BACKGROUND & AIMS: Little is known about the link between pathophysiologic factors and symptoms of irritable bowel syndrome (IBS), or whether these factors have cumulative effects on patient-reported outcomes (PROs). We investigated whether pathophysiologic alterations associated with IBS have cumulative or independent effects on PROs. **METHODS:** We performed a retrospective analysis of data from 3 cohorts of patients with IBS ($n = 407$; 74% female; mean age, 36 ± 12 years), based on Rome II or Rome III criteria, seen at a specialized unit for functional gastrointestinal disorders in Sweden from 2002 through 2014. All patients underwent assessments of colonic transit time (radiopaque markers); compliance, allodynia, and hyperalgesia (rectal barostat); anxiety and depression (Hospital Anxiety and Depression scale), as pathophysiologic factors. Dysfunction was defined by available normal values. PROs included IBS symptom severity, somatic symptom severity, and disease-specific quality of life. **RESULTS:** Allodynia was observed in 36% of patients, hyperalgesia in 22%, accelerated colonic transit in 18%, delayed transit in 7%, anxiety in 52%, and depression in 24%; each of these factors was associated with severity of at least 1 symptom of IBS. Rectal compliance was not associated with more severe symptoms of IBS. At least 3 pathophysiologic factors were present in 20% of patients, 2 in 30%, 1 in 31%, and none in 18%. With increasing number of pathophysiologic abnormalities, there was a gradual increase in IBS symptom

severity ($P < .0001$) and somatic symptom severity ($P < .0001$), and a gradual reduction in quality of life ($P < .0001$). **CONCLUSION:** Visceral hypersensitivity, including allodynia and hyperalgesia, abnormal colonic transit, and psychologic factors are all associated with IBS symptoms. These factors have a cumulative effect on gastrointestinal and non-gastrointestinal symptoms, as well as on quality of life, in patients with IBS and are therefore relevant treatment targets.

Keywords: Visceral Hypersensitivity; Colonic Transit; Psychologic Distress; Patient-Reported Outcomes.

Abbreviations used in this paper: ANOVA, analysis of variance; GI, gastrointestinal; GSRS-IBS, Gastrointestinal Symptom Rating Scale-IBS; HAD, Hospital Anxiety and Depression scale; IBS, irritable bowel syndrome; IBSQOL, Irritable Bowel Syndrome Quality of Life Questionnaire; IBS-SSS, IBS severity scoring system; PHQ-15, Patient Health Questionnaire-15; PRO, patient-reported outcome; VAS, visual analogue scale.

WHAT YOU NEED TO KNOW

BACKGROUND AND CONTEXT

Little is known about the link between pathophysiologic factors and symptoms of irritable bowel syndrome (IBS), or whether these factors have cumulative effects on patient-reported outcomes.

NEW FINDINGS

Visceral hypersensitivity, including allodynia and hyperalgesia, abnormal colonic transit, and psychologic factors are all associated with IBS symptoms, and have a cumulative effect on symptoms and QOL in IBS.

LIMITATIONS

Some important pathophysiologic factors in IBS, eg, factors in the gut microenvironment, were not investigated in this study.

IMPACT

The cumulative effect of visceral hypersensitivity, abnormal colonic transit, and psychologic factors on patient-reported outcomes in IBS highlight the importance of gut-brain interactions, and indicate that these pathophysiologic factors constitute relevant treatment targets.

Irritable bowel syndrome (IBS) is a common functional gastrointestinal (GI) disorder, characterized by abdominal pain associated with abnormal bowel habit, but patients also often suffer from other GI and non-GI symptoms, including psychologic symptoms and psychiatric comorbidity.¹ The efficacy of available therapeutic options for this large group of patients is limited, which partly relates to the fact that mechanisms underlying symptom generation are incompletely known.^{2,3} The pathophysiology of IBS is considered to be complex and most likely multifactorial, and abnormal gut-brain interactions are considered to be of great importance.⁴ Of the individual pathophysiologic factors, visceral hypersensitivity,⁵⁻⁸ abnormal GI motor function,^{5,6,9} and abnormal brain function with abnormal central processing of visceral afferent signals, which may be driven by psychologic symptoms modulating the processing and perception of these signals,¹⁰⁻¹² have all been widely studied and are believed to be of importance for symptoms in subsets of patients with IBS. Factors in the gut microenvironment are increasingly being recognized as belonging in the pathophysiologic model of IBS as well.^{4,13-17} However, the relevance of these factors for symptom generation and severity in IBS is largely unknown.

Visceral hypersensitivity is one of the best characterized pathophysiologic abnormalities in IBS. It consists of 2 components: allodynia, which means that an innocuous stimulus is perceived as painful, and hyperalgesia, which means an enhanced pain response (ie, a painful stimulus is felt more intensely).¹⁸ In IBS, most studies have focused on a lowered pain threshold as a marker of visceral hypersensitivity, which reflects allodynia.^{6-8,19,20} However, increased perceived intensity of a painful stimulus (ie, hyperalgesia) also has been reported.^{5,7} Several studies

have demonstrated an association between presence of visceral hypersensitivity, mostly defined as lowered rectal or colonic pain thresholds, and IBS symptom severity,^{6,7,21} and this can be observed even after controlling for psychologic symptoms and general symptom reporting.²² There are also studies that have demonstrated an association between intensity ratings (visual analogue scales, VAS) during painful rectal balloon distensions, reflecting hyperalgesia, and IBS symptom severity.⁷ Moreover, in studies assessing colorectal sensitivity, in which compliance is frequently measured as well, reduced rectal compliance has been reported in patients with IBS in some studies, but the association of this with IBS symptom severity is also less well established.^{20,21}

Abnormal GI motor function is another hallmark pathophysiologic factor in IBS, although a specific motor pattern for IBS has not been identified and clear correlations between motility findings and symptoms have been difficult to demonstrate.^{23,24} However, measurement of colonic or oroanal transit time as an indirect measure of colonic motility shows more consistent findings, with colonic transit abnormalities being associated with IBS subtype in that accelerated transit is seen predominantly in patients with diarrhea, and delayed transit in patients with constipation.^{5,9,25-27} Moreover, even though it has been hard to associate specific motility abnormalities in IBS with pain severity,⁵ some studies have found transit to be weakly but significantly associated with pain and/or bloating, in addition to the association with bowel habit abnormalities.^{9,27}

