b + WS + c * WS^2 + d * WS^3 + e * WS^4 + f * WS^5 + g * W \quad eq.2$$

33 The validity interval of these equations is W between 3 and 9% and WS from 0 to 50%.

34 Equations 1 and 2 were used to calculate the maximum value of WS content that can be
35 introduced in the ceramic mixtures without detriment of the ceramic properties. The
36 optimization software package used was the General Algebraic Modelling System (GAMS)
37 which is a high-level modelling system for mathematical programming problems and, the
38 problem has been solved within a relative tolerance of 0.01% from the global optimal value.

39 Table 3 shows the results of the optimization step as well as the lower and upper bounds
40 considered as the technical limits of the physical properties. In order to obtain ceramic products
41 suitable for the intended uses, the ceramic properties must meet the established quality
42 standards. The usual value of BD for facing bricks is in the range 2-2.15g/cm³. High quality

1 bricks typically exhibit LFS values below 8% [28, 29] and WA below 16 %. The typical WL on
2 heating for clays used in the manufacture of commercial bricks has been reported to be between
3 5 and 15% [28,30]. Higher WL values are associated with higher energy consumptions in the
4 firing process and also to higher emission values (CO₂ and volatile organic compounds) while
5 lower weight loss values are found in high density ceramics. Clays with low content in
6 carbonates usually show values of WL close to the lower limit (5%), while high content of
7 carbonates in the clay increases the WL during firing.

8 Results from the optimization process (Table 3) show that up to 21.5% in weight of WS can be
9 successfully introduced in the ceramic mixture without detriment in the resulting ceramic
10 properties. The use of larger amounts of WS must be avoided due to detrimental changes in the
11 bulk density of the products.

12 **Laboratory simulation of selected mixtures (group B)**

13 Selected mixtures containing up to 20% of WS were pressed at the optimum conditions (6% of
14 water moulding content and 100 bars) simulating the industrial firing cycle of facing bricks at
15 laboratory scale. The technological (WL, WA, LFS, OP, BD and MOR) and environmental
16 (leaching of potential hazardous pollutants during the life use and end of life stages) properties
17 of the ceramic products were assessed.

18 Figure 3 shows the effect of the WS content on the ceramic properties (weight loss, bulk density
19 and linear firing shrinkage, open porosity and flexural strength) of the second group of pressed
20 specimens. In the same way to the results found in the preliminary lab-trial, both firing
21 shrinkage (LFS) and weight loss (WL) of the ceramic products decrease with the WS content
22 which has a significant effect in the bulk density (BD) that also increases with the WS content.
23 As expected from the prelaminar lab test, the water absorption (WA) and open porosity (OP) of
24 these ceramic products increase with the WS content. On the contrary, the modulus of rupture
25 (MOR) decreases with the WS content. Mechanical strength is strongly dependent on the
26 microstructural characteristics of the fired ceramic. Results indicate that the additions of WS
27 introduce pore or cracks into the ceramic microstructure. This detrimental effect is presumably
28 due to the fact that the WS particles act as major flaws in the ceramic microstructure,
29 concentrating the stresses during the mechanical testing.

30 The results of the environmental behaviour of ceramic bodies during its useful life using the
31 Dutch diffusion leaching test is summarized in Table 4. It shows the E₆₄ value which represents
32 the accumulated concentration of potentially hazardous pollutants (in mg/m²) calculated from
33 data obtained from samples extracted at specific times during the diffusion leaching test. The
34 results show a high mobility of alkaline, alkaline earth, fluorine, chlorine and sulphate ions. It
35 can be notice that, the reference sample, without WS also presents high E₆₄ values for Na, Cl
36 and F. Ceramic products containing 20% of WS show higher mobility of SO₄⁼, and slightly
37 higher of Ca.

38 The environmental behaviour at the end of the useful life where these materials are considered
39 construction and demolition waste and disposed of landfills is presented in Table 5. In this table
40 is summarized the results of the leaching of potentially hazardous pollutants (As, Ba, Cd, Cr,
41 Cu, Hg, Mo, Ni, Pb, Sb, Se, Zn, Cl⁻, F⁻ and SO₄⁼) that are above the detection limit of the
42 equipment used. The concentrations of the elements are obtained from the compliance leaching

1 tests performed simulating closed (EN 12457-1) and open landfill conditions (EN 12457-2) with
2 liquid to solid ratios of 2 and 10 l/kg, respectively. If the relation between liquid to solid ratio
3 and mobility of pollutants is analysed, it can be seen that in general, the higher the liquid to
4 solid ratio, the higher the leaching of pollutants in the compliance leaching tests. As expected
5 from previous analysis, the higher mobility in the ceramic products is observed for SO_4^- , Cl^- and
6 F^- due to its higher contents. The range of pH values of leachates are between 9.30 and 10.10,
7 being smaller for L/S ratio 2 [31].

