# EFFECTS OF TYPE OF BIRTH, BREED OF SIRE, POSTWEANING NUTRITION AND AGE AT FIRST BREEDING ON LAMB AND WOOL PRODUCTIVITY

OF RANGE EWES

BY

#### DEBRA SUE MORRIS

A thesis submitted in partial fulfillment of the requirements for the degree Master of Science, Major in Animal Science, South Dakota State University 1981

SOUTH DAKOTA STATE UNIVERSITY LIRDARY

# EFFECTS OF TYPE OF BIRTH, BREED OF SIRE, POSTWEANING NUTRITION AND AGE AT FIRST BREEDING ON LAMB AND WOOL PRODUCTIVITY

OF RANGE EWES

This thesis is approved as a creditable and independent investigation by a candidate for the degree, Master of Science, and is acceptable for meeting the thesis requirements for this degree. Acceptance of this thesis does not imply that the conclusions reached by the candidate are necessarily the conclusions of the major department.

> A. L. Slyter Thesis Adviser

J. W. McCarty Acting Head, Animal Science Dept.

Date

#### ACKNOWLEDGMENTS

I would like to thank Dr. Lowell Slyter for his advice and patience, both of which were invaluable in the completion of this thesis.

I also wish to thank Dr. Lee Tucker for his assistance in the statistical analyses.

Thanks also go to Miss Margie Thom for her assistance in preparing and typing the manuscript.

I would especially like to thank my husband, Tom Heintz, for his loving encouragement and patience throughout these many months.

#### INTRODUCTION

In an effort to improve range sheep production in the United States, several of the traditional practices employed in this industry have been questioned. The use of whiteface ewes, breeding ewes to first lamb as 2-year-olds, selection for or against twin ewes and postweaning nutrition of replacement ewes are all areas in which some research has indicated that a change from the traditional practices may result in greater production.

Validity of research findings is often questioned because the research may have been conducted under conditions very different from the normal commercial operation. By conducting a study on various ranches, the results would then be more comparable to real life situations.

It was the objective of this study to determine which combination of factors (traditional <u>vs</u> innovative) would result in the greatest lamb and wool production from ewes on a typical range operation. This study was conducted over a 7-year period, with five groups of ewes being maintained on several different range operations in an effort to minimize differences due to management practices.

#### REVIEW OF LITERATURE

#### Prebreeding Growth

Hazel and Terrill (1946a), Slen and Banky (1959), Bennett <u>et al</u>. (1963), Vesely <u>et al</u>. (1966) and Sidwell and Miller (1971b) all found that male lambs, whether intact or castrated, wean at heavier weights than females. Average differences reported ranged from 4.9 kg (Hazel and Terrill, 1946a) to .8 kg (Vesely <u>et al</u>., 1966).

The weight advantage of single lambs over twins is evident at birth (Lambe <u>et al.</u>, 1964; Vesely and Peters, 1964) and is still present at weaning. deBaca <u>et al</u>. (1956), Bailey <u>et al</u>. (1960), Lambe <u>et al</u>. (1964), Sidwell and Miller (1971b) and Vesely and Peters (1972) found single lambs to have heavier weaning weights than twins. This difference was found to be as great as 7.7 kg (deBaca <u>et al.</u>, 1956).

Twins and singles exhibit the same potential for growth, although twin growth is retarded intrauterine and during the first few weeks of life when milk is the primary nutrient source (Guyer and Dyer, 1954).

Burris and Baugus (1955) found a high correlation (r = .90) between early lamb growth and a ewe's milk production; but, as lambs grew older, this correlation decreased.

The rate of gain for singles and twins after 2 months of age was found to be the same by Slen and Banky (1959). Cassard and Weir (1956) found similar results, reporting that from 0 to 70 days of age single lambs grew faster than twins and from 70 to 120 days of age twins grew faster. All weight differences for single and twin ewe lambs

were lost by 240 days of age. Dun and Grewal (1963) found that it wasn't until 18 months of age that twins weighed nearly as much as singles. When comparing yearling weights of 932 Rambouillet ewes, Hazel and Terrill (1946a) found that singles averaged 2.7 kg heavier than twins.

Gould and Whiteman (1975) found that the average weights of lambs from 111 Dorset x western twin dams were .9 kg heavier than lambs produced by 129 single ewes of the same breeding when the ewes were 15 months old. After that, the difference became smaller and there was no difference in 70-day lamb weights by the time the ewes were 4 years old.

Terrill and Stoehr (1942), in an experiment involving 758 Columbia, Corriedale and Rambouillet range ewes, found no consistent difference in lamb production of single and twin ewes remaining in the flock 5 years or longer.

#### Estrus in Lambs

It is generally agreed that some ewe lambs will show estrus during their first winter. The reported percentages of estrus occurrence in ewe lambs vary widely, however.

Burfening <u>et al</u>. (1971), in a study involving 1431 range ewe lambs, found among nutrition treatment groups that an average of 19% of ewe lambs showed estrus as detected by vasectomized rams with ochred briskets. Wiggins (1955) reported similar results, with 14.5 to 15.9% of range ewe lambs reaching puberty during their first winter.

In an experiment involving 399 crossbred ewe lambs from two birth years, Cedillo <u>et al.</u> (1977) found that 90% of the ewe lambs exhibited estrus during their first winter. The mean age of first estrus was 205 days, with a range of 157 to 243 days. These lambs had a mean body weight of 38.1 kg (range of 24 to 53 kg). All the ewes in the study were either from Columbia or Suffolk dams with four different breeds of sire. Of the half-Columbia ewes, 18% failed to show estrus during their first winter as compared to only 2% of the half-Suffolk ewes. The half-Suffolk ewes first cycled an average of 10 days earlier (P<.01) than the Columbia crosses. In an experiment by Southam <u>et al</u>. (1971), 96% of 130 ewe lambs reached puberty at an average age of 214.7 days and at an average weight of 43.1 kilograms.

