Abstract

Pediatric human immunodeficiency virus (HIV-1) infection remains a global health crisis. Children are much more susceptible to HIV-1 neurological impairments than adults, which can be exacerbated by coinfections. Neurological characteristics of pediatric HIV-1 infection suggest dysfunction in the frontal cortex as well as the hippocampus; limited MRI data indicate global cerebral atrophy, and pathological data suggest accelerated neuronal apoptosis in the cortex. An obstacle to pediatric HIV-1 research is a human representative model system. Host-species specificity of HIV-1 limits the ability to model neurological consequences of pediatric HIV-1 infection in animals. Several models have been proposed including neonatal intracranial injections of HIV-1 viral proteins in rats and perinatal simian immunodeficiency virus (SIV) infection of infant macaques. Nonhuman primate models recapitulate the complexity of pediatric HIV-1, neuropathogenesis while rodent models are able to elucidate the role specific viral proteins exert on neurodevelopment. Nonhuman primate models show similar behavioral and neuropathological characteristics to pediatric HIV-1 infection and offer a stage to investigate early viral mechanisms, latency reservoirs, and therapeutic interventions. Here we review the relative strengths and limitations of pediatric HIV-1 model systems.

As part of the United Nations Millennium Declaration, the global community took the initiative to halt and reverse the worldwide spread of HIV/AIDS by the year 2015.¹ Through the collective effort of international governments, organizations, local communities and advancements in scientific discovery, the number of new HIV-1 infections continues to decline.² Although there has been a decline in mother-to-child HIV-1 transmission over the past decade, an estimated 650 children under the age of 15 years become infected with HIV-1 each day,^{3–6} with approximately 50% of these children⁷ being perinatally infected through mother-to-child transmission (MTCT) via breast milk.^{8–10} The achievement in reducing perinatal infection rates has been accompanied by increased survival rates of HIV-1 infected children due, in part, to advances and access to antiretroviral therapy (ART),¹¹ both in North America and worldwide.^{2,12–15} However, of the estimated 2.5 million children under the age of 14 living with HIV-1, only about 25% receive antiretroviral therapy.² In 2012, over 200 000 children died from AIDS-related causes¹⁶ with resource-poor areas such as Sub-Saharan Africa accounting for the majority of children under the age of 14 years living with HIV-1 and new infections worldwide.⁴ Perinatal infection rates in North America are less than 2%, mainly due to interventions such as routine HIV-1 screening of pregnant women, use of antiretroviral drugs, avoidance of breastfeeding, and elective cesarean delivery.^{3,17–19} Currently, there are an estimated 10 000 perinatally infected HIV-1 children/adolescents in the United States, who are disproportionately distributed among Black/African-American and Hispanic/Latino populations.¹⁹

Long-term survival poses a set of unique management challenges as perinatally HIV-1 infected children transition to adolescence and adulthood.^{13,20,21} Early adolescence marks a period whereby adolescents begin to take charge of their own health management and lifestyles (life-long habits). There is a general paucity of data concerning the health outcomes of perinatally HIV-1 infected children and adolescents.²² Existing data suggest poor adherence to antiretroviral medications^{21,23,24} and marked obesity rates leading to physical complications such as cardiovascular disorders.^{14,22,25–29} This is further complicated by a high prevalence of neurodevelopmental and cognitive deficits,^{30–36} as well as increased frequency of reported psychiatric disorders within the perinatally HIV-1 infected adolescent population.³⁷

NEURODEVELOPMENTAL DISORDERS

Perinatally HIV-1 infected individuals are disproportionately affected by HIV-1 related neurological impairments in comparison to adult infected patients.^{38,39} Children will often display neurobehavioral deficits prior to significant immunosuppression.⁴⁰ Neurocognitive impairment is associated with a greater risk for disease progression and poorer morbidity, even in the advent of ART.⁴¹ In 2013, only 1 of 4 HIV-1 infected children needing access to ART, received it, and thus, the remainder were potentially susceptible to severe neurological damage.⁴² Early ART intervention partially ameliorates the neurological consequences of perinatal HIV-1 infection; however, deficits persist even with successful viral suppression.^{38,43–46}

In the presence of ART, HIV-1 infected infants present a range of neurodevelopmental delays and impairments,⁴⁷ which include fine and gross motor impairments, cognitive delays,^{48,49} verbal comprehension deficits,^{50,51} executive function impairments,^{40,41} working memory deficits, impaired visual-spatial integration,⁴⁰ abnormal muscle tone, and spasticity.^{30,32,33,38,40,43,52–56} A higher prevalence of seizure activity⁵⁷ and multiple-sclerosis-like illness have also been reported in perinatally infected infants.⁵⁸ The variety of neurological complications that affect perinatally infected children results in impaired emotional and social skills, hyperactivity, and anxiety.^{51,59} The neurobehavioral deficits noted in childhood persist through adolescence, with an increased incidence of anxiety and depression that typically require psychotropic medication.^{37,44} As with children, the neurocognitive impairments and psychiatric disorders in adolescence interfere with performance in social and schooling situations³⁶ and negatively affect overall health care management. The impact of HIV-1 viral load on neuropsychological impairment may be related to host chemokine receptor expression including CCR2,⁶⁰ as well as viral factors.⁶¹

