#### Abstract

**Background**—Prior studies have established that methamphetamine and HIV can have additive deleterious effects on neurocognitive functioning, but there has been relatively little research on other stimulants like cocaine. This study investigated the effects of cocaine and HIV on neurocognitive impairment in a large, well-characterized sample.

**Methods**—The sample included 193 adults across four groups: HIV-positive cocaine users (n=48), HIV-negative cocaine users (n=53), HIV-positive non-drug users (n=60), and HIV-negative non-drug users (n=32). Cocaine users met criteria for lifetime dependence and had pastmonth cocaine use. A comprehensive battery assessed substance abuse and neurocognitive functioning.

**Results**—Participants were mostly male (66%) and African-American (85%), with a mean age of 46.09 years. The rate of global impairment was 33%, with no significant main effects across groups on likelihood of impairment. There were main effects for cocaine on processing speed and executive functioning, with cocaine users having greater impairment (F=9.33 and F=4.22, respectively), and for HIV on attention, with HIV-infected persons having greater impairment

Conflict of Interest No conflict declared.

(F=5.55). There was an interaction effect for executive functioning, with the three patient groups having greater impairment than controls (F=5.05). Nonparametric analyses revealed significant additive impairment in the presence of both HIV and cocaine for processing speed.

**Conclusions**—While cocaine does not appear to increase vulnerability to global HIV-associated neurocognitive impairment, it does have independent adverse effects on executive functioning and processing speed. Given prior evidence that domain-specific deficits predict real-world impairments, our results may help explain the poorer behavioral and functional outcomes observed in HIV-infected cocaine users.

#### 1. INTRODUCTION

Drug abuse, particularly the use of stimulants such as cocaine and methamphetamine, is disproportionately prevalent in HIV-infected persons (Bing et al., 2001; Garin Escriva et al., 2014; Mimiaga et al., 2013; Pence et al., 2008; Siconolfi et al., 2013). In a recent study of >3,000 patients receiving HIV care in four United States (US) cities, 9.0% used amphetamines and 8.5% used crack-cocaine in the past 3 months (Mimiaga et al., 2013). In the only nationally representative sample of adults receiving HIV care in the US, approximately half reported illicit drug use in the past year, and a quarter of these drug users met criteria for current dependence (Bing et al., 2013). In the South, where nearly half of new HIV infections are occurring (Reif et al., 2013), cocaine remains the greatest drug burden, with its societal impact exceeding that of any other region (US Department of Justice, 2011).

Within days of infection, HIV can infiltrate the central nervous system, causing direct and indirect damage to brain structure and functioning (Valcour et al., 2011). If untreated, HIV patients may experience severe cognitive impairments, including dementia (Sacktor, 2002). Since the introduction of antiretroviral therapy (ART), milder cognitive disorders are more common (Antinori et al., 2007; Brew and Gonzalez-Scarano, 2007). The CHARTER study, a large multi-site study in the US that enrolled >1,500 persons between 2003 and 2007, reported a 52% prevalence of HIV-associated neurocognitive impairment, most prominently in learning, memory, attention, and executive functioning (Heaton et al., 2010, 2011). Neurocognitive impairment is most prevalent among patients with advanced HIV disease, including low nadir CD4 cell count, but high rates of mild impairment are present at all stages of HIV infection (Dawes et al., 2008; Heaton et al., 2010). HIV-associated neurocognitive impairment is of concern because it is associated with real-world impairments, including poorer medication adherence, declines in social and occupational functioning, and difficulty with instrumental activities of daily living (Doyle et al., 2013; Foley et al., 2013; Heaton et al., 2004a; Lovejoy and Suhr, 2009; Rabkin et al., 2004; Scott et al., 2011), which may be exacerbated by drug abuse (Meade et al., 2011; Morgan et al., 2014).