In a study involving purebred and crossbred ewes, 50% of the ewe lambs that were exposed conceived (Vesely and Peters, 1974). The conception rate in crossbreds was higher than in purebred ewes mated to rams of another breed. Prolificacy, however, was not significantly altered by crossbreeding.

Dickerson and Laster (1975) reported that of 825 ewe lambs of various breeds 52.6% were in estrus during the fall breeding season. The adjusted mean age at puberty was 232 days, and the adjusted weight at puberty was 42.8 kilograms. Puberty was delayed 1 week in twins and their average weight was 3 kg less.

Ch'ang and Rae (1969) found in an analysis of data collected on a flock of Romney ewes over a period of 11 years that the number of times a ewe cycles during her first autumn (2.4 times, average) was

unaffected by type of birth and rearing and was moderately affected by age of individual. Bowstead (1929) found that ewe lambs from ewes bred as lambs did not conceive as readily as their dams, but subsequent production was little affected.

#### Breeding as Lambs

In a study involving 98 ewes, Bowstead (1929) found that ewes bred to lamb as yearlings produced more and heavier lambs as 2- and 3year-olds than did ewes first bred as yearlings. Results also indicated that breeding ewe lambs did not cause a decrease in their mature weight.

In studying a flock of 139 Columbia and Targhee ewes, Levine <u>et al.</u> (1978) found that, per ewe entering the experiment, ewes lambing as yearlings weaned a higher number of lambs and more kilograms of lamb as compared to ewes first lambing as 2-year-olds, even when not considering the first lamb crop of the early-bred ewes. It was noted, however, these results could be due in part to heavier culling of ewes which failed to lamb as yearlings. The ewes may have had unsoundnesses which prevented breeding as lambs and resulted in culling from the herd.

Briggs (1936) reported that, in a study involving 244 Hampshire **x** Rambouillet cross ewes, the early-bred ewes (bred as lambs <u>vs</u> yearlings) produced more lambs and more kilograms of lamb in their lifetimes. The early-bred ewes took 10 months longer to reach mature weight, but by 31 months of age both groups weighed the same. The most noticeable difference in the groups was that the mouths of early-bred ewes did not hold up as well as those of the later-bred ewes. This was possibly because the early breeding did not allow the teeth to develop as well. Spencer <u>et al.</u> (1942), Longrigg (1961), Hulet <u>et al</u>. (1969), Burfening <u>et al</u>. (1972) and Tyrell (1976) all found results similar to those of Briggs when comparing productivity of ewes bred first as lambs to ewes first bred as yearlings.

#### Postweaning Nutrition

Burfening et al. (1971) studied the effects of postweaning and wintering nutrition on 684 Rambouillet, 391 Targhee and 356 Columbia range ewes lambs in a 3-year study. The ewes were fed either a ration consisting of range and/or grass hay and 454 g of a 30% protein supplement per day (H) or a ration consisting only of range and/or grass hay (L). The ewes were maintained on these rations from early fall weaning until the next spring. Mid-winter, half of each treatment group's ration was changed, resulting in four groups, HH, HL, LH and Estrus detection in the ewes was accomplished using vasectomized LL. rams with painted briskets. Results of this experiment showed that 26.6% of the HH and 26.15 of the HL ewes came into estrus their first winter, while only 13.6% of the LH and LL ewes showed estrus. These results indicated that a higher plane of postweaning nutrition was advantageous in achieving puberty in ewe lambs.

In a 1-year study of 158 ewe lambs of various breeds, Southam et al. (1971) found that range supplemented with .8 kg alfalfa pellets daily was adequate to provide the necessary growth to induce puberty in ewe lambs. The drylot lambs in the study, which were fed alfalfa pellets ad libitum, had higher but nonsignificant rates of pregnancy

(82 vs 73% of total) and percent lambing (74 vs 64%) when compared to the range lambs.

Jordan <u>et al</u>. (1970) found, when comparing two rations fed to 177 crossbred ewe lambs, the percentage of ewes conceiving and subsequently lambing was not affected by nutrition treatment from 10 to 24 weeks of age. Of the two rations compared, one permitted normal growth but restricted fattening (gain of .32 kg per day) and the other had enough corn added to produce maximum gains (.67 kg per day). The groups on the higher ration had a greater percentage of ewes showing estrus, more than two times during their first winter. This group also produced heavier lambs at birth. However, by 30 days of age there was no difference in lamb weights due to the nutrition of the dam.

#### Ewe Weight

Ch'ang and Rae (1972), in an ll-year study of a flock of Romney ewes, found yearling weight and subsequent fertility were positively correlated (r = .23). Subsequent fertility in this case was defined as the number of lambs born per ewe in her first three matings.

In a study involving 758 Columbia, Corriedale and Rambouillet range ewes, it was found that ewes heavier as yearlings weaned more kilograms of lamb during their lifetimes (Terrill and Stoehr, 1942). They found an inverse relationship between average lifetime body weight and kilograms of lamb produced per year when considered independently of yearling weight. These researchers suggested that ewes should be selected on the basis of prebreeding weight. Nichols and Whiteman (1966) found that yearling weight and average lifetime weight were positively correlated to lifetime production of lamb when analyzing the lifetime records of 164 Rambouillet and 3/4 Rambouillet-1/4 Panama ewes. Average lifetime weight, when adjusted to a common condition score, was correlated with total number of lambs born, total number of lambs raised, average lamb birth weight, average 70-day lamb weight (P<.01) and average lamb gain from 70 to 140 days of age (P<.01) with correlation coefficients (r) of .14, .09, .09, .24 and .28, respectively. Average lifetime condition score was negatively and nonsignificantly correlated with lifetime production, indicating that fatter ewes tend to be poorer producers.