Psychologic symptoms, such as anxiety and depressive symptoms, in more severe cases fulfilling the criteria for comorbid anxiety or depressive disorders, are common in patients with IBS,²⁸ and the presence of comorbid anxiety and depressive symptoms or syndromes is associated with the overall GI symptomatology.²⁹ In the latest edition of the diagnostic criteria for functional GI disorders, the Rome IV criteria, these disorders are referred to as *disorders of gut-brain interaction*, highlighting the importance of not only the gut but also the brain in symptom generation in these conditions.³⁰ Indeed, altered central nervous system or brain function has been demonstrated in patients with IBS compared with control subjects using brain imaging.¹¹ However, in one study the group brain differences between IBS and healthy controls disappeared when controlling for anxiety and depression,³¹ which indirectly suggests that measures of anxiety and depression can be used as proxy measures for abnormal brain function in patients with IBS, although abnormal brain dysfunction in IBS may indeed exist irrespective of anxiety and depression according to other studies.³²

Few studies have investigated how the different pathophysiologic factors in IBS relate to each other and how they interact to influence symptoms, that is, whether they are individually independent pathophysiologic factors or whether they are correlated in their presence and impact on symptoms. Visceral hypersensitivity is associated with psychologic factors, but its association with GI symptoms is not solely explained by psychologic factors.^{7,22,33} The association between visceral hypersensitivity and GI motility has

been assessed in a small number of trials with inconsistent results and with no attempts to assess their combined influence on symptoms.^{6,20} The association between GI motility and psychologic factors such as stress, anxiety and depression has been established with different methodologies,^{34,35} but their combined influence on symptoms has not been evaluated. In line with the current view on functional GI disorders as disorders of gut-brain interaction,³⁰ it seems reasonable to hypothesize that different factors involved in the complex pathophysiology of IBS may interact and influence symptoms in a cumulative fashion in these patients, but evidence from studies supporting this is not available. However, it also may be possible that these factors do not act cumulatively but instead influence symptoms in an independent way, which was suggested for colorectal motility and visceral hypersensitivity in one study.⁶

Therefore, the aim of the present study was to evaluate whether key pathophysiologic factors have a cumulative effect on symptoms and disease-specific quality of life in IBS. Specifically we aimed to determine the presence of visceral hypersensitivity as reflected by allodynia and hyperalgesia, abnormal rectal compliance, delayed or accelerated colonic transit, reflecting abnormal colonic motility, and anxiety and depression symptoms, reflecting abnormal brain function, and to evaluate how the presence of one or more of these influence relevant patient-reported outcomes (PROs) in IBS, that is, IBS and overall somatic symptom severity, and IBS-specific quality of life.

Materials and methods

Subjects

We included subjects with IBS aged 18 to 70 years from 3 prospective cohort studies that were conducted to assess the relevance of different pathophysiologic factors for IBS symptoms. For this study, we included only subjects who had completed measurements of rectal sensitivity and compliance, colonic (eg, oroanal) transit time, anxiety and depression, severity of GI and overall somatic symptoms and disease-specific quality of life (see later in this article for details; investigations and questionnaires completed within a 2-week period). The patients in the first cohort were included between 2002 and 2007, patients in the second cohort between 2007 and 2010, and patients in the third cohort between 2010 and 2014. The patients were included at a specialized unit for functional GI disorders at the University of Gothenburg, Sweden, and predominantly referred to the unit from primary care, but self-referral was also accepted. All patients were seen by a gastroenterologist (HT or MS) who confirmed the diagnosis based on a typical clinical presentation and additional tests if needed. However, most patients had already undergone sufficient examinations before referral. All patients fulfilled the current diagnostic criteria at the time of inclusion, that is, the Rome II criteria up to 2006,³⁶ and the Rome III criteria thereafter.³⁷ The patients were subtyped according to predominant bowel habit based on the Rome II or III recommendations,^{36,37} and defined as diarrhea-predominant or constipation-predominant IBS, whereas patients with IBS with mixed/alternating type and unsubtyped IBS were combined into 1 group for the analyses in this study (ie, nonconstipation- or

diarrhea-predominant IBS; nonC or nonD). Exclusion criteria were as follows: other GI disease(s) explaining the patient's symptoms; other severe disease(s) such as malignancy, severe heart disease, kidney disease, or neurological disease; symptoms indicating other severe disease(s) such as GI bleeding, weight loss not explained by altered eating habits; fever; severe psychiatric disease being the dominant clinical problem; a history of drug or alcohol abuse within 6 months before enrollment; or pregnancy at the time of the study. All subjects refrained from the use of drugs affecting GI function at least 48 hours before the investigations. The studies were approved by the Regional Ethical Review Board in Gothenburg, and all patients gave verbal and written informed consent before any study-related procedures were undertaken.

Pathophysiologic Measures

In all studies, a rectal barostat test, a measure of colonic transit (eg, oroanal transit time), and a questionnaire to assess anxiety and depressive symptom severity were included. However, the protocols used differed slightly between study cohorts (see later in this article). Other measures of potential relevance for IBS pathophysiology were included in the study protocols as well, but these were not consistent between the study protocols, have been reported elsewhere,^{16,17,38–45} and were not included in the analyses presented here. A proportion of the subjects have been included in previous publications focusing on the individual abnormalities assessed in this study,^{9,20,22} but not including the specific analyses performed in this study.