HIV-1 infection worldwide is attributed to different clades (A–K), which are unequally distributed by geographical region. Although clade C is predominant worldwide, namely, in India and throughout Africa,^{62,63} clade B has been more extensively studied as it is the prevalent form in North America and Europe.^{64–66} Clade-specific differences in disease transmission, including viral replication and progression, have been reported in adult populations.^{64,67,68} Clade-specific induction and severity of neuropathogenesis have been reported.^{64,67–69} Specifically, clade B has a higher neurotoxic potential than clade C and may account for the higher incidence of HIV-1 associated neurological disorders in adults in Western countries.^{67–70} The scarce reports of neurological manifestations of HIV-1 infection in children of developing countries suggest a similar neurological profile to infected children in Western countries where clade B HIV-1 is prevalent.^{44,71–76} However, clade-specific neuropathological manifestations within the pediatric population has not been clearly established. Although, there is a positive correlation between neurological impairment and plasma HIV-1 viral load,^{43,77} the direct relationship between specific neuronal lesions and viral load, which is critical for our understanding of disease progression, has not been established.^{41,61,78} Similarly, it has also been shown that low neuropsychological function is related to disease progression.⁴¹ The longitudinal neurobehavioral trajectory of vertically infected adolescents remains grossly understudied³⁶

but is of critical importance, as ART has reduced mortality and perinatally HIV-1 infected infants now survive into adolescence and adulthood.

NEUROIMAGING

Early neuroimaging studies commonly found global cerebral atrophy and basal ganglia calcifications.^{79–81} Imaging studies from HIV-1 infected children under the influence of ART have shown ventricular enlargement, sulcal widening white matter lesions,^{43,82} and altered metabolite concentrations in the frontal cortex and hippocampus.^{40,56,83,84} A recent MRI study in HIV-1 positive children under the age of 6 years found white matter signal abnormalities predominantly in the frontal and parietal lobes. Children in this study began ART by 8 weeks of life, suggesting that the white matter abnormalities manifest early during the infection, possibly due to early entry of HIV-1 into the central nervous system (CNS).⁸⁵ There is also an increased prevalence of cerebrovascular disease.⁸⁶ Diffusion tensor imaging also indicates reduced radial diffusivity, suggesting demyelination,⁵⁶ which is consistent with sparse reports of multiple-sclerosis-like disorders in HIV-1 infected children.⁵⁸ White matter abnormalities may occur very early in the infection, possibly within 8 weeks of life.⁸⁵

NEUROPATHOLOGY AND NEUROTOXICOLOGY OF HIV-1

The scarce pathology reports from HIV-1 infected children indicate that neurological damage is an indirect consequence of perivascular inflammatory cell infiltrates containing HIV-1 infected macrophages and multinucleated cells, leading to infection of astrocytes and activation of a neurotoxic cascade^{87,88} including apoptosis within the cerebral cortex.^{88,89} There is also evidence suggesting a possible direct neuronal infection in infants.⁹⁰ Pathology reports confirm imaging data suggesting ventricular enlargement, myelin pallor, cerebral atrophy, and basal ganglia calcification.⁹¹ Proinflammatory cytokines related to abdominal obesity have also been associated with progressive neurocognitive impairment in HIV-1 patients.⁹² Uninfected children (HIV-seroreverter) born to seropositive HIV-1 mothers also display neurobehavioral deficits,^{81,93,94} albeit not as severe or prevalent as vertically infected children.^{40,48,95} This could be due to inflammatory-mediated damage related to maternal HIV-1 infection or possibly mitochondrial toxicities related to maternal ART.^{96–99}

The pathophysiology of pediatric and adult HIV-1 infection appears to share key features. HIV-1 primarily targets CD4+ T cells by the binding of the HIV-1 envelope glycoprotein 120 (gp120) to the CD4 cellular receptor and a chemokine coreceptor, mainly CCR5 and CXCR4. Binding to these receptors causes conformational changes in the gp120 proteins that lead to fusion of the HIV-1 particle with the host cell. The capsid of the virus disintegrates and it releases HIV-1 RNA, reverse transcriptase, integrase, ribonuclease, and protease into the cell. Then, the single stranded RNA of the virus is reverse transcribed to double-stranded DNA, which is incorporated into the host cell genome and then replicated.^{11,100,101} The virus can kill infected cells directly, via immune-mediated mechanisms, or can cause apoptosis in uninfected cells.