Foote <u>et al</u>. (1959) found that yearling ewes having higher body weights shed a greater number of ova. The 449 ewes in this study were purchased as feeder lambs and allotted into two treatment groups. One group received a ration of hay only for 6 months, and the other received a ration of hay and grain (20% more TDN). The ewes on the higher plane of nutrition had a higher percentage of multiple ovulations than the ewes receiving only hay.

Lax and Brown (1967) found in over 400 Merino ewes 15 to 16 months of age that each 4.5-kg increase in body weight represented eight more lambs produced per 100 ewes bred. It was also reported that lamb survival increased with ewe body weight. For each 4.5-kg increase in ewe body weight, the ram and ewe lamb survival rates increased by 5 and 2%, respectively.

When observing 2,364 Rambouillet, 1,956 Targhee and 1,350 Columbia ewes, Hulet <u>et al</u>. (1969) found that ewes which showed estrus during their first winter had heavier weaning weights and fall body weights. Similarly, Levine <u>et al</u>. (1978) found when comparing 7-month (prebreeding) weights for 139 Columbia and Targhee ewe lambs over 5-year groups that the average weight of ewes which did lamb was greater than (up to 4.7 kg) or equal to that of ewes which did not lamb.

It was reported by Fletcher (1970) that for 189 mature Merino ewes with body weights from 42 to 57 kg there was a 1.3% increase in the number of twin ovulations per kilogram of weight. This increase was found to be due to inherent body weight differences regardless of feeding regime.

Evidence was found by Barlow and Hodges (1976) of a positive genetic correlation between weaning weight and reproductive performance of 190 Merino ewe lambs. Selection for weaning weight had an effect (P<.05) on the number of ewes lambing. Of the heavier ewes (average weight, 31.4 kg), 55% lambed compared with 20% of the lighter ewes (24.6 kg).

Another study (Curll <u>et al.</u>, 1975) involving 360 mature Border Leicester x Merino ewes showed that heavier ewes tended to produce more lambs per ewe bred. However, by the time the lambs were 10 weeks of age, there was little or no difference in numbers, partly due to dystocia problems in heavier ewes. These researchers reported that ewes weighing 44 kg at mating produced 107 lambs per 100 ewes bred and ewes weighing an average of 58 kg produced 152 lambs per 100 ewes.

#### Crossbreeding

Sidwell <u>et al</u>. (1964) in a study involving 4,331 lambs found crossbreeding to be a positive factor in improving weaning weights of lambs. Four-way cross lambs had average weaning weights 4.7 kg higher than purebred lambs. Three-way and two-way cross lambs had 4.3 and 2.4 kg higher weaning weights when compared to purebred lambs. The advantages of all crossbred lambs over purebred lambs involving the same breeds were 3.2 kg for weaning weight and .28 kg for birth weight.

Similar results were found by Sidwell and Miller (1971b) when comparing 299 Targhee and 63 Suffolk x Targhee lambs. Weights taken at weaning averaged 2.2 kg higher for the crossbreds as compared to the straightbred lambs.

Several researchers have found crossbred ewes to be superior to purebreds in nearly all lamb production traits. Vesely and Peters (1974) found fertility to be increased by crossbreeding, although prolificacy did not show improvement. In this study involving 18,181 lambs, survival ability of lambs was found to be increased by crossbreeding as was total weight of lambs marketed per ewe. Botkin and Paules (1965) and Southam <u>et al</u>. (1971) also found lamb production to be greater for crossbred ewes than for purebreds.

When studying livability of 3,621 purebred and crossbred lambs, Sidwell <u>et al</u>. (1962) found livability highest for lambs from crossbred ewes mated to purebred rams. The crossbred lambs from purebred ewes mated to a purebred ram of another breed had better survival rates than purebred lambs.

#### Wool Production

It has been shown in several studies that a ewe's wool production is dependent on several factors, including type of birth, age at first breeding, postweaning nutrition, breed and lamb production. In comparing clean fleece weights to grease weights, although shrinkage varies widely, on the average shorn grease wool shrinks about 55.5% (Ensminger, 1970).

Single ewes tend to shear heavier fleeces throughout their lifetimes. This difference is usually small and is often not statistically significant. Hazel and Terrill (1946b), Price <u>et al</u>. (1953), Slen and Bandy (1958, 1959), Lambe <u>et al</u>. (1964), Dun and Grewal (1963), Brown <u>et al</u>. (1966) and Sidwell and Miller (1971a) all found the fleece weights of single-born ewes to be heavier than those of twin ewes. For yearling fleeces, the differences for singles ranged from .05 kg (Lambe <u>et al</u>. 1964) to 15 kg (Dun and Grewal, 1963) more wool produced.

When analyzing 1,457 clean fleece weights of Canadian Corriedale, Rambouillet and Romnelet ewes, Slen and Banky (1958) found that the maximum clean fleece weight of twin ewes occurred at a slightly earlier age and began decreasing sooner than that of single ewes.

A ewe's wool production varies with her age as reported by Lush and Jones (1923), Slen and Banky (1958), Campbell (1962), Vesely <u>et al</u>. (1965), Brown <u>et al</u>. (1966), Nichols and Whiteman (1966) and Sidwell and Miller (1971a). It is generally observed that a ewe's wool production declines as age increases, although reports of the age of maximum production vary. Lush and Jones (1923) and Slen and Banky (1958) indicated that maximum wool production may occur as early as 2 years of age. Work by Spencer (1927) and Campbell (1962) showed a production peak at 3 years of age, which was similar to findings by Brown <u>et al</u>. (1966) of 3.5 years of age. Sidwell and Miller (1971a) found maximum production to occur later, from 4 to 7 years of age, with slightly lower wool weights reported for 3-year-olds and wool weights of 2-year-olds even lower than those of aged ewes 8 years and older.

