18 **ABSTRACT**

19 The four dengue virus serotypes (DENV-1-4) cause the most prevalent mosquito-borne viral  
20 disease of humans worldwide. DENV-2 Asian 1 (A1) genotype viruses replaced the Asian-  
21 American (AA) genotype in Vietnam and Cambodia, after which A1 viruses containing Q or M  
22 at envelope (E) residue 160 became more prevalent than those with 160K in both countries  
23 (2008-2011). We investigated whether these substitutions conferred a fitness advantage by

24 measuring neutralizing antibody titer against reporter virus particles (RVPs) representing AA,  
25 A1-160K, A1-160Q, and A1-160M using patient sera from Vietnam and a well-characterized  
26 Nicaraguan cohort. Surprisingly, we found that A1-160Q and A1-160M RVPs were better  
27 neutralized by heterologous antisera than A1-160K. Despite this, Vietnamese patients infected  
28 with A1-160Q or A1-160M viruses had higher viremia than those infected with A1-160K. We  
29 thus find that independent lineages in Vietnam and Cambodia acquired a substitution in E that  
30 significantly increased polyclonal neutralization, but nonetheless were successful in  
31 disseminating and infecting human hosts.

38 The four dengue virus serotypes (DENV-1-4) cause the most medically important arthropod-  
39 borne viral disease of humans worldwide. Up to 96 million dengue cases occur annually,  
40 including 500,000 hospitalizations due to severe disease [1]. Within each DENV serotype,  
41 multiple genetically distinct lineages have evolved in geographically separated regions [2].  
42 Historically in Asia and increasingly in Latin America, all four DENV serotypes and often  
43 multiple genotypes and/or clades of each serotype circulate simultaneously for extended periods  
44 of time [3]. Antigenic differences between lineages are thought to contribute to disease severity,  
45 epidemic cycling, and viral evolution [4-7].

46 Particular DENV genotypes generally have synchronized epidemic cycles and cause the  
47 majority of disease for 3-5 years, then become scarce as prevalence of another DENV serotype  
48 increases [8]. During periods of serotype dominance, diversification is often observed for all  
49 lineages of that serotype, but as serotype incidence wanes, one lineage disappears while another  
50 persists [5-7, 9-12]. Some lineage replacements result from competing clades and genotypes that  
51 evolve in close proximity for years, while others are due to introduction of a foreign lineage [6,  
52 13].

53 One hypothesis is that lineage replacement is stochastic, driven largely by mosquito and  
54 virus population bottlenecks, such as annual dry periods with low transmission [9, 12, 14-16].  
55 Another hypothesis is natural selection, as lineage replacement events occur over multiple years,  
56 suggesting a gradual effect by a selective pressure [6]. Furthermore, some clade replacement  
57 events coincide with dynamic changes in the prevalence of co-circulating serotypes, suggestive  
58 of interaction/competition between antigenically distinct viruses [5].

59 Two general mechanisms can explain why one virus population may gain a selective  
60 advantage over another. First, the dominant clade may have an intrinsic fitness advantage, such

61 as greater viral replication and dissemination in mosquitoes or humans [7, 17]. Alternatively, the  
62 dominant clade may have an extrinsic fitness advantage conferred by superior transmission in the  
63 presence of host immunity [4, 18]. As for all antigenically variable pathogens, a clade that  
64 evades prior host immunity would be able to infect more hosts and replicate better than one  
65 constrained by host immunity. However, unique to DENV, a clade that takes advantage of prior  
66 host immunity via antibody-dependent enhancement of infection may also have a selective  
67 advantage in the face of population immunity [6, 19, 20].