Addiction is a brain disease that disrupts neural circuitry, with reduced frontal activation in response to non-drug stimuli and altered dopaminergic transmission in limbic regions, especially the nucleus accumbens and ventral tegmental areas (Feltenstein and See, 2008; Nestler, 2005; Volkow et al., 2004). A recent meta-analysis concluded that cocaine users perform worse than controls on a range of neuropsychological tests, particularly sustained attention, memory, response inhibition, reward-based decision making, and psychomotor performance (Spronk et al., 2013). Similarly, a meta-analysis focused on methamphetamine reported poorer performance in memory, executive functioning, processing speed, motor skills, and attention (Scott et al., 2007). However, a subsequent critical review argues that modest differences have been over-interpreted, since most methamphetamine users perform within the normal range (Hart et al., 2012).

A small body of research has examined the potential additive effects of stimulant abuse and HIV infection on neurocognitive functioning. Much of this work, originating from the Western US, has focused on methamphetamine due to its relatively high prevalence in that region. Using a case-control design, one study found that HIV and methamphetamine had additive effects on rates of global neurocognitive impairment: 58% among HIV-positive methamphetamine users, 40% among HIV-negative methamphetamine users, 38% among HIV-positive non-drug users, and 18% among HIV-negative non-drug users (Rippeth et al., 2004). Subsequent studies also suggest that methamphetamine and HIV may have additive effects on neurocognitive impairment (Carey et al., 2006; Chang et al., 2005; Marquine et al., 2014).

While both cocaine and methamphetamine have neurotoxic effects, these stimulants appear to affect the brain differently (Simon et al., 2001; Winhusen et al., 2013), underscoring the importance of examining drug-specific effects. There has been relatively less research on the effects of cocaine on HIV-associated neurocognitive impairment. One study of HIV-infected adults found that current cocaine dependence was associated with poorer verbal memory and visuospatial construction (Meade et al., 2011). In a more recent analysis from the Women's Interagency HIV Study, frequency of crack-cocaine use was associated with poorer learning and memory in HIV-positive but not HIV-negative women (Meyer et al., 2013). Neurobiological studies support the hypothesis that cocaine use exacerbates HIV-associated neurocognitive impairment. At the cellular and molecular levels, cocaine exposure and HIV infection produce neuronal injury via overlapping mechanisms, including increased oxidative stress, induction of inflammatory cytokines, and greater permeability of the bloodbrain-barrier (for a review, see Buch et al., 2012). Taken together, this research suggests that HIV-infected persons may be more vulnerable to cocaine-related neurocognitive impairment, but case-control designs with human subjects are needed to establish independent effects of cocaine and HIV.

While the CHARTER study concluded that substance abuse does not affect HIV-associated neurocognitive impairment, substance use risk was defined as meeting lifetime diagnostic criteria for a substance use disorder, self-report of marked lifetime substance use (5 lifetime uses), or a positive urine toxicology screen (Byrd et al., 2011). Since the sample included infrequent and past users, their findings may underestimate neurocognitive impairment in active drug users. Additionally, substance use risk was collapsed across

categories of substances (Byrd et al., 2011). To fully understand the effects of drug use on neurocognitive impairment, studies must define clear criteria for recency, frequency, and quantity of use, including careful assessment at the time of the neuropsychological testing, and consider the potential differential effects of varying classes of substances.

This is the first case-control study to investigate whether HIV infection and cocaine dependence have additive effects on neurocognitive impairment. It was hypothesized that individuals with co-occurring HIV infection and cocaine dependence would have the highest rates of global impairment. Specifically, we expected additive effects in the domains of memory and executive functioning. A comprehensive substance use assessment ensured that our cocaine groups met diagnostic criteria for lifetime dependence and were currently using the drug, while our comparison group had no history of regular cocaine abuse. Moreover, we carefully controlled for confounding conditions (e.g., head trauma, other drug abuse, serious mental illness) that could bias results.