Oroanal transit time. The subjects ingested 10 radiopaque markers every morning for 5 days. On the sixth day they ingested 5 radiopaque markers in the morning and 5 at 8 PM. On the seventh day, the subject came to the laboratory at 8 AM and the remaining radiopaque markers were counted using fluoroscopy (Exposcop 7000 Compact; Ziehm GmbH, Nürnberg, Germany). Oroanal transit time (days) was calculated by dividing the number of remaining radiopaque markers by 10 (ie, the daily dose of radiopaque markers). To define accelerated and delayed oroanal transit time we used normal values (5th and 95th percentile) obtained from investigations in 199 healthy volunteers at our laboratory (women 0.9–3.9 days; men 0.7–2.1 days).^{9,27,46–48}

Rectal barostat. Two different rectal barostat protocols were used to study rectal sensitivity and compliance. In the first and second cohorts we used a protocol with phasic isobaric distensions lasting 30 seconds followed by a 30-second interval at the individual operating pressure.^{7,20} Distensions were performed with stepwise increments starting at the individual operating pressure and increasing 5 mm Hg until the subject reported pain or when a pressure of 70 mm Hg was reached. At the end of this protocol (ie, at the pain threshold), the intensity of pain was rated by the patients using VAS. For this study, the pain threshold (mm Hg) was used as a measure of allodynia, and the VAS pain intensity rating at the pain threshold was used as a measure of hyperalgesia. The first 5 distension steps of the pressure-volume curves were used for analysis of compliance, as the initial part of the curve is linear, which enables quantification of dynamic compliance as the linear slope of the curve. Furthermore, data up to the fifth distension step were available in most subjects, because most subjects had not yet reached the pain threshold at this step.²⁰

To identify patients with allodynia, hyperalgesia, and increased/decreased compliance, respectively, we used normal values (5th and 95th percentile) obtained from investigations in 35 healthy volunteers at our laboratory (pain threshold <31 mm Hg; pain intensity at pain threshold >54 mm; compliance 2.9–10.4 mL/mm Hg).^{7,20,22} In the third cohort, allodynia (pain threshold) and compliance were measured by using ramp inflations starting from 0 mm Hg with 4 mm Hg increments every minute until the subject reported pain.^{22,49} The balloon pressure at half the maximum observed volume was used as a summary value for compliance, whereby a smaller pressure corresponds to higher compliance.⁴⁹ After the ramp inflations, 60-second phasic distensions of 12, 24, 36, and 48 mm Hg above the operating pressure were each applied once in random order. The subjects rated the intensity of sensations of gas, urgency, discomfort, and pain at each of these distensions. For the purpose of this study, the pain threshold (mm Hg) was used as a measure of allodynia, and pain ratings at the 24 mm Hg distension were used as measure of hyperalgesia, because this was in the painful range for most subjects. To identify patients with allodynia, hyperalgesia, and increased/decreased compliance, respectively, we used normal values (5th and 95th percentile) obtained from investigations in 50 healthy volunteers at our laboratory (pain threshold <20 mm Hg; pain intensity at 24 mm Hg phasic distension >76 mm; compliance (pressure at half maximal volume): 12–27 mm Hg).²²

Anxiety and depression. The presence of anxiety and/or depressive symptoms was used as a proxy measure for abnormal central nervous system or brain function, hence abnormal central processing of visceral afferent signals, in this study. All patients completed the widely used and thoroughly validated Hospital Anxiety and Depression scale (HAD), and the validated cutoff score of >7 on either the anxiety or depression subscales was used to define abnormality.^{50,51}

PRO Instruments

In all 3 cohorts, the patients completed questionnaires to assess IBS symptom severity, overall somatic symptom severity, and disease-specific quality of life. However, the questionnaires used differed between the cohorts (see later in this article).

IBS symptoms. In the first cohort, the Gastrointestinal Symptom Rating Scale-IBS (GSRs-IBS) was used to determine IBS symptom severity. GSRs-IBS consists of 13 questions, summarized in 5 domains (abdominal pain, bloating, constipation, diarrhea, and satiety).⁵² In the second and the third cohort, IBS symptom severity was determined using the IBS severity scoring system (IBS-SSS), and this questionnaire is based on 5 items: severity and frequency of abdominal pain, severity of abdominal distension, dissatisfaction with bowel habits, and interference of IBS with daily life.⁵³ The patients also completed a stool diary for 1 week using the Bristol Stool Form scale⁵⁴; from these diaries, information about average stool frequency and average stool consistency over a week was obtained.

Overall somatic symptoms. We used 2 different measures of overall somatic symptom severity, often referred to as somatization. Patients in the first cohort completed the Symptom Checklist-90, a questionnaire developed to measure psychological symptom patterns of psychiatric and medical patients.⁵⁵ It consists of 9 primary symptom dimensions, but for this study we used only the somatization subscale. In the second and third cohorts, the Patient Health Questionnaire-15

(PHQ-15) was used. PHQ-15 assesses the perceived severity of 15 different somatic symptoms, which are summarized into an overall somatic symptom severity score.⁵⁶

Disease-specific quality of life. IBS-specific quality of life was measured in all 3 patient cohorts with the Irritable Bowel Syndrome Quality of Life Questionnaire (IBSQOL).⁵⁷ This 30-item questionnaire measures 9 quality of life domains found to be of relevance for IBS: emotional health, mental health, sleep, energy, physical functioning, food/diet, social functioning, physical role, and sexual relations. Each scale score is transformed to a scale of 0 to 100, with 100 representing the best possible quality of life.

Data Analysis and Statistics

The first step in the data analysis was to identify patients with IBS with pathophysiologic abnormalities. Patients with results from the barostat and transit tests used in this study that were outside the 5th and/or 95th percentile in healthy control subjects, as appropriate, were defined as having rectal allodynia, rectal hyperalgesia, increased/decreased rectal compliance, or accelerated/delayed transit, respectively, and validated cutoff values for the HAD questionnaire were used to identify patients with anxiety and depression (see previously).^{50,51} To be included in the next step of the analyses, a pathophysiologic factor had to be associated with the severity of ≥ 1 IBS-related symptom (IBS-SSS pain frequency and severity, bloating severity, dissatisfaction with bowel habits; GSRs-IBS abdominal pain, bloating, constipation, diarrhea; average stool frequency and consistency from Bristol Stool Form stool diaries), and in the expected direction, that is, more severe symptoms in patients with the pathophysiologic factors than in those without. This was tested with independent samples *t* tests between subjects with and without the pathophysiologic abnormality. For the identification of relevant pathophysiologic factors to be included in the next step in the analyses, we used uncorrected *P* values <.05 as the cutoff, but we also performed false discovery rate correction for multiple testing to indicate *P* values that survived false discovery rate correction. The number of pathophysiologic abnormalities in each patient was thereafter defined. To test the hypothesis that the pathophysiologic abnormalities have a cumulative effect on PROs, 1-way between-groups analysis of variance (ANOVA) with linear trend analyses to analyze the presence of a linear trend were performed,⁵⁸ with number of pathophysiologic abnormalities as independent variable and the patient-reported outcome variable (IBS symptom severity, overall somatic symptom severity or IBS-specific quality of life) as the dependent variable. Effect size was evaluated using the following definition: small: partial eta squared 0.01; medium: partial eta squared 0.06; large: partial eta squared 0.14.⁵⁹ To be able to use single measures for IBS and overall somatic symptom severity for these analyses across all 3 patient cohorts, scores from the questionnaires measuring these variables in the studies (IBS-SSS and GSRs-IBS; Symptom Checklist-90 somatization subscale, and PHQ-15)^{52,53,55,56} were transformed to *z* scores (defining how many standard deviations a value is from the mean, which is set to 0), and those *z* scores were thereafter used as the IBS and somatic symptom severity variables for all patients. In addition to analyses performed in the entire cohort, we repeated the linear trend analyses in the 3 individual IBS cohorts to assess congruence of findings across the cohorts.