Neuronal damage within the CNS is mediated through viral proteins Tat (trans-activator of transcription), Nef, Vpr (viral protein R), and gp120. Indeed, both Tat and gp120 have been shown to directly induce neuronal apoptosis, while Nef and Vpr are key regulators of

apoptosis of infected cells.^{11,102} Indirect neurotoxicity may result from the release of cytokines, metalloproteinases, gp120, and Tat from HIV-1 infected macrophages and microglia.^{11,103} HIV-1 associated proteins have been shown to directly impact the viability and function of the neurons.¹¹ They also affect neurotoxicity by affecting the formation of ion channels that trigger excitatory responses in hippocampal neurons.¹¹ HIV-1 pathogenesis in infants goes beyond gp120 and Tat toxicity, as elevated levels of proinflammatory cytokines (TNF- α , INF- γ , IL-12) are negatively correlated to neurocognitive function in HIV-1 positive children.³⁴ Neural progenitor cell proliferation is also adversely affected by HIV-1 infection and related viral proteins.^{11,104,105} Moreover, postmortem studies of brain specimens from patients with HIV-1 associated neurological disorders showed a greater decrease in neural progenitor cells in the dentate gyrus, compared to HIV-1 negative controls and HIV-1 positive individuals that did not possess the same neurocognitive deficits.¹⁰⁶

The ability of HIV-1 infected monocytes or T cells to progress into the brain relies on the ability of the virus to transverse the blood-brain barrier (BBB),¹⁰⁷ to replicate within the brain, and to initiate the cascade of neuroinflammation. The BBB functions as a selective barrier between the CNS and the bloodstream. The BBB also adjusts inflammatory and immune responses by reducing the passage of toxins and pathogens into the CNS from the bloodstream. Like the immune system, the perinatal brain BBB is in an immature state¹⁰⁸ and it is hypothesized that HIV-1 infection interferes with the formation of the BBB by reducing the population of pericytes, a significant constituent of the BBB.^{109,110} Neuroinflammation and breakdown of the BBB have been implicated as mechanisms contributing to HIV-1 related neurological disorders.^{87,111–115} Once the virus transverses the BBB in cell-free or cell-associated form, the ability of HIV-1 to infect new cells within the brain depends on the presence of CCR5 and CXCR4, which are known to be transiently expressed during early development of the CNS in primates.¹¹⁶ Expression of the main HIV-1/SIV receptor CD4 and of the chemokine coreceptors CCR5 and CXCR4 in the brain are critical in the neuropathogenesis of HIV-1,¹¹⁶ and signaling through these receptors might alter the balance between survival and proinflammatory neuronal death.¹¹⁷ These receptors are expressed on neural progenitor cells and have been proposed to play a role in HIV-1 induced reductions in neurogenesis.^{11,103,118,119} The ability of HIV-1 to induce neuroinflammatory and neuroapoptotic cascades appears to be pathway specific.^{118–120} For example, cathepsin B, which is secreted from activated macrophages, has been linked to HIV-1 induced neuroapoptosis¹²⁰ and activation of the p38 mitogen-activated protein kinase is involved with HIV-1-induced deterioration of the BBB.¹¹¹

ANIMAL MODEL SYSTEMS

As evidenced from the scarcity of neuroimaging and pathological reports, a main and obvious obstacle in pediatric HIV-1 research is sample access. The developing immune system is clearly more susceptible than the adult to adverse viral infections;¹²¹ therefore, it is critical to design and test potential intervention therapies in pediatric animal model systems.¹²² There are relatively few research groups investigating the pathogenesis and prevention of pediatric HIV-1 infection in animal models.^{123–129} Here we will examine

recent neurological findings in both rodent and primate models of pediatric HIV-1 that will guide the discussion on validity and choice of model systems.

Rodent Models

Small animal model systems such as mice and rats provide an efficient and accessible method of investigating neuropathogenic mechanisms of pediatric HIV-1. There are, however, a number of limitations of rodent models. Foremost, mice and rats are not the natural hosts of HIV-1 and are not susceptible to HIV-1 infection and therefore do not develop disease.¹³⁰ To date, there are no known HIV-1 rodent homologues. Alternate strategies to study HIV-1 pathogenesis in rodents¹³¹ include intracranial administration of Tat/gp120 proteins,^{132,133} inducible Tat/gp120 transgenic mouse models,^{104,134} and humanized mouse models.^{135,136} Although rodent models are the most common non-tissue-culture means of investigating HIV-1 neuropathogenesis, only the Tat/gp120 intracranial administration has been used to model the neurological consequences of pediatric HIV-1 infection.^{132,133}