#### 2. METHODS

#### 2.1. Participants

The sample included 193 adults across four groups: HIV-positive cocaine users (HIV+/COC +, n=48), HIV-negative cocaine users (HIV-/COC+, n=53), HIV-positive non-drug users (HIV+/COC-, n=60), and HIV-negative non-drug (HIV-/COC-, n=32). For individuals with documented HIV infection, HIV status was verified by medical record review. For others, an OraQuick<sup>®</sup> rapid HIV test was conducted; everyone who was screened tested negative. The COC+ groups had to meet the following three criteria: (1) 4 days of cocaine use in the past month or a positive urine drug screen for cocaine, (2) 1 year of regular cocaine use, and (3) lifetime cocaine dependence. The COC- groups had to meet the following five criteria: (1) no lifetime cocaine use disorder, (2) no history of regular cocaine use, (3) 0 days of cocaine use in the past year, (4) a cocaine negative drug screen, and (5) no current alcohol or marijuana dependence. In all groups, alcohol, marijuana, and nicotine use were permitted. For the COC+ groups, current alcohol and marijuana dependence were permitted if cocaine dependence was the principal diagnosis. For other drugs, individuals in all groups were excluded for lifetime abuse or dependence, history of regular use, any use in the past year, and/or a positive drug screen. Additional exclusion criteria were: English non-fluency or illiteracy; <9<sup>th</sup> grade education; documented severe learning disability with functional impairment; serious neurological disorders (e.g., seizure disorder, multiple sclerosis); acute opportunistic brain infections (e.g., cryptococcal meningitis, toxoplasmosis) or a history of such infections without documented return to normal cognition; severe head trauma with loss of consciousness >30 minutes and evidence of persistent functional decline; severe mental illness, use of mood stabilizing or antipsychotic medications, or acute psychiatric distress; pregnancy; physical disabilities impeding participation (e.g., blindness); and impaired mental status. These exclusions are consistent with current guidelines for classifying contributing or confounding conditions to HIV-associated neurocognitive disorders (Antinori et al., 2007).

#### 2.2. Procedures

Participants were recruited from the Raleigh-Durham area between May, 2010 and May, 2014 via advertisements in local newspapers and websites, flyers posted and brochures distributed at community-based organizations and infectious diseases clinics, and participant referrals. Interested individuals completed a structured telephone screen to assess preliminary eligibility (e.g., HIV infection, drug use history). Eligible callers were invited for a comprehensive in-person screening.

At the screening, participants provided written informed consent. A breathalyzer was used to ensure sobriety. Participants then provided a urine sample for drug and pregnancy screening and completed clinical interviews and questionnaires. Eligible participants returned on another day to complete the neuropsychological testing, additional clinical interviews and questionnaires, and another urine drug test. Participants were paid \$35 for the screening, regardless of eligibility, and \$65 for the testing visit. All procedures were approved by the institutional review boards at Duke University Health System and University of North Carolina at Chapel Hill.

#### 2.3. Measures

**2.3.1. Screening measures**—Module E of the Structured Clinical Interview for DSM-IV-TR identified current and past substance dependence (First et al., 1996). The Addiction Severity Index-Lite assessed lifetime substance use and associated impairments (McLellan et al., 1992). Timeline follow-back methodology was used to assess frequency of substance use in the past 90 days (Robinson et al., 2014; Sobell and Sobell, 1996). Self-report of recent drug use was corroborated with a urine toxicology screen for cocaine, cannabis, amphetamine, methamphetamine, oxycodone, methadone, other opioids (including heroin), benzodiazepines, and barbiturates. The Mini International Neuropsychiatric Interview identified mood, anxiety, and psychotic disorders (Sheehan et al., 1998). Participants reported on their history of HIV and hepatitis C testing and, if applicable, HIV staging (e.g., CD4 cell counts, opportunistic infections) and treatment (RAND Corporation, 2007). The Wechsler Test of Adult Reading, which asks participants to read aloud 50 words that have atypical grapheme to phoneme translations, estimated premorbid verbal IQ (Wechsler, 2001). Finally, participants completed a computerized survey that assessed demographics and smoking history.