Table 1. Demographic and Disease-related Information

	Whole IBS cohort (n = 407)	IBS cohort 1 (n = 137)	IBS cohort 2 (n = 128)	IBS cohort 3 (n = 142)	<i>P</i> ^a
Age, yr, mean ± SD (range)	36.0 ± 12.0 (19–67)	36.8 ± 12.2 (19–67)	36.8 ± 12.2 (19–67)	34.4 ± 11.5 (19–67)	.17

IBS-C, constipation-predominant IBS; IBS-D, diarrhea-predominant IBS; IBSnonCnonD, nonconstipation or diarrhea-predominant IBS, hence patients with IBS mixed/alternating type and untyped IBS; SD, standard deviation.

^aANOVA or χ^2 test among the 3 different cohorts.

We also used an alternative grouping of pathophysiologic abnormalities, whereby we identified patients with psychological distress (anxiety and/or depression using the same cutoff values as described previously), hypersensitivity (allodynia

and/or hyperalgesia, defined as described previously) and abnormal transit (delayed or accelerated, as described previously). The same analytical approach as described previously regarding association between the number of these

Figure 1. (A) Proportion of subjects with pathophysiologic abnormalities relevant for IBS symptoms based on normal values in healthy volunteers (allodynia, hyperalgesia, transit abnormalities) and validated questionnaire cutoff scores (anxiety and depression), and (B) proportion of subjects with different numbers of pathophysiologic abnormalities relevant for IBS symptoms: allodynia, hyperalgesia, delayed/accelerated oroanal transit, anxiety, and depression.

pathophysiologic factors and patient-reported outcome variables were also used for these factors. In addition, we performed multivariate linear regression models with presence of abnormal transit, hypersensitivity, and psychological distress as dichotomous independent variables in 2 models, one with IBS symptom severity and another with overall somatic symptom severity as the dependent variable. In general a P -value $<.05$ was considered statistically significant, and data are presented as mean \pm standard deviation and proportions as appropriate.

Results

Subjects

We included 407 subjects with IBS; 137 in cohort 1 diagnosed according to the Rome II criteria, and 128 and 142 in cohorts 2 and 3, respectively, both diagnosed according to the Rome III criteria. Demographic and disease-related information can be seen in [Table 1](#). There were no differences in mean age, gender distribution, or distribution of IBS subtypes among the 3 cohorts. Moreover, except for a slightly lower rectal pain threshold in cohort 2 than in cohort 1, all the parameters used in the main analyses in this study were equivalent across the cohorts, that is, oroanal transit time, overall IBS symptom severity z scores, somatic symptom severity z scores, and anxiety and depression scores (HAD). The rectal pain threshold in cohort 3 was numerically lower, and the rectal pain intensity numerically higher than in cohorts 1 and 2, but this was expected, because a different barostat protocol with different normal values was used in this cohort. Therefore, the 3 cohorts are combined in all analyses in this report. Oroanal transit time differed between IBS subtypes (ANOVA, $P < .0001$; post hoc comparisons, Bonferroni adjusted, $P < .05$ between all groups), and patients with IBSnonCnonD had lower HAD depression scores (ANOVA, $P = .02$; post hoc comparisons, Bonferroni adjusted, $P < .05$

between IBSnonCnonD and constipation-predominant IBS only), but otherwise the pathophysiologic measures and PROs were similar among IBS subtypes ([Supplementary Table 1](#))

Pathophysiologic Factors

Based on normal values and validated cutoff scores, allodynia was found in 145 patients (36%), hyperalgesia in 86 patients (22%), accelerated oroanal transit in 73 patients (18%), delayed oroanal transit in 29 patients (7%), anxiety in 211 patients (52%), and depression in 97 patients (24%) ([Figure 1A](#)). All of these factors were associated with the severity of at least 1 IBS symptom, that is, more severe symptoms in patients with vs without the pathophysiologic factor ([Table 2](#)). Anxiety and depression were associated with the largest number of IBS symptoms, transit abnormalities primarily with bowel habit disturbances, and allodynia and hyperalgesia with pain and bowel habits. Rectal compliance, which was increased in 58 patients (14%) and reduced in 38 patients (9%) was not associated with more severe IBS symptoms, and therefore not included in the subsequent analyses. At least 3 pathophysiologic abnormalities relevant for symptoms were present in 82 patients (20.1%), 2 abnormalities in 121 patients (29.7%), 1 abnormality in 28 patients (31.4%), and 76 patients (18.7%) had none of the abnormalities under consideration ([Figure 1B](#)). There were no associations between the number of pathophysiologic abnormalities and sex ($P = .12$), age ($P = .15$), or IBS subtype ($P = .21$).