Brown <u>et al</u>. (1966) found that the increase in wool weight from 1.5 to 3.5 years of age was due to an increase in the number of fibers, and the yearly decline thereafter of grease fleece weight of .09 to .14 kg per year was due to a decrease in volume. Work by Campbell (1962) showed that a ewe's fleece weight decreased 25% from 3 to 10 years of age.

Lush and Jones (1923) demonstrated that shearings 4 to 5 years apart showed a positive correlation (r = .52). Similarly, Hill (1921) found a high degree of correlation (r = .70) between the weight of wool produced in the first year and the average weights of fleeces produced in the two subsequent years when comparing clean fleece weights of 29 Rambouillet wethers in a drylot situation.

Sidwell <u>et al</u>. (1971) reported that for yearling ewes the average grease fleece weight of 25 Suffolk x Targhee crossbred ewes (3.70 kg) was less than that of 61 purebred Targhee ewes (4.82 kg). Of the nine crosses studied, the Suffolk x Targhee cross was the only one that showed a depression in fleece weight due to crossbreeding.

Southam <u>et al</u>. (1971) found that the average yearling grease fleece weight was higher for 71 ewes fed a high postweaning plane of nutrition as compared to that of 59 ewes fed a lower nutritional plane. The rations compared in the study were alfalfa pellets fed <u>ad libitum</u> in a drylot situation <u>vs</u> fall range plus .8 kg alfalfa pellets per day. These rations were fed during a 60-day prebreeding period.

When comparing 177 crossbred ewe lambs fed two different rations, Jordan <u>et al</u>. (1970) found that yearling fleece weights were significantly higher for the ewes on the fattening rations as compared to those of the ewes on the growing ration.

Vesely <u>et al</u>. (1965) reported that barren ewes had higher fleece weights than ewes which lambed. Seebeck and Tribe (1952) also found this to be true and found that ewes bearing single lambs had higher fleece weights than those bearing twins. Slen and Whiting (1956) found similar results when comparing single- and twin-bearing ewer. They also determined that both early and advanced pregnancy and lactation affect wool growth. However, the difference was averaged out for all ewes by the end of lactation.

When analyzing 2,424 grease fleece weights, Ray and Sidwell (1964) found that ewes lambing and lactating produced significantly less wool than open ewes. They found the effects of pregnancy to be less pronounced than those of parturition and lactation.

Studies indicate that breeding ewes to lamb as yearlings seems to have little or no effect on lifetime wool production. Briggs (1936) found that early breeding had no effect on wool production when studying

# SOUTH DAKOTA STATE UNIVERSITY LIBRARY

244 Hampshire-Rambouillet ewes. Hulet <u>et al</u>. (1969), in an experiment involving 2,634 Rambouillet, 1,956 Targhee and 1,350 Columbia ewes, found that there was no significant association of the incidence of early estrus and wool production. However, in the Targhee and Rambouillet ewes, lifetime grease fleece weights were slightly lower for those showing estrus in their first winter.

It was found by Tyrell (1976) that ewes bred at 8 months of age had 7% lower yearling fleece weights than those bred as yearlings, but there was no difference in succeeding years. Spencer <u>et al</u>. (1942) and Levine <u>et al</u>. (1978) found that breeding ewe lambs did cause a slight decrease in lifetime wool production.

#### Ewe Losses

Due to differences in management and environment, ewe losses from the herd, either due to death or culling or both, vary widely among flocks.

For 2,255 range ewes, Matthews <u>et al</u>. (1977) found that the average age of removal of ewes from the herd was similar for Targhee ewes bred to either Targhee or Suffolk rams and for Suffolk x Targhee ewes bred to Suffolk rams. The ages were 6.09, 6.29 and 6.10 years, respectively.

Campbell (1962) found ewe losses to average 4.6% per year over a 20-year period in a flock of Rambouillets in which the average flock size was 173 ewes. A lower average death rate of 2.2% per year for ewes 1.5 to 7.5 years of age was found by Turner <u>et al</u>. (1959) when studying a flock of 1,000 Merino ewes. During drought years this was

found to increase to 3.8% for ewes 1.5 to 6.5 years of age, with the increase for older ewes being much greater.

In a study involving 501 ewes, the percentage of 1- to 6-yearold ewes leaving the flock due to death was 3.2% of the original number of ewes (Slyter, 1968).

#### MATERIALS AND METHODS

#### **Objectives**

The objectives of this experiment were set in an effort to evaluate the wool and lamb productivity of range ewes while comparing different management practices. The objectives were:

- To determine whether single- or multiple-born (twin or triplet) ewes are more productive.
- To determine whether the common type of whiteface range ewe or whiteface-blackface crossbreds are more productive.
- To determine whether ewe lambs fed a high-energy ration or those fed a moderate ration postweaning are more productive.
- 4. To determine whether ewe lambs bred at 7 months of age, ewes not exposed until 19 months of age or ewes exposed but not bred at 7 months of age are more productive.

#### Management

The female progeny of 250 straightbred Targhee ewes were utilized in this study. These ewes were maintained at the South Dakota State University Antelope Range Field Station near Buffalo, South Dakota. In the autumn of 1970, these ewes were randomly assigned to two breeding groups. One group was exposed to Targhee rams and the other group was exposed to Suffolk rams. In subsequent years (1971 through 1974), the two groups of ewes had the breed of sire rotated between Targhee and Suffolk rams. These ewes were exposed each autumn for approximately 35 days, with the lambs born in late February and March.