**2.3.2. Medical record review**—At screening, participants provided a release of information for us to obtain their medical record and abstract relevant data. This was critical for identifying several confounding conditions that participants did not self-disclose. For HIV clinical variables, self-report and medical record data were reconciled to yield the most complete and accurate data possible. While the medical record generally trumped self-report, if it was incomplete, self-report was used (e.g., if the medical record did not specify the date of HIV diagnosis, but the participant was certain of the date, then self-report was used).

**2.3.3. Neurocognitive functioning**—Trained psychometrists administered a 60-minute battery to assess neurocognitive functioning across seven domains:

- 1. *Processing speed:* Wechsler Adult Intelligence Scale-III (WAIS-III) Digit Symbol subtest total number correct (Wechsler, 1997); and Trail Making Test Part A number of seconds to completion (Reitan and Wolfson, 1993).
- Learning (immediate recall): Hopkins Verbal Learning Test Revised (HVLT-R)

   total number of words recalled on trials 1-3 (Brandt and Benedict, 2001); and
   Brief Visuospatial Memory Test-Revised (BVMT-R) total score for figures
   correctly recalled on trials 1-3 (Benedict, 1997).
- **3.** *Memory (delayed recall):* HVLT-R number of words recalled on trial 4 (Brandt and Benedict, 2001); and BVMT-R total score for figures correctly recalled on trial 4 (Benedict, 1997).
- Executive functioning: Stroop Color and Word Test interference score difference between actual and predicted score on the Color-Word trial (Golden, 1978); and Trail Making Test Part B – number of seconds to completion (Reitan and Wolfson, 1993).
- **5.** *Verbal fluency:* FAS letter fluency number of words generated; and category fluency number of animals generated (Benton et al., 1983).
- Attention: Paced Auditory Serial Addition Task-100 number correct (Diehr et al., 2003); and NAB Digits Forward/Digits Backward Test number correct (Stern and White, 2009).
- 7. *Motor skills*: Grooved Pegboard Test dominant and non-dominant hand number of seconds to completion (Klove, 1963).

Using up-to-date published norms, raw scores were converted to demographically corrected T-scores (M=50, SD=10; Diehr et al., 2003; Heaton et al., 2004b; Norman et al., 2011; Stern and White, 2009; Wechsler, 1997). Each case was scored by two research assistants. Any discrepancies were resolved by a third research assistant re-scoring the case. *2.3.4. Other measures.* At the testing visit, participants completed another computerized survey that included the 6-item depression subscale of the Brief Symptom Inventory (Derogatis, 1993). Past week depression was assessed using a 5-point scale (not at all to extremely). Participants completed another urine toxicology screen for cocaine, cannabis, methamphetamine, opioids, and benzodiazepines, and the timeline follow-back was used to assess the number of days of substance use since the screening visit.

#### 2.4. Data analysis plan

We computed the Global Deficit Score (GDS), which reflects the number and severity of impaired performances on the neuropsychological test battery (Heaton et al., 1995). The GDS gives relatively less weight to performances that are within normal limits. To compute deficit scores, the T-score for each test was converted to a 0-5 deficit rating: T 40 =0 (no impairment), 35-39 =1, 30-34 =2, 25-29 =3, 20-24 =4, and <20 =5. The GDS was computed by adding the deficit ratings of the individual tests and dividing by the total number of tests. Domain Deficit Scores (DDS) were computed by adding the deficit ratings of the tests within each domain and dividing by the total number of tests within the domain. Impairment in a test was defined as a deficit score of 1 (equivalent to a T-score <40). Global

impairment on the GDS was defined as 0.5 and domain-specific impairment on the DDS was defined as >0.5; these cutoffs have been found to provide optimal sensitivity and specificity (Carey et al., 2004).