Rodent models have demonstrated that Tat₁₋₇₂ and gp120 are involved in the neuropathophysiology of HIV-1 infection, with the hippocampus being particularly susceptible to the neurotoxic cascade of HIV-1 proteins.^{124,132,137} Bilateral intrahippocampal administration of Tat₁₋₇₂ on postnatal day 1 (PND1; third trimester equivalent) in rats has been shown to alter prepulse inhibition that lasted from adolescence into adulthood (PND 30 and 60 for males; PND 30, 60, and 90 for females), suggesting impaired sensorimotor gating, which is a reflection of cognitive processing.¹³⁸ Tat₁₋₇₂ administration also impairs spatial memory in adolescence.¹³² In contrast, neonatal intrahippocampal gp120 administration transiently alters sensory-motor function (deficit at PND 3 but not PND 8);^{139,140} however, it may alter dopaminergic activity, leading to long-term sensorimotor gating deficits (assessed at PND90–120).¹⁴¹ Combined gp120/Tat₁₋₇₂ affects eye opening and negative geotaxis (examined at PND 14–16 and PND 3–4, respectively).¹³² Neonatal administration of the Tat₁₋₈₆ protein, encoding for exons 1 and 2, results in altered reflex development, increased response latency for negative geotaxis, and failure to habituate in a locomotor activity chamber.¹³³ In this model, design-based stereology revealed that neonatal intrahippocampal gp120 and Tat₁₋₇₂ administration results in differential and regionally selective cell loss within the hippocampus. gp120 reduces the neuronal population within the of the cornu ammonis subfields 2/3 (CA2/3). In contrast, neonatal intrahippocampal Tat administration reduced the neuronal population in the CA2/3 subfields and the hilus of the dentate gyrus (DGH), elevated the astrocyte population in the DGH and subiculum, and elevated the oligodendrocyte population in the DGH (~PND 200).¹³⁷ The postnatal timing of intrahippocampal Tat₁₋₇₂ administration is related to the toxicity of this viral protein. When Tat₁₋₇₂ administration is delayed to PND10, still in the rodent third trimester equivalent, neuronal numbers within the hippocampus are not altered. However, glial cells and astrocytes are increased in the DGH and subiculum and oligodendrocytes are increased in the DGH, similar to the effects following PND1 Tat₁₋₇₂ administration.¹²⁴ Neither intrahippocampal neonatal Tat₁₋₈₆ or gp120 administration was able to induce inflammatory proteins such as IL-1 β , or transcription factors NF- κ B and I- κ B.¹³³ The effect on cell number in the DGH was indicative of the spatial memory

alterations observed in adulthood.¹³² These results support the hypothesis that Tat plays a significant role in pediatric HIV-1 neuropathogenesis and the development of psychological impairments that are found in HIV-1 infected children.¹²⁴

The main limitation with neonatal intracranial viral protein administration is that it is not an infection model. The humanized mouse model has the potential to overcome this limitation. Within the past two decades, humanized rodent models have been utilized to study HIV-1 infection.^{142,143} HIV-1 infection in the humanized rodent model leads to persistent HIV-1 infection and immunopathogenesis, including immune-activation and depletion of human CD4 T cells.¹⁴⁴ In recent years, improvements in the ability to engraft human cells and tissues into immunodeficient mice have led to successful infection by various strains of HIV-1, namely, by “knockout” or “knockin” host innate immune system.¹⁴⁵ Adult HIV-1 infection in the NOD/*scid*-IL-2R γ ^{null} humanized mouse model leads to an influx of CD8+ cells in the brain, microglia activation, neuronal reductions, compromised oligodendrocyte numbers, and meningitis.^{135,136,142} Behaviorally, these mice have a lack of habituation to the open field, memory loss, and anxiety-like behavior,¹⁴² similar to that seen in neonatal gp120/ Tat intracranial injections.¹³³ The humanized mouse model has the potential to unravel the complex neuropathogenesis of HIV-1 infection and be a vessel for testing therapeutic approaches, however this model system has not yet been employed to investigate pediatric HIV-1 infection. Hypothetically, it is possible to humanize mice at a young age, but it does require surgery as well as a 12 week latency between transplantation and reconstitution thereby limiting its value as a potential model of *neonatal and pediatric* HIV-1 infection.¹⁴⁶

The EcoHIV mouse also holds potential as a pediatric model as it takes advantage of a murine retrovirus, ecotropic murine leukemia virus, to recapitulate HIV-1 infection. EcoHIV can be injected systemically with minimal invasiveness to the immunocompetent host.¹⁴⁷ EcoHIV has been shown to infect the liver, lung, and brain with an accompanying elevation of IL-6 and TNF α expression, suggesting systemic inflammation after 3–4 weeks of infection of adult mice.^{148,149} The EcoHIV model presents a relatively inexpensive and accessible model in which to investigate pediatric HIV-1 infection. However, immune and brain development in neonatal rodents differs substantially from human neonates, suggesting limited use of the humanized mouse model to answer questions related to pediatric HIV-1 induced neuropathogenesis.^{122,150}

Nonhuman Primate Models

The complex neuropathogenesis of HIV-1 infection is not readily recapitulated in rodents, necessitating the need for alternative models. Simian immunodeficiency virus (SIV) infection in macaques is a valid alternative, because SIV and HIV-1 have similar pathogenesis, including routes of transmission, infection of CD4+T cells and macrophages, immune suppression, disease progression and neurological complications in juvenile and adult primates.¹⁵¹ Moreover, mother-to-child transmission (MTCT) can occur by the same routes in both monkeys and humans.¹²² In addition, infant macaques show similar immune and neurodevelopment to human infants.^{122,152,153}