After weaning at an average age of 70 to 80 days, the ewe lambs were trucked to the U.S. Irrigation and Dryland Field Station. Newell, South Dakota, in 1971 and the South Dakota State University Sheep Unit in the years 1972 through 1975 for their postweaning treatment. At this time, the ewe lambs were randomly assigned within type of birth groups, single or multiple (hereafter referred to as "twin"), and within breed groups to a high or moderate energy ration. These two rations were designed to supply approximately the NRC (1964) requirements for replacement ewe lambs (moderate energy) vs fattening lambs (high energy). All ewe lambs were fed in drylot for approximately 100 days on a 60% cracked coin (IFN 4-02-854), 40% alfalfa (IFN 1-00-111) ration. The moderate energy level group was hand fed what they would consume, up to 1.14 kg per head per day during the first 70 days of the trial, and 1.36 kg per head per day during the last 30 days. The high energy group was self-fed. The ration was fed in ground form in all years except 1972, when it was fed as a pellet.

After the postweaning feeding period, the lambs were randomly allotted within previous treatment groups to be exposed to rams at either 7 or 19 months of age. Two-thirds of the lambs were exposed for 34 days at 7 months of age and one-third were exposed for the first time when they were approximately 19 months of age. Finnsheep crossbred ram lambs

were used during all breeding seasons except 1972, when Columbia ram lambs were used. The rams' briskets were painted daily with dyecolored grease to determine which ewes had been bred.

Following the breeding season of the group exposed at 7 months of age, all groups were combined and managed as a single flock with the following exception: All ewes lambing at 12 months of age received supplemental grain prior to and following lambing and they nursed their lambs for approximately 60 days before the lambs were weaned in late May.

Each year during the first week in June, all yearling ewes were sold as a group under a research contract to producers in northwestern South Dakota who agreed to provide the university with subsequent lifetime production data. The ewes were then maintained on range sheep operations typical of that area.

No lambs in the study were culled, and mature ewes were culled only if they had unhealthy udders or had not lambed for 2 years in succession. Ram lambs were generally castrated within 10 days of birth. If rams were left intact, it was random across all treatments within location. All lambs within a production unit were weaned as a group. Ewes were shorn prior to lambing and their fleeces were tied and weighed on a hanging dial scale. Their lambing date was recorded and their lambs were ear tagged and weighed within 24 hours after birth.

#### Data Collected

The data presented are for ewes born in the years 1971 through 1975 and their production data collected through and including 1977.

In this study, 1,458 ewes lambed as a result of 1,749 matings. Ages given (i.e, 12 months) for annual production data are approximate.

Preweaning data for the ewes include year of birth, birth weight, type of birth, breed of sire and weaning weight. Information collected on all ewes at or after the end of the postweaning period included total feed consumption, body weight, wither height and age at first breeding. Subsequent yearly data collected included date of lambing, number of lambs born, sex of lambs, number of lambs weaned, weaning date of lamb crop, lamb weaning weight, fleece weight and ewe weight and wither height at weaning of the lamb crop. Deaths of ewes and lambs were noted and categorized as to cause whenever possible. Producers were often assisted by university personnel at times of data collection.

Data reported for ewes in this study were year of birth, type of birth, breed of sire and age at first breeding. Yearly production data reported included fleece weight, number of lambs born, sex of lambs, number of lambs weaned and lamb weaning weight.

#### Statistical Analysis of Data

Statistical procedures in all analyses were performed according to Steel and Torrie (1960). In this manuscript, the levels of probability considered were .05, .01 and .005 for all F-tests. The Tukey and Chisquare tests were performed at the 5% level.

Comparisons of treatments (breed of sire, age at first breeding, postweaning nutrition, type of birth and year) were performed using a least squares analysis of variance with one- or two-way classifications. When there were significant differences between treatments as determined

by the F-test, Tukey's  $\omega$  procedure was employed for mean comparisons. One-way Chi-square analyses were used in comparing lambing percentages of different groups of ewes.

Because of the large amount of data in this study, discussion of individual significant two-way interactions will be deleted. These data are presented in tabular form in the appendix. Nearly all the interaction differences that were significant (P<.05) were magnitude differences rather than rank differences. Analysis of variance and Chi-square analysis of variance are shown in the appendix tables.

#### RESULTS AND DISCUSSION

#### Prebreeding Growth

In order to determine if differences existed between treatment groups prior to administration of any treatment, ewe date of birth, birth weight and weaning weight were analyzed. Weight and wither height measurements were taken at 7 months of age and a ratio was computed to aid in determining if size at this age affected productivity. Factors considered in the analysis were year, type of birth, breed of sire, postweaning nutrition and age at first breeding. These results are presented in table 1.

Birth date differed (P<.005) by year, due in part to different breeding dates imposed by management.

Birth weights were different (P<.005) within all factors except age at first breeding. Single ewes were .80 kg heavier than twins. This agreed with results of studies reported by Lambe <u>et al</u>. (1964) and Vesely and Peters (1964). Suffolk x Targhee ewes were .42 kg heavier at birth than Targhees, which was similar to results obtained by Sidwell <u>et al</u>. (1964). By chance those ewes on the higher plane of nutrition were .16 kg heavier at birth than the ewes on the moderate ration. Birth weights for ewes born in different years ranged from a high of 5.01 kg in 1974 to a low of 4.60 kg in 1971.

Weaning weights differed (P<.005) within breed of sire, type of birth and year groups. The Suffolk x Targhees weaned 2.37 kg heavier than the Targhees, which agreed with research reported by Sidwell <u>et al</u>. (1964) and Sidwell and Miller (1971b), with weaning weights 2.2 kg to

\*\*\* P<.005.

3.2 kg heavier. The single ewes were 5.09 kg heavier than the twins. This was supported by several studies including those by deBaca <u>et al</u>. (1956), Bailey <u>et al</u>. (1961), Lambe <u>et al</u>. (1964), Sidwell and Miller (1971b) and Vesely and Peters (1972). The ewes weaned in 1971 were lightest at 22.50 kg and the ewes weaned in 1974 were heaviest at 31.61 kilograms.