8 Independently on the liquid to solid ratio, the WS content increases the leaching of Mo, and
9 SO_4^- in the samples mainly. Previous studies showed that the mobility of Mo is not only
10 dependent on the corresponding contents in the initial mixtures but is also related to certain
11 parameters such as: (i) open porosity or specific surface area [14, 32]; (ii) the presence of alkalis
12 and alkaline earth compounds in the mixtures, which allows the oxidation of molybdenum to
13 Mo (VI) to form soluble molybdates that promote Mo leaching and; (iii) the mineralogical
14 composition of the fired products, namely the amount of the glassy phase, which depends on
15 both the major oxides contents and the firing temperature [17, 33].

16 **Industrial proof of selected ceramic products (group C)**

17 The analysis of the technological properties of selected ceramic products (group B) was
18 performed in the same way as the group B. Figure 4 shows the effect of the WS content on
19 the ceramic properties (weight loss, bulk density and linear firing shrinkage, open porosity and
20 flexural strength) obtained in the industrial trial using natural gas as fuel. A similar behaviour to
21 the ceramics obtained in the second laboratory trial simulating the industrial firing cycle (group
22 B) is observed for the products obtained at industrial scale. The higher the WS content, the
23 lower the firing shrinkage (LFS), the weight loss (WL) and the flexural strength (MOR) but the
24 higher the bulk density (BD), open porosity (OP) and water absorption (WA).

25 Most of the technological properties of all the industrial products containing up to 20% of WS
26 meets the lower and upper bounds considered as the limit of the physical properties (see Table
27 3) established for the most restricted use of clay bricks. However, industrial bricks containing
28 20% of WS show values of BD and WL that do not fall within the lower and upper limits
29 summarized in Table 3. It should be noticed that even the reference sample containing only clay
30 has WL slightly below the lower limit, so the products obtained do not meet this criterion for
31 brick. The application of the products obtained with WS content, can be different to facing
32 brick, uses that requires high density ceramics.

33 In the same way as group B species, the analysis of the environmental properties of selected
34 ceramic products was carried out for the group C species, during its useful life using the Dutch
35 diffusion leaching test and at the end of the useful life, simulating closed and open landfill
36 conditions.

37 The results of the diffusion test, E_{64} accumulated concentration value (mg/m^2), of the species as
38 function of WS content are summarized in Table 4. Most of the potential hazardous pollutants
39 are far below this limit, except for anionic compounds (chlorides, fluorides and sulphates),
40 which exceed the limit value and thus might be considered as critical pollutants. However, the
41 reference sample, without WS, already exceeds the limit for chlorides and fluorides. This is due
42 to the high solubility of alkaline and alkaline earth salt. In fact, the addition of WS reduces the

1 content in chlorides and fluorides but increases the contents in sulphate and calcium salts,
2 probably by the formation of calcium sulfate, due to the high Ca content in the slag, 20%, which
3 can give rise to efflorescents.

4 Table 5 shows the results of the leaching of potentially hazardous pollutants at the end of its
5 useful life. As it happened in the case of species of group B, the higher the liquid to solid ratio
6 the higher the leaching of pollutants in the compliance leaching tests. Results from these tests
7 were compared to the threshold limits established for waste acceptance at non-hazardous
8 landfills. Results show that the leaching of most of the metals as well as chlorides, fluorides and
9 sulphates anions is far below the acceptable limits for non-hazardous landfills and, only the
10 leaching of Mo in products containing WS are above the corresponding threshold limit for non-
11 hazardous waste. Mo is considered as a critical pollutant whose leaching needs to be further
12 studied. According to Verbinnen and colleagues [34], the addition of stabilizing additives to the
13 initial mixture might be able to decrease oxyanions mobility.

14 **Effect of the trial scale on the properties of selected ceramic products**

15 Laboratory and industrial-scale facing bricks containing up to 20 % were compared in terms of
16 the overall technical performance and the behaviour of the critical environmental pollutants
17 during the useful life, SO_4^- , Cl^- and F^- , and at the end of life, Mo.