There are several reported models investigating the neuropathogenesis of pediatric SIV infection. In the pigtailed macaque (*Macaca nemestrina*) model, vertical infection was induced by intravenous inoculation of the dam during the third trimester with HIV-2₂₈₇, with 58% of the infants being infected at birth. These infants displayed significant cognitive and motor delays in the Well and Screen Task used to test object permanence and the Fine Motor Task used to evaluate motor capabilities. Deficits in motor and cognitive development were correlated with CD4⁺ lymphocyte cell counts at birth.¹⁵⁴ Another cohort of pigtailed macaques that received perinatal intravenous or intrathecal HIV-2₂₈₇ on PND36 displayed similar behavioral manifestations to those infected in utero. Viral RNA was detectable in the cerebrospinal fluid (CSF) within one week postinoculation and peaked within 2–3 weeks followed by a decline. The concentration of quinolinic acid, an associated marker of neuronal death, was elevated 4–8-fold within 5 weeks postinoculation. Histopathologically, these infected animals displayed evidence of periventricular white matter loss, microgliosis, perivascular lymphocyte infiltration, and neuronal degeneration.^{154,155} The extent and type of cell loss, however, has not been reported in this model.

In the rhesus macaque (*Macaca mulatta*) model, three isolates of SIV (SIV_{mac239}, SIV_{mac239/316}, and SIV_{mac251}), known to penetrate the CNS, have been used to investigate pediatric HIV-1. In one study comparing the three isolates, subjects ($n = 18$) were intravenously inoculated within 24 h of birth with approximately 10^3 50% tissue culture infectious doses/kg with one of the isolates.¹²⁸ Histological lesions of the CNS included perivascular lymphocyte infiltration with in the basal ganglia and cortical white and gray matter. Only one subject had detectable gp120 protein by immunohistochemistry in the CNS. In order to detect the virus in the CNS, a more sensitive PCR-based probe had to be used. This method detected viral DNA as early as 3 days postinoculation mainly in the cortical gray matter and basal ganglia. Viral RNA was detectable in the CSF of all subjects within 14 days of inoculation.¹²⁸

As described extensively, SIV_{mac251} infected newborn rhesus macaques infected intravenously or orally with virulent, uncloned SIV_{mac251} show persistently high viremia and rapid immunosuppression, with the majority of animals developing clinical disease and meeting the criteria for euthanasia (often including neurological signs) within 6 months of infection.¹⁵⁶ In one study, newborn rhesus macaques received 100 tissue culture doses of 50% (TCID₅₀) of SIV_{mac251} within 72 h by the intravenous route to ensure a 100% infection rate.¹²² Animals were sacrificed when they met clinical criteria for euthanasia of retrovirus-infected animals, as early as 7–10 weeks post-infection. Brains were extracted and prepared for histological analysis.¹⁵⁷ Each brain was serially sectioned, with each hemisphere yielding approximately 1400 sections and banked in antigen preserve. This method of serial sectioning and brain banking maximizes the utility for design-based stereological analysis and immunohistochemistry.^{158–160} Design-based stereology is a mechanism for quantitatively estimating cell populations within a given brain region while reducing the bias of cell shape, size, orientation, and distribution.¹⁵⁸ Data from this model indicates that, within two months of infection, SIV significantly reduces the hippocampal neuronal population (Figure 1) in the pyramidal layer of the CA1, CA2, and CA3 subregions.

Immature neurons within the dentate gyrus also experience a significant loss (Figure 2).¹⁶¹ This is congruent with adolescent and adult rodent models that have also demonstrated attenuated neurogenesis. The loss of immature neurons and pyramidal neurons may explain the neuropathogenesis and long-term neurological consequences observed in HIV-1 positive children.^{104,121,162–164} Potentially exacerbating the neurological consequences of pediatric HIV-1 infection is potential demyelination. In humans, myelination is developmentally protracted throughout childhood with adult levels not being obtained until sexual maturity.¹⁶⁵ The effects of HIV-1 infection on this prolonged myelination are still unclear; however, clinical data suggests multiple sclerosis type behavior⁵⁸ and reduced radial diffusivity, an indicator of demyelination, in diffusion tensor imaging⁵⁶ have been reported. There are also reductions in hippocampal myelination in our perinatally SIV-infected subjects¹⁶⁶ (Figure 3), which may provide the anatomical basis for clinical reports. Data from this model do not preclude deficits in other brain areas. The brain banking of histological sections provides versatility for exploring the extent and type of neuronal loss in other brain areas and potential mechanisms of neurotoxicity through immunohistochemistry.

Can Animal Models Be Utilized to Study Neurological Consequences of Pediatric HIV-1 Infection?