Descriptive statistics were used to characterize the sample. We then examined differences between groups on DDS and GDS using 2 (HIV+/HIV-)  $\times$  2 (COC+/COC-) between-subjects general linear model analyses. To test the additive risk of HIV and cocaine on DDS and GDS scores, we used the nonparametric Jonckheere-Terpstra test for ordered alternatives (Jonckheere, 1954; Terpstra, 1952). This between group trend test assesses whether the distribution of median deficit scores differs based on number of risk factors (COC-/HIV- =0, COC+/HIV- or COC-/HIV+ =1, COC+/HIV+ =2). We also ran parallel analyses using the three patient groups compared to the control group (i.e., COC-/HIV-). Finally, we conducted multivariate logistic models to predict global and domain-specific impairment as a function of cocaine dependence and HIV infection.

#### 3. RESULTS

#### 3.1. Participant characteristics

The sample included 128 men and 65 women, primarily non-Hispanic (97%) and African-American (85%), who ranged in age from 19 to 70 years (M=46.09, SD=9.86). Table 1 compares the four groups on demographic, substance abuse, HIV, and other characteristics. The majority (85%) had a high school education, but cocaine users had significantly fewer years of education compared to non-drug users. The groups also differed on premorbid verbal IQ and current depressive symptoms.

Among the COC+ groups, participants had been using cocaine regularly for an average of 17.88 years (SD=7.43, range 2-34). The predominant route of cocaine administration was smoking (88%); no one reported current injection. The COC+/HIV- group used cocaine on more days in the past 90 days, but both groups used it frequently (M=32.43, SD=23.85). The COC+ groups were significantly more likely than the COC- groups to report current use of alcohol to intoxication, marijuana, and nicotine. Among participants who reported alcohol to intoxication, the COC+ groups also reported more days of use.

The HIV+ participants had been diagnosed with HIV for an average of 12.89 years (SD=7.34, range 5 months to 32 years). The COC+/HIV+ and COC-/HIV+ groups were comparable on current and nadir CD4 cell counts, AIDS diagnosis, and suppressed viral load (< 50 copies/mL).

#### 3.2. Domain and global deficit scores

Table 2 lists the raw scores and demographically corrected T-scores for each task by group. Table 3 summarizes the DDS and GDS. A main effect of cocaine was observed in processing speed and executive functioning, with the COC+ groups having greater impairment compared to the COC- groups in both cases. A main effect of HIV was observed in attention, with the HIV+ groups having greater impairment than the HIV- groups. A significant HIV\*COC interaction was found in executive functioning, such that the three patient groups had greater impairment than the control group. A similar significant

interaction was found for verbal fluency, though the magnitude of impairment scores was relatively low across all groups. The Jonckheere-Terpstra test was significant only for processing speed (J\* statistic=3.36, p=.001), indicating additive risk in the presence of both HIV and cocaine.

#### 3.3. Rates of neurocognitive impairment

Figure 1 illustrates the rates of impairment globally and by domain, and summarizes the results of multivariate logistic regression models predicting impairment as a function of cocaine dependence and HIV infection. Based on the GDS, the rate of global impairment in the sample was 33%, with no significant main effects of cocaine dependence or HIV infection. For processing speed, there was a significant main effect of cocaine, with the COC + groups being 3.34 times more likely than the COC- groups to have impairment. All models were repeated with the addition of a COC\*HIV interaction term, and the only significant interaction effect was found in executive functioning [AOR=0.07 (0.01-0.70), p=.023]. The patterns of results did not change when controlling for premorbid verbal IQ, depressive symptoms at testing, any alcohol to intoxication, any marijuana use, any nicotine use, and any history of hepatitis C diagnosis; therefore, the original results (without the control variables included) are presented.