Psychologic distress (anxiety and/or depression) was seen in 227 patients (56%), hypersensitivity (allodynia and/or hyperalgesia) in 190 patients (47%), and abnormal transit (accelerated or delayed) in 102 patients (25%); all 3 of these abnormalities were present in 19 patients (4.7%), 2 in 150 patients (36.9%), 1 in 162 patients (39.8%), and 76

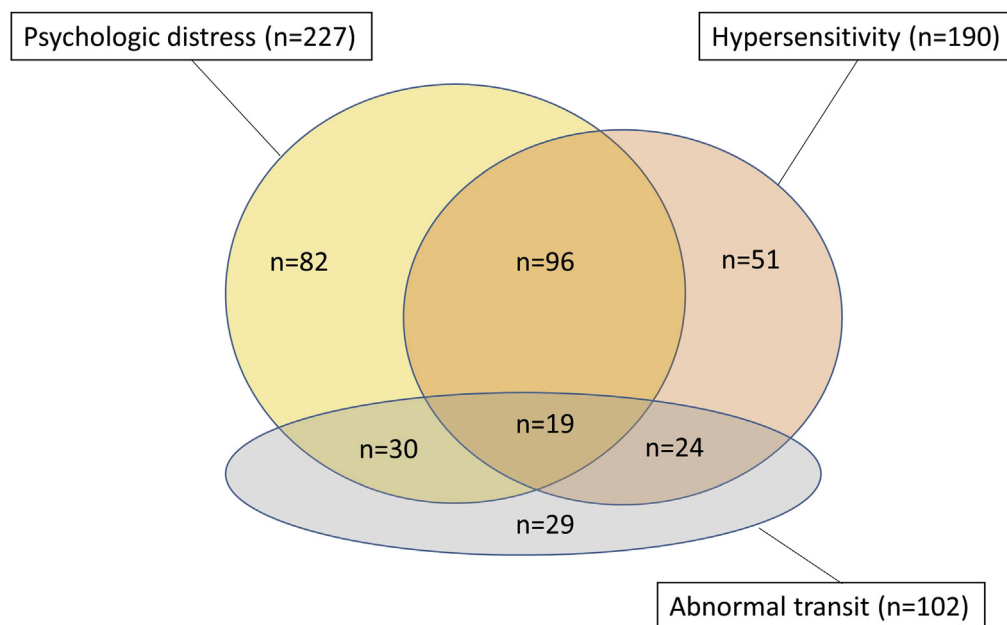

Figure 2. Venn diagram demonstrating the overlap between pathophysiologic factors in our IBS cohort ($n = 407$), using the model with 3 pathophysiologic abnormalities: psychologic distress (anxiety and/or depression), hypersensitivity (allodynia and/or hyperalgesia), and abnormal transit (delayed or accelerated). Seventy-six of the patients (18.7%) had none of the abnormalities; these patients are *not* included in the figure. The size of the different areas are not entirely proportional to the number of subjects in each area.

Table 2. IBS Symptom Severity in Patients With Vs Without Pathophysiological Factors

NOTE. Comparisons between patients with and without the pathophysiologic factor. Comparisons for IBS-SSS are done in cohorts 2 and 3 (n = 270), GSRS-IBS in cohort 1 (n = 137), and for stool diaries using Bristol Stool Form (BSF) Scale in the entire cohort (n = 407). The number of patients with the individual pathophysiologic factors are shown. Exact *P* values at the uncorrected level are displayed and significant differences (*P* < .05) at the uncorrected level are shown in **bold**. The *P* values that survive FDR (false discovery rate) correction for multiple testing are indicated with # (all but 5 survive FDR correction). Comparisons displaying an inverse correlation, that is, more severe symptoms in patients *without* the pathophysiologic factor present, are displayed within parentheses.

patients (18.7%) had none of the abnormalities. The overlap between these variables can be seen in Figure 2.

Association Between Number of Pathophysiologic Factors and PROs

For analysis purposes, the patients were placed in 4 groups based on the number of pathophysiologic abnormalities relevant for IBS symptom severity; none, 1, 2, or 3 or more abnormalities. Symptom severity showed a gradual increase with increasing number of pathophysiologic factors, with medium effect size for IBS symptom severity (Partial $\eta^2 = 0.093$; $P < .0001$) and large effect size for overall somatic symptom severity (Partial $\eta^2 = 0.159$; $P < .0001$) (Figure 3A; Table 3). There was a gradual decrease in quality of life with increasing number of pathophysiologic factors with medium to large effect sizes for all IBSQOL domains except for the food domain (small effect size) (Figure 3B, Table 3). Separate analyses in the 3 IBS cohorts yielded similar results with medium to large effect sizes for IBS and overall somatic symptom severity, as well as for most of the IBSQOL domains; significant linear trends were seen for all the analyses except for 2 IBSQOL domains in IBS

cohort 2 and 1 in IBS cohort 3 (Supplementary Figure 1, Supplementary Table 2).

In a subsequent step we performed the same analyses but removed anxiety and depression, that is, used only 3 pathophysiologic factors (allodynia, hyperalgesia, and abnormal oroanal transit), and placed individuals into 3 groups (none, 1, or 2 or more abnormalities). For all the PROs except for the IBSQOL emotional subscale, significant linear trends with gradually increasing symptom severity and decreasing IBS-specific quality of life with increasing number of pathophysiologic abnormalities were seen, but the effect sizes were reduced to small (Table 3). When only anxiety and depression were used in the analyses (no, 1, or 2 abnormalities), significant linear trends with gradually increasing symptom severity and decreasing IBS-specific quality of life with increasing number of pathophysiologic abnormalities with medium to large effect sizes were seen (Table 3).

Using the alternative grouping of pathophysiologic factors (psychologic distress, hypersensitivity, and abnormal transit) yielded similar results with significant linear trends, but a tendency toward smaller effect sizes compared with the model with a larger number of pathophysiologic factors