Significant effects were observed in prebreeding weight (at 7 months of age) for all factors reported except age at first breeding. The single ewes were 4.8 kg heavier than the twins. The Suffolk x Targhees were 4.6 kg heavier than the Targhees. The ewes which had been on the higher plane of nutrition were 5.4 kg heavier than those on the moderate ration. Overall, the 1971 group was lightest at 41.5 kg and the 1973 group was heaviest at 52.6 kilograms.

Wither height differed (P<.005) within type of birth, postweaning nutrition and year groups. There was also a difference (P<.05) between age at first breeding groups. Single ewes were 1.52 cm taller than twins. Those ewes on the higher plane of nutrition were 1.48 cm taller than the ewes on the moderate ration. The ewes that were bred at 7 months of age were .78 cm taller than the ewes which were exposed but not bred at 7 months. The 1974 ewes were tallest at 63.30 cm and the 1971 ewes were shortest at 58.22 centimeters.

The weight:height ratio (calculated from data taken at 7 months of age) differed (P<.005) for all factors except age at first breeding. A higher ratio indicated more weight per centimeter of height or a fatter animal. Single ewes had higher ratios than twins, Suffolk x

Targhees had higher ratios than Targhees and ewes on the higher nutritional plane had higher ratios than ewes fed less. Ewes born in 1973 had the highest ratio and the 1971 ewes had the lowest ratio.

#### Annual Weight

The results of the analysis done on annual ewe weights are found in tables 2 and 3. The significance of the factors decreased with age. The weight of single ewes was consistently heavier than that of twins. The Suffolk x Targhee tended to be heavier than the Targhees. Postweaning nutrition was significant (P<.005) only at 12 months of age, indicating that the extra nutrients accelerated the growth process but did not alter mature weight. Age at first breeding was significant at 12 months (P<.005) and at 72 months (P<.01). At 12 months, the ewes which were bred at 7 months were lighter than ewes from the other two groups, indicating that by allowing ewe lambs to remain open one can expect more weight gain. At 72 months, the ewes first bred at 7 months were lighter than those first exposed at 19 months. The weight of ewes exposed but not bred at 7 months did not differ significantly from either of the other two groups. The significance at this age may have been due in part to low numbers and/or culling practices.

Briggs (1936) reported similar results, indicating that earlybred ewes took 10 months longer to reach mature weight, but by 31 months of age there was no difference between groups.

When comparing average weights for the entire flock (table 2) <u>vs</u> those of ewes weaning a lamb[s] (table 3), the same general pattern of significance was seen with the exception of one factor. Postweaning

\*\*\* P<.005.

nutrition caused no difference at 12 months of age in the group of ewes weaning a lamb(s).

Those ewes weaning a lamb(s) tended to be lighter than the overall group. Suggestions are numerous as to why this was observed. One possibility was that open ewes, not enduring the stress of pregnancy and lactation, weighed more. Some studies indicate that heavier ewes are poorer producers. Terrill and Stoehr (1942) found an inverse relationship between body weight and kilograms of lambs produced per year when considered independently of yearling weight. Nichols and Whiteman (1966) found average lifetime condition score to be negatively correlated with lifetime production, indicating that fatter ewes tend to be poorer producers. Curll <u>et al</u>. (1975) found that heavier ewes at breeding tended to produce more lambs, but by the time the lambs were 10 weeks of age there was little or no difference in numbers.

#### Annual Wither Height

The results of the analysis of height data are found in table 4. Age at first breeding was not a significant factor in wither height of the ewes. When type of birth was significant, the single ewes were taller. The Targhees were taller than the Suffolk x Targhees. Postweaning nutrition was significant only at 12 months when those ewes on the higher ration were taller.

For those ewes weaning a lamb(s), less significant differences were found (table 5), but the same trend was seen. Where significance was noted, it was shown that single ewes were taller, Targhees were

TABLE 5.	LEAST	SQUARES	MEANS	AND	STANDARD	ERRORS	FOR	ANNUAL	WITHER	HEIGHT	(CM)	
			OF THO	DSE 1	EWES WEAN	ING A LA	MB (S	5)				

a T = Targhee, S x T = Suffolk x Targhee. b,c,d Means with different superscripts in the same column and within main effect differ (P<.05).

\* P<.05. \*\* P<.01. \*\*\* P<.005.

taller and ewes first exposed at 19 months were taller than ewes bred at 7 months.

When the two groups were compared, it was seen that those ewes weaning a lamb(s) were shorter than the overall group. When weight was also considered, it appears that smaller mature ewes (shorter and lighter) wean a lamb(s) more often.

# Date of Lambing

The results of this portion of the study are presented in table 6. Type of birth was a significant factor but was not consistent. At 12 and 24 months, the single ewes lambed earlier and at 48 months the twin ewes lambed earlier. At 12 and 24 months, the single ewes may have been cycling earlier in the fall as a result of the extra mutrition received as single lambs.

Breed was significant at 12, 36 and 48 months but was not consistent. The Suffolk x Targhees lambed earlier at the two younger ages, and the Targhees lambed earlier at 48 months. Postweaning nutrition was not a significant factor, and age at first breeding was significant only at 48 months, with those ewes exposed but not bred at 7 months lambing later than the other two groups. Year was highly significant at all ages.

# Percentage of Ewes Lambing of Those Exposed

The results of this Chi-square analysis are presented in table 7 and figure 1. As a result of 1,749 matings, 1,458 ewes lambed. This resulted in an 83.4% overall percentage, which was used as the basis for comparison.

