Abstract

We report on a nine-month-old girl who presented with persisting cough, and diminished ventilation of the left hemithorax. Viral pneumonia was suspected after Adenovirus detection by PCR, but chest X-rays showed a persistent shadowing of the left hemithorax and persistent coughing despite clinical improvement. Because of the discrepancy between clinical and radiological signs further investigations by ultrasound and CT scan were performed, which visualized an intrathoracic tumor. Histopathology confirmed diagnosis of a teratoma.

This case highlights the need for careful evaluation by the treating physicians. If the chest X-ray provides a discrepancy to the clinical findings or persistent pathologies exist, differential diagnosis should be discussed and further diagnostics be performed.

Introduction

Teratomas are germ cell tumors that arise in children from a variety of locations. They are considered tumors that originate from primordial cells with the potential to differentiate into many different types of tissue [1]. The most common sites in children include sacrococcygeal (40%), ovary (25%), testicle (12%), brain (5%) and rarely other locations [2]. In more than half of the patients mediastinal teratomas present with unspecific symptoms or are asymptomatic. Often, they are discovered on radiological evaluation by chance [3]. In the thoracic cavity they can be easily missed or may masquerade as pneumonic infiltrations. Reported complications are due to intrathoracic compression effects, rupture of the tumor or secretion of hormones. Early diagnosis and resection is favored. Here, we report on a nine-month-old girl that presented in our outpatient clinic with symptoms of an airway infection, and suspected pneumonia.

Case Report

A 9-month-old girl presented in the outpatient clinic with persistent cough for three weeks and subfebrile temperatures (max. 38.5 °C). No recurrent chest infections were observed in the medical history. On clinical examination there was no tachypnea (SO₂ 96%), but diminished breath sounds were auscultated over her left thorax, the percussion was damped suitable for the clinical suspected pneumonia. Therefore, a chest X-ray was undertaken which revealed a large, homogenous shadowing of the left hemithorax with a mild shifting of the mediastinum (Figure 1A). The child was hospitalized with suspected pneumonia and treated accordingly with antibiotics. Adenovirus infection, however, could be detected by PCR of the nasopharyngeal aspirate. The clinical condition improved quickly, but the ipsilateral difference in auscultation persisted as well as the cough. Therefore, chest X-ray was repeated four days later and showed persistent left side opacities (Figure 1B). Because of the discrepancy of clinical and radiologic findings, further diagnostics were added and the working diagnosis of viral pneumonia was reevaluated. Thoracic ultrasound did not show an effusion, but revealed a paracardial consolidation (Figure 1C). Consecutively, low dose computed tomography of the chest was performed. It showed a large, well-defined heterogeneous mass in the left hemithorax (6.5x4.5x8cm) evolving in the anterior

upper mediastinum and extending into the pleural cavity (Figure 1E). The lesion showed areas of irregular nodularity, calcifications as well as fat attenuation along with soft tissue components. No signs of local infiltration or lymphadenopathy were seen. These features were considered suggestive of a mature teratoma. Laboratory evaluation including tumor markers (alpha fetoprotein, NSE, β -HCG) and catecholamine metabolites were within the normal limits.

En-bloc tumor resection was performed by way of a hemiclamshell incision of the left pleural cavity. Intraoperatively, a capsulated, circumscribed inhomogenous, white-grayish colored mass was found (Figure 1F). It was dissected from the mediastinal structures including portions of the thymus gland, taking care to preserve the left phrenic nerve, the diaphragm and the lung. The thoracic cavity was closed using resorbable sutures, and a chest tube was placed in order to initiate postoperative suction therapy to support re-expansion of the atelectatic left lung (20 cm H₂O). The postoperative course was uneventful, the chest drain was removed on the second postoperative day and the chest control X-ray showed a normalized left thorax apparatus without postoperative complications (Figure 1D). Histopathological work-up confirmed a mature teratoma with immature neural elements. Further clinical and radiological (thoracic x-ray and postoperative MRI) follow-up showed complete remission without limitations of the lung capacity. The patient is currently doing well two years after resection without respiratory limitations or signs of a tumor relapse. Tumor markers remained negative.

Figure 1: Depicts different radiologic and intraoperative images of the tumor

A) Depicts the chest X-ray on presentation with the radiological missed diagnosis of a bronchopneumonia. Note the fine calcifications in the ill-defined mass (arrow)

B) Depicts the chest X-ray after 4 days of antibiotic treatment with an unchanged consolidation. Note the fine calcifications in the ill-defined mass (arrow)

C) Depicts ultrasound-scans preoperatively, which showed an unclear, paracardial consolidation with mixed hypo- and hyperechogenicity (arrows)

D) Depicts the chest X-ray immediately after thoracic surgery with a normalized aspect of the left lung. The chest drain in the left thoracic apparatus could be removed at the second postoperative day

E) Depicts a CT-scan preoperatively, which showed a large, well-defined heterogeneous mass (with areas of irregular nodularity, calcifications as well as fat attenuation along with soft tissue components) in the left hemithorax (6.5x4.5x8cm), evolving in the anterior upper mediastinum and extending into the pleural cavity. The broken line marks the operative approach for tumor resection (hemiclamsell incision)

F) Depicts the completely resected teratoma

Discussion

Teratomas account for up to 2% of childhood tumors and are seen in approximately 1 in 30,000 live births [4]. They originate from primitive cells and usually represent all of the three germ layers: endoderm, ectoderm and mesoderm. These tumors can be classified as mature (benign), intermediate and malignant. Most commonly, teratomas are found in sacrococcygeal, ovarian or testicular locations. The remaining locations (24%) are in the mediastinum, the retroperitoneum and other midline structures [5-7]. Teratomas arising within the chest have been described to be located in the anterior or posterior mediastinum in the vicinity of the aorta, esophagus, pericardium, lung and diaphragm [5,7,8]. Other tumor entities such as manifestations of lymphomas, neuroblastomas, sarcomas or other kinds of small round blue cell tumors and metastases have to be excluded, as well as non-malignant causes which mimic a tumor as an infectious manifestation.

Mediastinal tumors and cysts often may cause no symptoms and are found on chest radiography, e.g. performed for symptoms of airway infections [9]. However, complications by obstruction, disruption or superinfections have been described [2,9,10]. Early diagnosis and resection therefore are important to avoid these complications. In our case the initial clinical presentation with persistent cough, signs of airway infection and the pathological lung auscultation together with the radiologic findings led first to the diagnosis of pneumonia, possibly due to Adenovirus, detected by PCR. However, the discrepancy between obvious clinical improvement, but unchanged pathology in the repeated chest X-rays does not fit with the working diagnosis of viral pneumonia. Therefore the diagnosis had to be reevaluated and differential diagnosis of pathologic auscultation and persistent cough had to be discussed. Therefore infectious causes as atypical pneumonia and pertussis had to be ruled out as well as a pleural effusion, congenital emphysema or malformation as well as a (benign or malign) tumor. The repeated X-ray led at last to the suspicion of an intrathoracic tumor, and additional confirmation by thoracic ultrasound and CT.

Complete surgical removal of the mediastinal teratoma is the curative treatment of choice. After complete resection of a mature teratoma, adjuvant therapy is not necessary and prognosis is usually excellent [11,12]. Even though recurrence or malignant transformations are unlikely in mature teratoma, follow-up examinations by radiography and tumor markers are recommended.

Conclusion

Our case highlights the need for careful evaluation by the treating physicians. If the chest X-ray provides a discrepancy to the clinical findings with persisting intrathoracic opacities, differential diagnosis should rule out intrathoracic or other malignant and non-malignant tumors with further diagnostics in order to prevent potential complications.