Cell culture systems have been used extensively to elucidate the cytotoxic roles of HIV-1 genes (gag, pol, env, tat, rev, vif, vpr, vpu, vpr, and nef), but are limited in their ability to address dynamic physiological interplay between cell types, proteins and organ systems.¹⁶⁷ Animal models are critical for investigating the complex neuropathogenesis of HIV-1 during each phase of infection. The development and choice of animal model depends on the question being proposed. The seminal work of Willner¹⁶⁸ set forth a convention of criterion to evaluate animal model validity that included face, predictive and construct validity. These criteria have further been expanded to include homological, pathogenic, mechanistic, face, and predictive validity.¹⁶⁹

1. Homological validity is used to assess species and strain in relation to the research question.
2. Pathogenic validity addresses disease process similarities (i.e., transformation into a pathological condition).
3. Mechanistic validity refers to the ability of the model to assess proposed mechanisms of action in the human condition by producing similar behavioural/cognitive signs and biological markers that are reactive to human therapeutic agents.
4. Face validity refers to the similarity of observable disease features between the animal and human condition, including disease-induced behavioral and biomarker alterations.
5. Predictive validity concentrates on the ability of the model to make predictions about the efficacy of pharmacological interventions aimed at reducing disease related signs in the model system as well as the relationship between disease induction and its observable effects on the organism.¹⁶⁹

These five criteria will be used in this Review to assess the relative strengths and limitations of both rodent and nonhuman primate animal models that investigate the neurological consequences pediatric HIV-1 infection (Table 1).

Homological Validity

On the surface, it would seem that nonhuman primate model systems would provide the highest degree of homological validity considering the similarities with humans in overall fetal and infant development, including neurodevelopment,¹⁵⁰ homologous brain areas,^{170,171} immune systems,^{122,172} and the homologous nature of SIV to HIV-1.^{122,151} The degree of homological validity depends on the investigative question, which is interrelated to mechanistic validity. For example, to study the roles of specific HIV-1 proteins on the developing dopamine system, intracranial injection rodent models would provide homologic validity.¹⁷³ Alternatively, if the aim of the investigation is to examine the host–virus interaction to include systemic infection and related inflammatory cytokine actions in the pediatric setting, then the humanized mouse, EcoHIV mouse, or SIV primate models could also provide the homologous validity.

Pathogenic Validity

Although neonatal intracranial injection of viral proteins results in long-term behavioral and anatomical alterations, it is not pathogenic and neuroinflammatory cytokine activity is not elevated^{38,132,133,137,138,140} and therefore is limited in pathogenic validity. The humanized mouse and EcoHIV mouse models have the potential to overcome this limitation^{124,148,149,174} but have not yet been used in the pediatric setting. Infant macaques infected with SIV_{mac251} will generally progress into simian AIDS within 6 months.¹²² Neonatally, SIV can be delivered either orally or intravenously, rapidly disseminate within 1 week, and cause elevated systemic proinflammatory cytokine activity and monocyte infection.^{122,126,128,154} Neonatally SIV-infected animals also show CNS penetration of the virus.¹²⁸ Given that the humanized and EcoHIV mouse models have not yet been tested in neonatal mice, the pediatric SIV models reviewed here offer a superior pathogenic validity.

Mechanistic Validity

Neonatal rodent and primate models offer unique strengths in terms of mechanistic validity. First the neonatal rodent intracranial injection model allows for the *in vivo* analysis of specific HIV-1 proteins on neurodevelopment. In this manner, it is possible to dissociate the mechanistic actions of each of the HIV-1 related proteins.^{117,111,102,116} The limitation of this approach is that CNS and systemic inflammatory proteins, which are thought to participate in the pathogenesis of HIV-1,^{87,111–115} are not activated. Pediatric SIV infection overcomes this limitation, but then suffers from the inability to delineate specific roles of viral proteins.

Face Validity

Similar to mechanistic validity, both neonatal rodent and primate models parallel the observable disease features of the human condition. Impaired sensorimotor gating, cognitive processing,¹³⁸ spatial memory,¹³² and sensory-motor function^{139,140} along with elevated

numbers of glial cells and astrocytes¹²⁴ and differential decreases in hippocampal neuronal populations¹³⁷ have all been reported in neonatal rodent models. Likewise, in the several models of pediatric SIV infection, subjects have shown cognitive and motor delays,¹²⁹ elevated CSF markers of neuronal death, periventricular white matter loss, microgliosis,¹³⁰ perivascular lymphocyte infiltration,^{106,130} hippocampal neuronal loss, immature neuronal loss, and demyelination.¹⁵⁵ Results from both rodent and nonhuman primate models support face validity based on similar behavioral/cognitive signs and biological markers to those reported in HIV-1 infected children.¹²⁴

Predictive Validity

Since the advent of ART, the prevalence of severe neurological impairment has declined in both the pediatric^{38,43–50} and adult¹⁷⁵ clinical settings. Despite ART therapy success in partially ameliorating the neurological consequences and increasing the life expectancy of infected individuals, there remains controversy in its use in both pediatric and adult HIV-1 patients.^{175–178} In particular, there is potential for chronic ART to contribute to CNS and peripheral nervous system (PNS) neurotoxicity through oxidative stress mechanisms.^{175,176,179} The majority of therapeutic interventions have concentrated on controlling systemic viral infection and its neurological consequences through ART.^{175,176} There is robust literature reviewing the efficacy of ART in adult nonhuman primate and rodent models,^{175–177,179} so the evaluation of predictive validity here will concentrate on the pediatric primate model system.