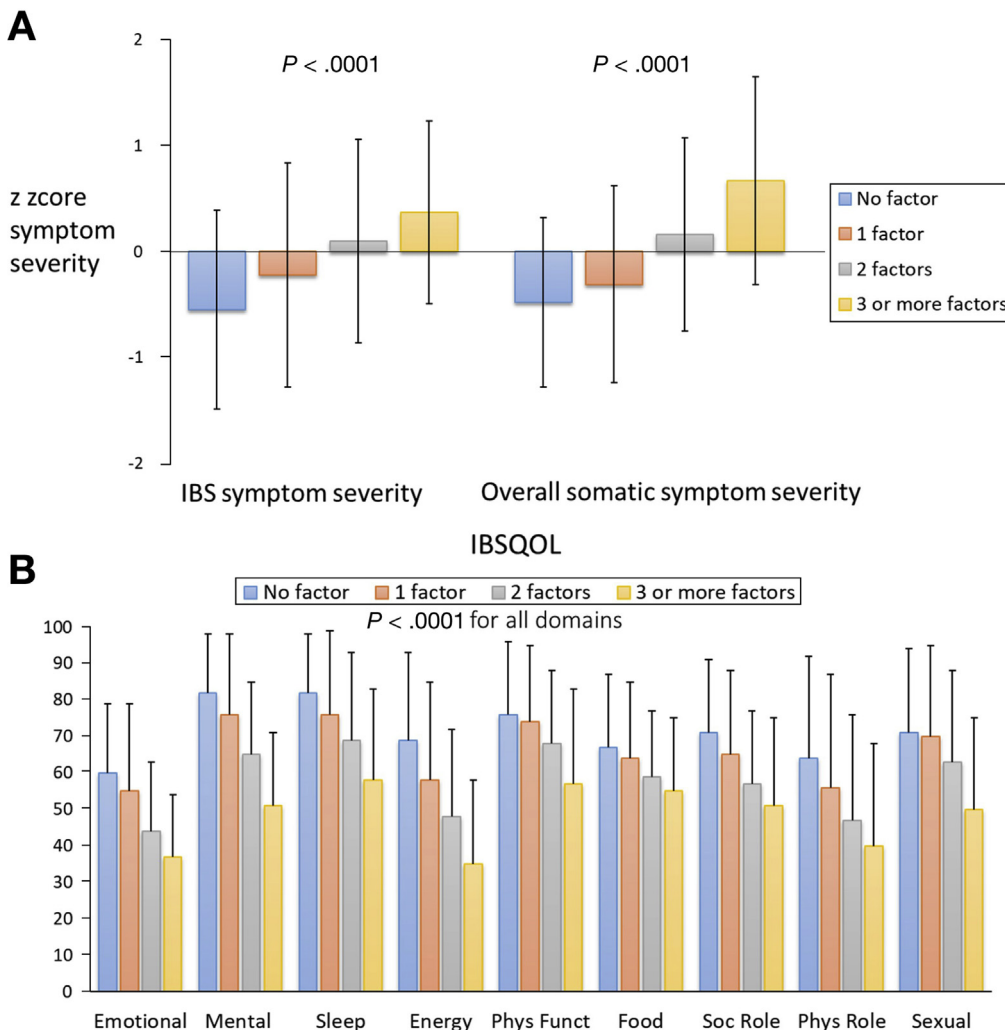

Figure 3. Gradual increase in (A) IBS symptom severity (z score of IBS-SSS and GSRS-IBS total scores) and overall somatic symptom severity (z score of PHQ-15 and Symptom Checklist-90 somatization subscale), and (B) gradual decrease in IBSQOL for all domains with increasing number of pathophysiologic abnormalities. P values from ANOVA with linear trend analysis.

(Table 4). Furthermore, multivariate linear regression models with IBS symptom severity and overall somatic symptom severity as dependent variables, and psychologic distress, hypersensitivity, and abnormal transit as dichotomous independent variables, demonstrated that hypersensitivity and psychologic distress were both independently associated with the outcome variables (Supplementary Tables 3 and 4).

Discussion

In this study, we have demonstrated in a large group of patients with IBS that well-defined pathophysiologic factors that are putatively involved in symptom generation in patients with IBS seem to influence relevant patient-reported outcome variables in a cumulative fashion. Specifically, visceral hypersensitivity, that is, allodynia and hyperalgesia, abnormal oroanal or colonic transit, and psychologic factors were all associated with GI symptom severity in IBS, and demonstrated a cumulative effect on the severity of GI and non-GI symptoms, as well as on quality of life impairment in IBS. Our findings fit well with the current view on the important role of gut-brain interactions (ie, reciprocal communication between the gut and the brain) in symptoms in patients with functional GI disorders such as IBS.^{1,30}

All of the pathophysiologic factors we included in this study have been shown in previous studies to be associated with, and hence of potential relevance for, severity of symptoms in patients with IBS.^{5–7,9,21,22,25–27,29} Regarding the association with IBS symptoms, previous studies have indicated that colonic motility (mostly measured as colonic or oroanal transit time) is more clearly associated with the abnormal bowel habits in IBS,^{5,9,25–27} whereas visceral hypersensitivity seems to be more clearly associated with abdominal pain.^{6,7} Only psychologic distress and visceral hypersensitivity have demonstrated an association with overall IBS symptom severity.^{7,21,22,29} Our analyses confirm

these findings with a general pattern of association between motility/transit and bowel habit abnormalities, visceral hypersensitivity and abdominal pain, and psychologic factors being of importance for the overall IBS symptomatology. However, our study extends beyond the previous studies, as it also demonstrates a striking cumulative effect of these factors on the overall IBS symptomatology, and also on overall somatic symptom severity and disease-specific quality of life, highlighting the importance of considering and assessing combinations of pathophysiologic factors in IBS and pointing toward the importance of the gut-brain

axis in this process.³⁰ Our findings also seem robust, as different approaches to grouping the pathophysiologic factors yielded similar results, and the findings in the overall IBS cohort were congruent with findings in the 3 individual IBS cohorts analyzed separately. Moreover, even though anxiety and depression were the strongest factors when it comes to the overall symptomatology in our IBS sample, removing these factors from the analyses did not eliminate the significant linear trend between the number of pathophysiologic factors and the severity of PROs, although the effect sizes were reduced. However, even though our study indicates that abnormal transit seems to contribute the least of the pathophysiologic factors to the PROs, it is of importance because it contributed significantly to several of the models tested. This indicates that the cumulative effect seen is not solely explained by the psychological factors included in our study.