# TABLE 7. PERCENTAGE OF EWES LAMBING OF THOSE EXPOSED

a T = Targhee, S x T = Suffolk x Targhee. b Does not include 7-month breeding. Including 7-month breeding, percentage was 76.5 (705) lambing/922 exposed).

\* P<.05.

\*\* P<.01.

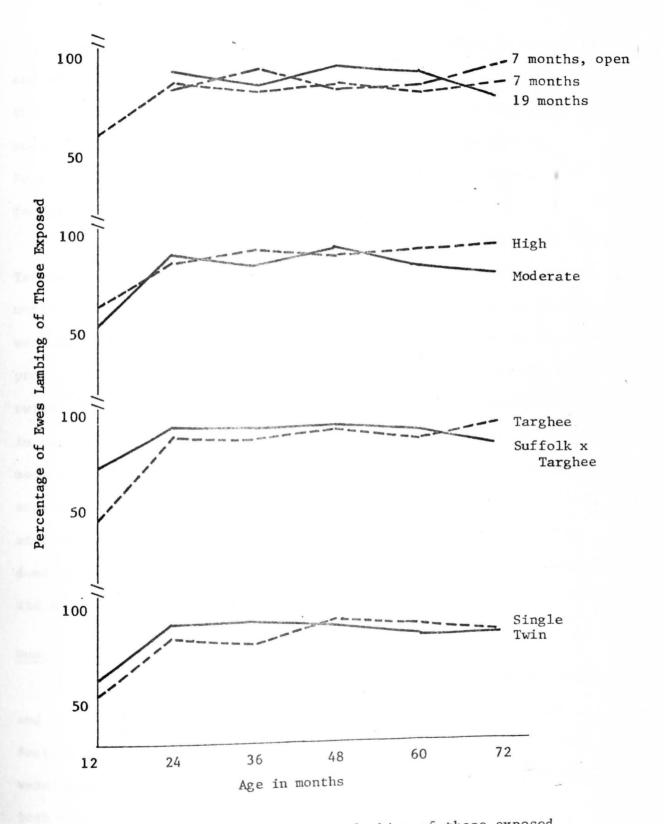

Figure 1. Percentage of ewes lambing of those exposed.

Significant differences between breeds were found at 12 months and overall. An average of 7.4% more Suffolk x Targhee ewes lambed than did Targhee ewes. Type of birth was significant at 24 and 36 months and overall with a higher percentage of the twins lambing. Postweaning nutrition and age at first breeding were not significant factors.

In looking at figure 1, it can be seen that the Suffolk x Targhees had a higher lambing percentage than straight Targhee ewes until 72 months of age. At this age, numbers were low and reliability was somewhat decreased. Singles, it seems, took longer to reach maximum productivity, but, once it was attained, they were as productive as twins. The two nutrition groups showed no difference in productivity in early years, although by 72 months it appeared that ewes on the moderate ration may have been less productive. Age at first breeding seemed to have no consistent effect, except that those ewes first bred at 7 months averaged slightly lower than the other two groups. This does not take into account the 12-month lamb crop, because some ewes did not have the opportunity to lamb at 12 months of age.

# Number of Lambs Born and Weaned Per Ewe Exposed and Bred

The results of these analyses are presented in tables 8, 9, 10 and 11. Ewe breed and year were the only consistently significant factors in this portion of the study. The only exceptions were postweaning nutrition at 12 months and age at first breeding at 24 months, both for number of lambs weaned per ewe lambing.

TABLE 11. LEAST SQUARES MEANS AND STANDARD ERRORS FOR NUMBER OF LAMBS WEANED PER EWE LAMBING

a T = Targhee, S x T = Suffolk x Targhee. b,c,d Means with different superscripts in the same column and within main effect differ (P<.05).

\* P<.05.

When breed was significant, Suffolk x Targhees were superior in all cases. Botkin and Paules (1965) and Southam <u>et al</u>. (1971) also found lamb production to be greater for crossbreds than for purebreds.

# Kilograms of Lamb Weaned Per Ewe Weaning a Lamb

These data are presented in table 12. Ewe type of birth was significant at 36 and 48 months. The twin ewes produced more kilograms of lamb. Breed was significant at all ages except 72 months. With the exception of the 24-month production, the Suffolk x Targhees produced more lamb than the Targhees. Postweaning nutrition was significant only at 36 months, with the ewes on the moderate ration being more productive. Age at first breeding was a significant factor at 24, 36 and 48 months. The results were not entirely consistent, although at 36 and 48 months those ewes first exposed at 19 months were the most productive and the ewes first breed at 7 months were least productive. Year was significant at 12 and 36 months. Lamb type of birth was significant at 24, 36, 48 and 60 months. In all cases, the more lambs born, the more kilograms of lamb were weaned.

In this portion of the study, it was shown that postweaning nutrition does not affect lifetime lamb productivity, that twin ewes are generally more productive and that Suffolk x Targhees generally Produce more kilograms of lamb than Targhees. The results of crossbreeding are similar to those found by Botkin and Paules (1965), Southam <u>et al.</u> (1971) and Vesley and Peters (1974).

# Lamb Weaning Weight

The results of this portion of the study are found in table 13. Ewe type of birth had little effect on lamb weaning weight. There was a significant difference at 36 months, with lambs from twin dams being heavier. This tends to agree with the findings of Terrill and Stoehr (1942). Ewe breed was significant at 12, 36 and 48 months. The lambs from Suffolk x Targhee dams were heavier. This agreed with results reported by Sidwell et al. (1964), which showed that three-way cross lambs were heavier than two-way crosses which were heavier than purebreds at weaning. Postweaning nutrition was significant only at 36 months. Age at first breeding was significant at 36 and 60 months but with no consistency in the results. Year was significant at 12, 24 and 36 months. Lamb type of birth was significant at all ages, with singles always weighing more than twins. This agreed with data from the parent ewes. Because of the low numbers, the weight differences of triplets were inconsistent. deBaca et al. (1956), Bailey et al. (1961), Lambe et al. (1964), Sidwell and Miller (1971b) and Vesely and Peters (1972) all found singles to have heavier weaning weights than twins. Sex of lamb was significant only at 36 months, with the male lambs being heavier. These results were inconsistent with most of the literature. Hazel and Terrill (1946a), Slen and Banky (1959), Bennett et al. (1963), Vesely et al. (1966) and Sidwell and Miller (1971b) all found that male lambs, whether rams or wethers, weaned heavier than ewe lambs.