Among COC+ participants, there was no association between global impairment based on the GDS and years of regular cocaine use [AOR=0.98 (0.93-1.04)], heavy cocaine use in the past 90 days [AOR=0.69 (0.30-1.57)], a positive urine drug screen at testing [AOR=0.79 (0.26-2.36)], alcohol use to intoxication in the past 90 days [AOR=0.82 (0.35-1.92)], and marijuana use in the past 90 days [AOR=0.71 (0.31-1.62)]. Among HIV+ participants, there was no association between global impairment and years since HIV diagnosis [AOR=1.01 (0.95-1.06)], suppressed viral load [AOR=1.49 (0.67-3.33)], nadir CD4 cell count [AOR=1.00 (1.00-1.00)], current CD4 cell count [AOR=1.00 (1.00-1.00)], or being on an Efavirenz-based ART regimen [AOR=1.39 (0.61-3.18)].

#### 4. DISCUSSION

Despite the relatively high prevalence of cocaine use among HIV-infected persons (e.g., Mimiaga et al., 2013), this is the first case-control study designed to isolate the independent effects of cocaine and HIV on neurocognitive impairment. The rate of global impairment, based on the GDS, was 33%, and neither cocaine dependence nor HIV infection significantly increased the risk of global impairment. However, both conditions had independent effects in specific, different cognitive domains. Individuals with cocaine dependence and/or HIV infection had significantly greater deficits in processing speed, executive functioning, and attention, with additive effects in the domain of processing speed.

While cocaine dependence did not appear to increase vulnerability to global HIV-associated neurocognitive impairment, we did identify main effects in executive functioning and processing speed. This finding is consistent with several prior studies that also reported greater impairments in cocaine users compared to healthy controls in executive functioning, specifically response inhibition (Fernandez-Serrano et al., 2012; Fillmore and Rush, 2002;

Kjome et al., 2010) and reward-based decision making (Camchong et al., 2011; Kjome et al., 2010; Lane et al., 2010). Impairments in executive functioning are theorized to play a role in the maintenance of drug addiction (Bechara, 2005; Schoenbaum et al., 2006) and have been found to predict poorer outcomes in response to drug treatment (Stevens et al., 2014). In contrast, most studies report no effects of cocaine on processing speed (Spronk et al., 2013), suggesting that deficits in this domain may become more prominent in the context of HIV infection. Given prior research indicating that cognitive deficits are less pronounced in cocaine users with a positive drug screen (Woicik et al., 2009), current cocaine use in our sample may have masked additional underlying cognitive impairments.

Compared to the CHARTER study, in which approximately half of HIV-infected Americans demonstrated neurocognitive impairment, with prominent deficits in learning, memory, attention, and executive functioning (Heaton et al., 2010), we found that HIV had an independent effect only in the domain of attention. Our results are consistent with two recent studies that reported no difference in neurocognitive impairment between HIV-positive and HIV-negative participants using the GDS algorithm among: British men who have sex with men (32% and 27%, respectively; McDonnell et al., 2014) and US military beneficiaries (19% vs. 30% respectively; Crum-Cianflone et al., 2013). In a Danish Nationwide Cohort Study, the rate of severe neurocognitive disorders in HIV-infected persons dropped by half after 2004 when the use of combination ART became widespread, with rates almost comparable to healthy controls (Lescure et al., 2011). Crum-Cianflone et al (2013) suggested that early recognition and management of HIV infection in their sample, in which only 15% had low (<200 cells/mm<sup>3</sup>) nadir CD4 counts, may have protected against the development of neurocognitive impairment. In our sample, participants had been living with HIV for a mean of 12 years, some for over two decades, and over half had a history of low nadir CD4 counts; however, all were currently engaged in HIV care, and only one person was not yet receiving combination ART. In contrast, only 71% of CHARTER participants were on ART at time of testing (Heaton et al., 2010). Taken together, these studies suggest that continued improvements in ART regimens, coupled with earlier initiation of these medications, may have a positive impact on neurocognitive functioning. However, it is important to note that the HIV-negative controls in our sample demonstrated relatively high levels of impairment across several domains (e.g., 38% impairment in learning), which may have masked more subtle effects of HIV within these domains.