18 **Technological properties:** In general, the industrial bricks were found to have higher
19 mechanical resistance (MOR), LFS, WA and OP when compared with the laboratory bricks.
20 The higher strength and LFS values of the industrial-scale bricks may be due to better mixing
21 and compaction in the industrial process [35]. In addition, the more oxidizing atmosphere at
22 laboratory scale favours the oxidation of FeO into Fe_3O_4 , increasing the volume but favouring
23 the porosity development in a lesser extent than in the industrial kiln, where the reducing
24 atmosphere favours the reverse reaction, increasing the hollow volume. The lower LFS of the
25 laboratory bricks affects the WA which has the same behaviour as OP. Although there is a
26 pronounced increase in OP of the industrial bricks, a lower decrease in the porosity is observed
27 when 20% of WS is introduced, compared to laboratory bricks. This might be attributed to the
28 higher LFS of the bricks obtained at industrial scale.

29 On the contrary, laboratory bricks show slightly higher values of BD and surprisingly much
30 higher values of WL compared to the industrial bricks. The lower WL of the industrial bricks
31 might be related to the higher initial water content in the samples.

32 **Environmental performance during the useful life stage:** Results show that the mobility of F^-
33 , Cl^- and SO_4^- during the diffusion leaching tests is slightly higher at industrial scale. The higher
34 porosity of industrial WS-bricks enhances the solubilisation of chlorine, fluorine and sulphur
35 containing compounds during the diffusion leaching tests.

36 **Environmental performance during the end-of-life stage:** As shown in Table 5, Mo is the
37 main pollutant whose mobility is above the threshold limit for non-hazardous materials when
38 WS is added to the clay. Mo leaching values tends to be higher at industrial scale. Again, the
39 higher OP of the industrial products compared to those obtained at laboratory scale might play a
40 key role contributing to their higher Mo leaching.

41 The characteristics of the industrial bricks confirm substantially the results achieved during the
42 laboratory testing. However, differences in the properties of the bricks obtained at laboratory

1 and industrial-scale could be attributed to disparities in test methods: (i) moulding process
2 (pressure versus extrusion) that also requires introducing significant differences in the content
3 of the moulding water (6% versus 16-20%) to obtain the plasticity necessary for the extruder,
4 (ii) the kiln environment (electrical versus natural gas), (iii) the cooling rate (natural versus
5 controlled).

6 The results suggest that the use of WS as alternative raw materials in the production of facing
7 bricks is feasible and could be transferred to the industrial sector for large scale production,
8 taking into account a maximum recommended percentage of 10 % of WS. Higher WS contents
9 strongly affect the reproducibility and scale-up of the laboratory trials due to relevant
10 differences on most of the technological, chemical and environmental properties of the
11 laboratory and industrial bricks.

13 **Conclusions**

14 The present paper assesses the use Fe-rich Slag as a clay substitute for the production of facing
15 bricks at laboratory and industrial scale. Three trials varying the process conditions and the
16 Waelz slag (WS) content have been performed.

17 A similar behaviour of technological and environmental properties has been observed at
18 laboratory and industrial scale with the introduction of WS. However, ceramic bodies obtained
19 at industrial scale have a higher increase of open porosity (OP) than those obtained at laboratory
20 scale. This difference could be due to differences in the atmosphere of the kilns. The oxidizing
21 atmosphere of the electric oven used at laboratory scale favours the oxidation of FeO in Fe₃O₄,
22 that increase the volume of solid mass; while the reducing atmosphere of industrial facilities
23 promotes the inverse reaction increasing the hollow volume.

24 Based on these analyses, it can be concluded that WS could be used as alternative raw material
25 on the facing bricks production cycle with high performance up to certain amounts without
26 significant detriment on the technological properties of the final products. In addition, the
27 introduction of WS in clay bricks seems to be easily scaled-up for additions of WS ≤10%. The
28 addition of 20% of WS promotes relevant differences in the properties of the laboratory and
29 industrial bricks. The main technical limitation of the use of 20% of WS is the increase in the
30 weight loss (WL) whose value does not fall within the lower and upper limits. From the
31 environmental point of view, only Mo is considered as a critical pollutant at the end of life stage
32 (landfill), not, on the other hand, during the useful life stage. The difference in behavior can be
33 attributed to the fact that in one scenario the test is performed on monolithic material and in the
34 other on granular material milled below 4 mm. While the anions, only, according to the limits
35 proposed by BMD, not currently regulated, its behaviour presents a limitation in its utilization
36 stage, due to the formation of salts on the surface of the products, called efflorescences. Further
37 studies are being performed to evaluate the potential benefits of the use of additives to decrease
38 the Mo leaching from the ceramic products for non-hazardous waste landfill, as well as avoiding
39 the presence of efflorescents on the surface, and in this way not limit the scenarios of use of the
40 products final ceramics