# Wool Production

The results of the wool production analyses can be found in table 14. Wool production is shown only for ewes weaning a lamb(s). Type of birth was significant only at 12 months, with singles shearing heavier (P<.01) fleeces. Singles continued to shear heavier fleeces, although not significantly as age progressed. This corresponded well with the literature. The literature revealed that single ewes tended to shear heavier fleeces in their lifetimes, although the difference was usually small and not significant. This was reported by Hazel and Terrill (1946b), Price <u>et al</u>. (1953), Slen and Banky (1958, 1959), Dun and Grewal (1963), Brown <u>et al</u>. (1966) and Sidwell and Miller (1971a). The difference of .15 kg in yearling fleece weight reported by Dun and Grewal(1966) was similar to the .19 kg reported in this study.

At all ages, Targhees sheared heavier (P<.005) fleeces by as much as .74 kilogram. The difference at 12 months, .48 kg (3.30 <u>vs</u> 2.82 kg), was less than that reported by Sidwell <u>et al</u>. (1971) of 1.12 kg (4.82 <u>vs</u> 3.70 kg) in a study involving Targhee and Suffolk x Targhee ewes.

Postweaning nutrition was significant only at 12 months, with ewes on a higher plane of nutrition having fleeces .17 kg heavier (P<.05) than the ewes fed a moderate ration. This advantage, although not significant, continued until the ewes were 60 months of age. Both Jordan <u>et al</u>. (1970) and Southam <u>et al</u>. (1971) found yearling fleece weights to be higher for ewes fed on a higher postweaning plane of nutrition.

LEAST SQUARES MEANS AND STANDARD ERRORS FOR FLEECE WEIGHT (KG) FOR EWES WEANING A LAMB(S) TABLE 14.

 $a_{T}$  = Targhee, S x T = Suffolk x Targhee. b,c,d,e Means with different superscripts in the same column and within main effect differ (P<.05).

\* P<.05.

\*\* P<.01.

Age at first breeding was a significant factor only at 24 months, with the ewes exposed but not bred at 7 months of age having heavier (P<.005) fleeces than ewes from both remaining groups. This difference may be due in part to the fact that this group had a lower lambing percentage than the other two groups the preceding year, thus increasing wool production. The results of a study by Ray and Sidwell (1964) showed that ewes lambing and lactating produced significantly less wool than open ewes.

Results of analyses of data from succeeding shearings showed no consistent difference in wool production for ewes bred first as lambs <u>vs</u> those bred as yearlings, which was somewhat different from the results found in the literature. Spencer <u>et al.</u> (1942) and Levine <u>et al.</u> (1978) found that breeding ewe lambs did cause a decrease in lifetime wool production. Tyrell (1976) found that after a 7% difference at 12 months of age there was no difference in succeeding years. Hulet <u>et al.</u> (1969) found that there was no significant association of the incidence of early estrus and wool production on an overall comparison in a study involving Targhee, Rambouillet and Columbia ewes; but within the Targhee group, the lifetime fleece weights were lower for those showing estrus in their first winter.

Year effects on wool production were highly significant at 12, 24, 36 and 60 months.

# Ewe Losses

Table 15 lists the causes of ewe losses from the flock from the beginning of the study through and including 1977. The "unknown" category includes all ewes missing with no date of death or those having a reported date of death but with no recorded reason. Also included in this group were any ewes whose identity was lost. Those ewes listed as having been culled were culled either for having bad udders, a bad mouth or failure to lamb for two consecutive years. Suspected predator losses were recorded as unknown unless the kill was verified by actual sight or examination of the carcass.

Table 16 shows the percentages of ewes remaining in the flock each year. Out of 607 ewes, 203 or 33.4% were lost from the flock over the 6-year period.

Cause of loss	No. (607)	Percentage of total loss
Unknown	130 (21.4) <sup>a</sup>	64.0
Culled	23 ( 3.8)	11.3
Vaginal prolapse	14 ( 2.3)	6.9
Rectal prolapse	12 ( 2.0)	5.9
Lambing problems	6 ( 1.0)	3.0
Other	18 ( 3.0)	8.9
Total	203 (33.4)	100.0

#### SUMMARY

The objectives of this study were to determine which combinations of factors (traditional <u>vs</u> innovative) would result in the greatest lamb and wool production from ewes on a typical range operation. The factors studied were type of birth, breed, postweaning nutrition and age at first breeding.

Breed was the only factor studied which affected wool production. Targhee ewes were clearly superior to Suffolk x Targhee ewes in this trait. Single ewes and ewes on the higher plane of nutrition tended to shear heavier fleeces, although not significantly so. Age at first breeding did not affect wool production consistently.

Lamb production was affected most by ewe breed, with the crossbred ewes being superior over the straightbred ewes. The higher energy ration postweaning had a positive effect, although not significantly so. Type of birth results were in favor of twin ewes when there was a difference. Age at first breeding did not consistently affect lamb production.

In conclusion, it may be determined from this study that age at first breeding and postweaning nutrition do not affect annual lamb and wool production of mature ewes, that twin ewes tend to produce more lamb and that straightbred Targhees produce more wool while Suffolk x Targhees Produce more lamb.