Additional design considerations may have contributed to the relatively low HIV-associated neurocognitive impairment in our sample. First, we had strict eligibility criteria to eliminate the potential confounding effects of comorbid conditions. In contrast, the CHARTER study had no formal exclusion criteria. When participants were classified based on commonly encountered comorbidities, the rate of neurocognitive impairment was 83% in participants with confounding conditions compared to 59% in those with contributing and 40% in those with incidental conditions (Heaton et al., 2010). Second, we applied the most up-to-date norms to correct for demographic factors, including age, education, gender, and race, which are known to affect neuropsychological test performance (Diehr et al., 2003; Heaton et al., 2004b; Manly et al., 2005; Norman et al., 2000). For example, neurocognitive impairment was significantly overestimated in African-Americans when using previously published normative standards (Norman et al., 2011). Given that the vast majority of our participants

were African-American, many with low educational attainment, the availability of these new norms was important for accurately estimating neurocognitive impairment.

Despite the strong case-control design and comprehensive assessment of substance use to isolate the effects of HIV and cocaine, this study had several notable limitations. First, due to the cross-sectional design, it is not possible to determine whether differences between the study groups preceded the onset of cocaine dependence and/or HIV infection. Second, because our sample included HIV-negative persons, we used the GDS to estimate prevalence of neurocognitive impairment, rather than the Frascati criteria, which are specific for diagnosing HIV-associated disorders. Third, while comparable in demographic and socio-economic characteristics, our control group performed unexpectedly poorly on tasks involving learning and motor skills, and demonstrated higher verbal IQ and lower depression relative to the three patient groups. However, results did not change when we controlled for these and other potential confounds. Finally, as expected given high rates of poly-substance use among cocaine users (Fischer et al., 2010; Harrell et al., 2012; Roy et al., 2013), the cocaine groups were more likely to use alcohol and marijuana, but use of these substances was not related to global impairment.

The findings of this case-control study highlight the complexity of neurocognitive impairment in the context of HIV infection and cocaine use. While cocaine dependence did not increase vulnerability to global HIV-associated neurocognitive impairment, it was associated with deficits in several domains. Specifically, individuals with cocaine dependence and/or HIV infection demonstrated greater impairments in executive functioning, processing speed, and attention, and additive effects of cocaine and HIV were observed in processing speed. As demonstrated in prior studies of HIV-associated neurocognitive impairment, these domain-specific deficits have real-world implications, including impairments in occupational functioning, medication management, driving, and multi-tasking (Doyle et al., 2013; Foley et al., 2013; Heaton et al., 2004a; Lovejoy and Suhr, 2009; Rabkin et al., 2004; Scott et al., 2011). These impairments may help to explain the generally poorer behavioral and functional outcomes observed in HIV-infected stimulant users. Longitudinal studies are necessary to examine within-subject changes in neurocognitive functioning in relation to drug addiction and HIV disease progression. As we continue to learn more about how drug abuse and HIV infection affect the brain in the era of improved ART regimens, it is important for future research to identify effective interventions to improve neurocognitive outcomes.

#### **RESEARCH HIGHLIGHTS**

- We examined the effects of HIV infection and cocaine on neurocognitive impairment.
- HIV and cocaine had independent effects on impairment, but in different domains.
- Cocaine use did not increase risk of overall HIV-associated impairment.
- Cocaine was associated with deficits in processing speed and executive functions.
- These deficits likely contribute to poorer behavioral and functional outcomes.

#### Figure 1.

Rates of impairment globally and by cognitive domain as a function of cocaine and HIV status (N=193). Multivariate logistic regression models provide the adjusted odds of impairment as a function of cocaine dependence and HIV infection. AOR = adjusted odds ratio. In model 1, cocaine dependence and HIV infection were entered in a single block. In model 2, participants with HIV and/or cocaine were compared with the control group. The pattern of results did not change when adjusting for premorbid verbal IQ, depression symptoms at testing, any alcohol to intoxication, any marijuana use, any nicotine use, and any history of hepatitis C diagnosis. The analyses were not run for verbal fluency due to there being no cases of impairment in the control group.

Sample characteristics of the four study groups (N=193)