Current therapeutic options in IBS have limited efficacy. Positive effects on symptoms are achieved in only subsets of patients, and in most patients the available therapies only produce partial improvement in symptoms and rarely lead to complete symptom resolution.^{2,3} This fits well with the findings in this study, in which many patients demonstrated the presence of several pathophysiologic abnormalities, with a complex overlap pattern, and greater number of these abnormalities associated stepwise with greater symptom severity. Hence, targeting only one of these key pathophysiologic factors is unlikely to lead to complete symptom resolution, even if that abnormality is present in the individual patient. Based on our findings, it is tempting to speculate that combining therapies that target different levels of the gut-brain axis and different pathophysiologic factors simultaneously might lead to improved treatment outcomes. However, that hypothesis of course needs to be tested in prospective treatment trials. Furthermore, in today's clinical setting, the symptom profile is used to guide therapy,² and knowledge about the pathophysiology in the individual patients is rarely available, which probably further reduces the likelihood of treatment success. In the future, more personalized treatment approaches based on the underlying pathophysiology, including combinations of abnormalities, may optimize the treatment approach to these subtypes of patients with IBS defined on more complex merits than bowel habits and dominant symptoms.²

Our study had several strengths. We studied a well-characterized and large group of patients with IBS evaluated at an expert center for functional GI disorders and used the current state of the art methodology for assessment of pathophysiology in IBS. Moreover all patients were studied in a single center using uniform study methodology and design, except for use of different questionnaires and rectal barostat protocols during different time periods. However, the slight differences in the methodology across the cohorts were of minor importance because the main findings in the overall cohort were also seen in the 3 individual IBS cohorts. Moreover, being evaluated at an expert center can be considered as a weakness as well, because the findings might not be generalizable to patients with IBS in the community. We believe that this a minor issue in this cohort

because almost all patients were referred from primary care or through self-referral specifically for general advice regarding treatment and investigations, but were otherwise managed in primary care, just as community patients with IBS. The update of diagnostic criteria for IBS over the course of this study (ie, Rome II to Rome III)^{36,37} also could be viewed as a weakness, but because the 3 cohorts were similar regarding demographic factors as well as GI, overall somatic, and psychological symptom severity, we consider it unlikely that this had any relevant impact on our findings. Moreover, we focused on a limited number of pathophysiology factors, and there are of course other factors of potential relevance in IBS that were not included in this study, such as variations in the gut microenvironment.¹³⁻¹⁷ We also used psychological symptoms as a proxy measure for abnormal brain function, which may not be entirely accurate, but for the purpose of the analyses in this study we consider this approach to be acceptable.

In conclusion, we have demonstrated in this study that visceral hypersensitivity, that is, allodynia and hyperalgesia, abnormal colonic or oroanal transit, and psychological factors, are all associated with GI symptom severity in IBS. These factors seem to have a cumulative effect on GI and overall somatic symptoms, as well as on quality of life in IBS, and therefore constitute relevant treatment targets. Future studies should assess whether other pathophysiologic factors, such as abnormal gut microenvironment, can add to this model and explain even more of the variance in the symptomatology in patients with IBS and interact with the pathophysiologic factors investigated in this study. Moreover, treatment studies targeting multiple pathophysiologic factors simultaneously in patients with IBS with combinations of these abnormalities should be performed to assess if this approach leads to greater therapeutic impact on symptoms than current treatment approaches targeting predominant symptoms without specific knowledge about the underlying pathophysiology in the individual patient.

Reprint requests

Address requests for reprints to: Magnus Simrén, MD, PhD, Department of Internal Medicine and Clinical Nutrition, Institute of Medicine, Sahlgrenska Academy, University of Gothenburg, 40530 Gothenburg, Sweden. e-mail: magnus.simren@medicine.gu.se; fax: +46 31 7412917.