The SIV_{mac251} pediatric animal model of SIV-infected newborn macaques has been used to test the efficacy of antiviral drugs. Early studies demonstrated that pre- or early postexposure zidovudine treatment led to reduced viremia, delayed disease progression with improved CNS function in SIV_{mac251}- or SIV_{smm/B670}-infected newborn macaques.^{180–182} In a later study, treatment of SIV_{mac251}-infected infant macaques with the more potent drug tenofovir (PMPA) was the first demonstration of in vivo efficacy of this c gtopound against established SIV infection.¹⁸³ Some tenofovir-treated animals survived for 7–14 years, without any significant lesions observed on routine brain histopathology.^{183,184} This high efficacy of tenofovir was translated into clinical practice, as tenofovir has become a widely used drug to treat adult and pediatric HIV-1 infection. Despite the limited data in SIV-infected newborn macaques, several antiretroviral drug studies in SIV-infected juvenile or adult macaques included more detailed evaluation of neurological function, histopathology or virus levels in the CNS. In an established model of neuropathogenesis in which animals are infected with a combination of neurovirulent SIV/17E-fr and the immunosuppressive strain SIV/Delta670, relative early therapy (12–24 days after infection, i.e., acute viremia) with maraviroc, quadruple antiretroviral therapy, or with the antibiotic minocycline had neuroprotective effects based on viral RNA levels in CSF and brain, markers of inflammation and immune activation, and amyloid precursor protein levels.^{185,186} Simian immunodeficiency virus infected macaques treated with highly active antiretroviral therapy have reduced central nervous system viral replication and inflammation but persistence of viral DNA.^{186,187} Few studies investigated the effect of drug treatment during chronic infection. Fox et al.¹⁸⁸ demonstrated that tenofovir treatment

of SIV-infected adult macaques during the chronic stage of infection normalized neurophysiological abnormalities, but not movement abnormalities.

Limiting the effectiveness of ART to treat neurological consequences of HIV-1 infection is the ability of the various antiretrovirals to penetrate the CNS. The CNS penetration effectiveness (CPE) ranks provides a scale based on the pharmacodynamic properties of the antiretroviral drugs to penetrate the CNS and reduce CSF viral loads with higher scores correlating to lower detectable CSF viral loads. For example, tenofovir has a CPE score of 1 with few reports of adverse CNS effects, while nevirapine has a rank of 4 but patients have reported psychotic symptoms.¹⁷⁸

A recent trend is to develop and test non-ART pharmacological agents to treat HIV-1 related neuropathology. In both adult and neonatal HIV-1 models, neurogenesis and proliferation are altered by viral infection^{103,161,164,189} which can be a prime target for intervention.^{104,105,190} Like most other areas of HIV-1 research, the focus has been on adult models, but pediatric rodent and nonhuman primate models presented here offer a unique platform to test therapeutic intervention aimed at ameliorating the negative consequences of HIV-1 in the CNS.

In summary, the use of SIV-infected nonhuman primates as a model for pediatric neuropathogenesis has been limited, possibly due to cost, accessibility, or institutional infrastructure. Available data suggests that perinatally infected primates share a similar neuropathophysiology to their human counterparts, and that antiretroviral treatment, especially if initiated early, has beneficial effects. Pediatric SIV models evaluating CNS involvement are scarce, but could be utilized effectively in future studies to close gaps in our knowledge, such as mechanisms of early infection, the effects of ART on neurodevelopment, the potential of the CNS as reservoir for latent virus, the long-term behavioral implications, and the development of new strategies to reduce mechanisms of neurological dysfunction that are not resolved by antiretrovirals.

CONCLUSIONS

Early ART intervention partially ameliorates the neurological consequences of perinatal HIV-1 infection; however, deficits persist even with successful viral suppression.^{38,43–46} Despite the neurologic improvement with ART, there is evidence to suggest that some ART regimens may act synergistically with HIV-1 to induce neuronal damage in the CNS^{46,179,191} and thus remain controversial. Thus, given the persistent high rate of HIV-1 infection in infants in resource-poor countries, and increased life expectancy of HIV-1 infected children receiving an overall health benefit ART, there is an urgent need to assess the impact of HIV-1 infection and ART therapy on neurodevelopment, with the goal of optimizing ART regimens. Neonatal rodent HIV-1 and perinatal SIV models support clinical evidence that the neurons of the hippocampus, as well as hippocampal neurogenesis, are particularly susceptible to the neurotoxic cascade of HIV-1 proteins.^{132,133,137,140,161} Although the immature neuronal population is susceptible to perinatal HIV-1 infection, it may also be the key to therapeutic intervention aimed at reducing the impact of HIV-1 induced neurological impairment.^{39,104,121,192} The extent of HIV-1 infection of specific cell

types, neuronal loss, and its relationship to viral loads, and the CNS as a potential reservoir for latent HIV-1 in infants is currently unknown. This limits the ability to develop and evaluate therapeutic paradigms to minimize the neurological impairments as a result of HIV-1 infection. While each animal model presents its own limitations, rodent and nonhuman primate models are poised to address specific mechanistic and therapeutic questions.

Figure 1.

Hippocampal neuronal loss. SIV infected infants have apparent enlarged ventricles and thinned pyramidal neuronal layers (A, B) compared to control subjects (C, D). In these cresyl violet stained sections, neurons can be differentiated from glia based on a clearly visible nucleolus surrounded by cytoplasm. The CA fields were delineated on the basis of cyto- and chemoarchitecture, and equidistant sections were evaluated throughout the entire length of the hippocampus. Design-based stereology of the hippocampal CA subregions found an overall 42% neuronal reduction. There were no overall volume differences in hippocampus. Magnifications of (A, C) 1.25 \times and (B, D) 20 \times ; scale bars = 5 mm and 200 μ m, respectively. Figure adapted from Curtis et al., 2014.¹⁵⁷

Figure 2. Immature neuronal loss. Serial sections from the entire extent of the hippocampus were immunostained with doublecortin, a putative marker for immature neurons.¹⁹³ At this developmental period, immature neurons densely populate the dentate gyrus as evidenced in the control subjects (C, D). In the SIV subjects (A, B), however, individual neurons can be detected throughout the dentate gyrus, suggesting an apparent lack of doublecortin positive neurons. Magnifications of (A, C) 1.25 \times and (B, D) 20 \times ; scale bars = 5 mm and 200 μ m, respectively. Figure adapted from Curtis et al., 2014.¹⁵⁷

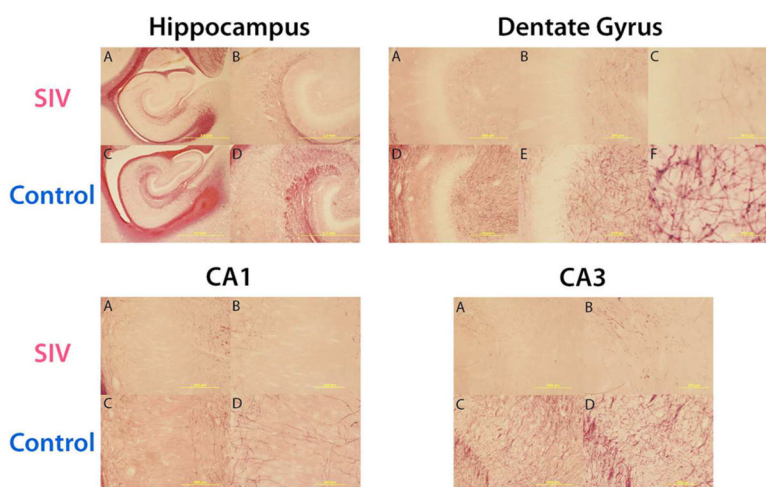

Figure 3. Myelination. Matched sections throughout the hippocampus were stained with gold chloride, a putative marker for myelin.¹⁹⁴ Reductions in myelination are apparent in each region of the hippocampus of SIV infected subjects as compared to control subjects. It is not clear if the reduction of myelination is due to decreased neurons, axonal degeneration, or demyelination of axons. These reductions of myelination further validate the clinical relevance of this model. Magnifications: hippocampus 1.25 \times (A, C), 4 \times (B, D); dentate gyrus 10 \times (A, D), 20 \times (B, E), and 100 \times (C, F); CA1 and CA3 10 \times (A, C), 20 \times (B, D).

Animal Models of Pediatric HIV-1^a

Table 1

species	method	model task	homological validity	pathogenic validity	mechanistic validity		face validity		predictive validity		ref
					behavioral/ cognitive	biological markers	behavioral/ cognitive	biological markers	ART	nonART

^aCompared to juvenile and adult studies, there are relatively few animal models that specifically investigate the neurological consequences of perinatal HIV-1 infection. While no single animal model fully recapitulates pediatric HIV-1 infection, each model possesses its own unique strengths and limitations. Here we summarize the relative strengths and limitations of pediatric HIV-1 models according to validity criteria.¹⁶⁹ The relative strength of each model in the various categories depends on the proposed research question and results obtained in published reports. Within predictive validity, these models have not yet tested specific pharmacological treatments aimed at reducing the neurological burden of HIV-1 infection. With that caveat, each of the presented models possesses the potential to test novel non-cART therapies aimed at reducing the neurological consequences of pediatric HIV-1. NA*: Published data for these categories are not available in these specific animal models; however, these models do hold potential for these categories.