Acknowledgments

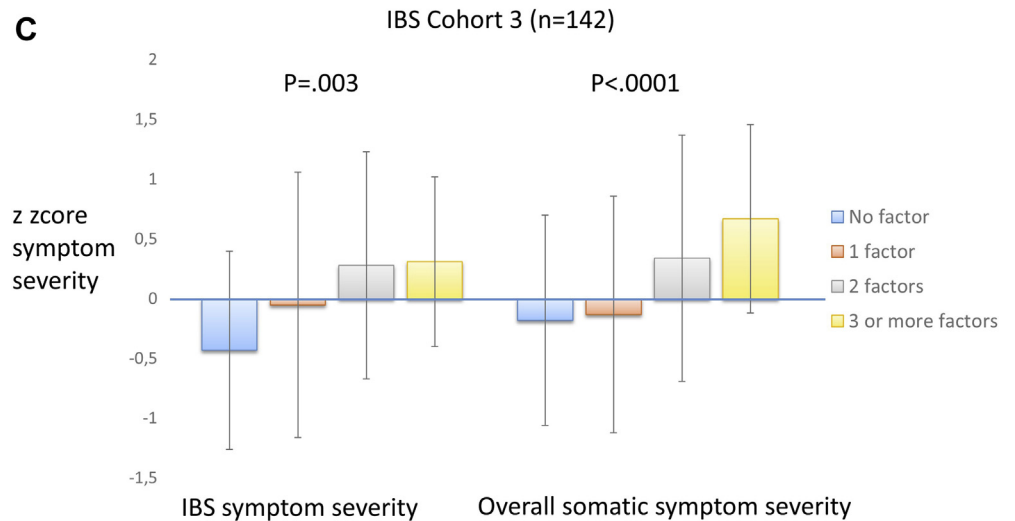

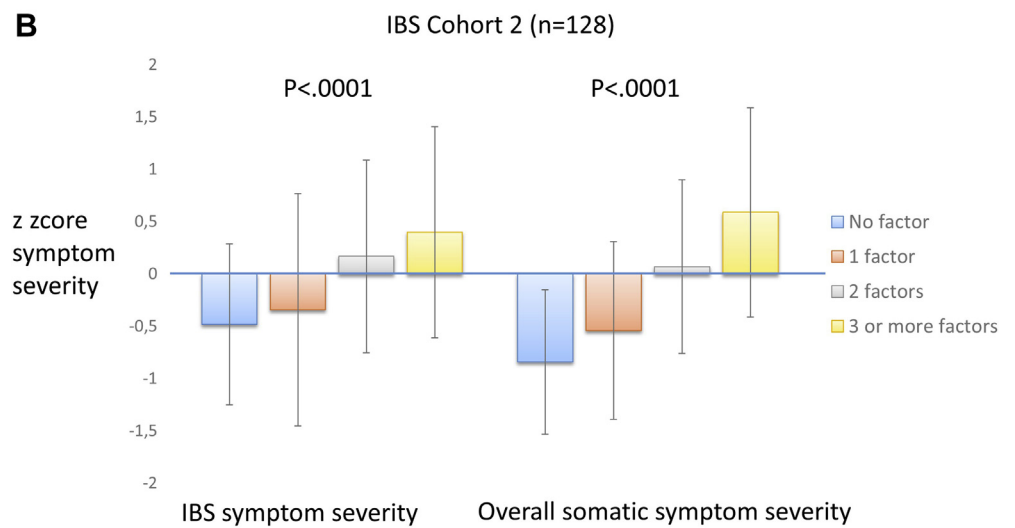

Author contributions: MS: Principal investigator; study concept; patient inclusion and study conduct; first manuscript draft; statistical analyses; study design; interpretation of results; critical revision of manuscript. HT: Patient inclusion and study conduct; study design; interpretation of results; critical revision of manuscript. JT: Study concept; study design; interpretation of results; critical revision of manuscript. LVO, OSP, WEW: Study design, interpretation of results and critical revision of manuscript.

Conflicts of interest

The authors disclose no conflicts.

Funding

This study was supported by the Swedish Medical Research Council (grants 13409, 21691, and 21692), AFA Insurance, by the Faculty of Medicine, University of Gothenburg, and by unrestricted grants from Ferring Pharmaceuticals and Glycom A/S.

Supplementary Figures 1. Gradual increase in IBS symptom severity (z score of IBS-SSS and GRS-IBS total scores) and overall somatic symptom severity (z score of PHQ-15 and Symptom Checklist-90 somatization subscale) with increasing number of pathophysiologic abnormalities in all IBS cohorts (A-C). *P* values from ANOVA with linear trend analysis.

Supplementary Table 1. Pathophysiologic Measures and Patient-Reported Outcomes Among IBS Subtypes

	IBS-C (n = 99)	IBS-D (n = 145)	IBSnonCnonD (n = 163)	<i>P</i> ^a
Age, y, mean ± SD	36.2 ± 11.3	36.9 ± 12.1	35.3 ± 12.4	.51
Gender, female/male	81/18	103/42	117/46	.14
HAD anxiety	8.8 ± 4.6	8.3 ± 4.8	7.6 ± 4.2	.08
HAD depression	5.7 ± 4.0	5.5 ± 3.8	4.6 ± 3.2	.02
Z score somatic symptom severity	0.1 ± 1.0	0.1 ± 1.0	-0.1 ± 1.0	.06
Z score IBS symptom severity	0.0 ± 0.9	0.0 ± 1.1	-0.2 ± 1.0	.34
Oroanal transit time, <i>d</i>	2.2 ± 1.3	1.2 ± 0.7	1.5 ± 0.9	.000
Rectal pain threshold, <i>mm Hg</i> (protocol 1)	32 ± 12	32 ± 13	33 ± 13	.82
Rectal pain intensity, <i>mm</i> (at pain threshold; protocol 1)	35 ± 22	35 ± 25	31 ± 22	.48
Rectal pain threshold, <i>mm Hg</i> (protocol 2)	27 ± 9	28 ± 9	27 ± 8	.90
Rectal pain intensity, <i>mm</i> (at 24 mm Hg; protocol 1)	55 ± 32	47 ± 32	44 ± 33	.29

IBS-C, constipation-predominant IBS; IBS-D, diarrhea-predominant IBS; IBSnonCnonD, nonconstipation or diarrhea-predominant IBS, hence patients with IBS mixed/alternating type and unsubtyped IBS; SD, standard deviation.

^aANOVA or χ^2 test among the 3 different cohorts.

Supplementary Table 2. ANOVA With Linear Trend Analyses: Number of Pathophysiologic Factors and Patient-Reported Outcomes in the 3 IBS Cohorts

	IBS cohort 1 (n = 137)		IBS cohort 2 (n = 128)		IBS cohort 3 (n = 142)	
	Partial η^2	<i>P</i>	Partial η^2	<i>P</i>	Partial η^2	<i>P</i>
IBS sx	.128^b	.000	.100^b	.000	.061^b	.003
Somatic sx	.203^c	.000	.256^c	.000	.085^b	.000
IBSQOL_Emoational	.174^c	.000	.173 ^c	.000	.090^b	.001
IBSQOL_Mental	.226^c	.000	.319^c	.000	.149^c	.000
IBSQOL_Sleep	.109^b	.000	.154^c	.000	.059^a	.000
IBSQOL_Energy	.198^c	.000	.244^c	.000	.082^b	.001
IBSQOL_PhysFunct	.119^b	.000	.018	.14	.103^b	.000
IBSQOL_Food	.100^b	.000	.076^b	.002	.005	.41
IBSQOL_SocialRole	.147^c	.000	.069^b	.003	.043^a	.019
IBSQOL_PhysicalRole	.109^b	.000	.054^a	.010	.047^a	.014
IBSQOL_Sexual	.064^b	.017	.043	.058	.147^b	.000

NOTE. Significance indicated in **bold**.

The effect size (Partial η^2) is as follows:

^aSmall (0.01–0.05).

^bMedium (0.06–0.13).

^cLarge (≥ 0.14).

Supplementary Table 3. Linear Regression Analysis, IBS Symptom Severity (z Score), $R^2 = 0.10$

	Estimate (B)	SE	β	<i>P</i>
Constant	-0.495	0.090		.000
Psychologic distress	0.512	0.098	0.250	.000
Hypersensitivity	0.325	0.098	0.160	.000
Abnormal transit	-0.03	0.112	-0.014	.773

NOTE. Factors independently associated with the outcome variables indicated in bold.

Supplementary Table 4. Linear Regression Analysis, Overall Somatic Symptom Severity (z Score), $R^2 = 0.17$

	Estimate (B)	SE	β	<i>P</i>
Constant	-0.549	0.086		.000
Psychologic distress	0.699	0.094	0.348	.000
Hypersensitivity	0.361	0.093	0.181	.000
Abnormal transit	-0.040	0.107	-0.017	.709

NOTE. Factors independently associated with the outcome variables indicated in bold.