68 DENV is composed of 90 homo-dimers of envelope (E) glycoprotein, the main antigenic  
69 target for neutralizing antibodies. E is composed of three domains (EDI, EDII, and EDIII) [21].  
70 EDI is the central structural domain, while EDII contains the highly conserved fusion loop that  
71 allows for virus-host membrane fusion. Finally, EDIII contains an immunoglobulin-like fold  
72 likely involved in receptor binding [22]. Strongly neutralizing human antibodies target EDIII and  
73 the hinge region between EDI and EDII [1, 23-28]. The fusion loop region is targeted by both  
74 strongly and weakly neutralizing cross-reactive antibodies [29, 30]. Substitution of just a few  
75 amino acid positions can substantially alter DENV type-specific neutralization [31], and  
76 antigenic differences between genotypes have been described using monoclonal antibodies [32],  
77 as well as antisera from experimentally inoculated animals, human vaccine recipients, and  
78 naturally infected humans [4, 7, 33, 34]. However, the specific amino acid substitutions/epitopes  
79 that determine lineage differences as recognized by polyclonal sera have not been identified.

80 Between 2004 and 2008, the DENV-2 Asian 1 (A1) genotype began replacing the  
81 resident Asian-American DENV-2 (AA) genotype in Vietnam and Cambodia. In both countries,  
82 the genotype replacement was followed by years of DENV-1 circulation, with DENV-2 again  
83 emerging as the dominant serotype a few years later. A study found that A1-infected patients had

84 higher viremia than AA-infected patients, although no significant difference in replication in  
85 mosquito cells or mosquito infectivity was noted [13]. We sought to investigate the possible role  
86 of pre-existing immunity in driving the genotype replacement and subsequent evolution of the  
87 A1 lineage.

88 Here, we describe the unusual observation of a naturally occurring substitution in the E  
89 protein of successful DENV-2 A1 lineages that appears to confer an antigenic fitness cost.  
90 During the replacement of the AA by the A1 genotype in Vietnam and Cambodia, three separate  
91 lineages arose almost simultaneously with substitutions at E position 160 (two with K160M and  
92 one with K160Q). We explored the possible role of pre-existing immunity on selection of these  
93 viruses by testing polyclonal sera against RVPs representing the previously circulating AA as  
94 well as three A1 E-160 variants. Surprisingly, A1-160Q and A1-160M RVPs were better  
95 neutralized by polyclonal sera in vitro than A1-160K and AA RVPs. Despite this apparent fitness  
96 disadvantage, we found that lineages with 160Q and 160M increased in prevalence in both  
97 countries over time and achieved higher viremia in patients than lineages with A1-160K.

98

## 99 **METHODS**

### 100 **Cloning of RVPs structural plasmids**

101 RVPs were produced as previously reported [35]. One plasmid encodes the West Nile Virus  
102 (WNV) non-structural proteins (NS1-NS5) with a green fluorescent protein (GFP) reporter  
103 protein substituting the structural proteins (provided by T.C. Pierson, NIH), and the second  
104 plasmid encodes the DENV structural C-prM-E proteins. Structural genes of the DENV-2  
105 reference strain 16681 were first cloned into a pcDNA3.1/V5-His-TOPO vector (provided by  
106 T.C. Pierson) and served as a cloning intermediate. Substitutions were then made in the 16681 C-

107 prM-E plasmid using the QuikChange Site-Directed Mutagenesis kit (Stratagene) to construct  
108 the AA genotype and A1 genotype variants A1-160K, A1-160Q, and A1-160M (**Table 1**).

109

### 110 **Generation of RVPs**

111 To produce RVPs,  $4 \times 10^5$  cells were plated per well of a 6-well plate and incubated overnight at  
112 37°C in high-glucose DMEM medium supplemented with 10% Fetal Bovine Serum (FBS;  
113 Gibco) and penicillin/streptomycin solution (Gibco). The WNV reporter replicon (1µg), the  
114 DENV C-prM-E plasmid (3µg), and MIRUS TransIT-LT1 Transfection Reagent (12µl) were  
115 transfected into 293T cells according to the manufacturer's protocol and incubated for 4 hours  
116 (h) at 37°C. The medium was then changed to low-glucose DMEM medium supplemented with  
117 10% FBS and penicillin/streptomycin and incubated for 20h at 37°C and 48h at 28°C. The RVP-  
118 containing supernatant was harvested and frozen at -80°C.

119

### 120 **Serum samples**

121 The Nicaraguan Pediatric Dengue Cohort Study [36] was approved by the Institutional Review  
122 Boards of the University of California, Berkeley, and the Nicaraguan Ministry of Health; 18  
123 serum samples collected following primary DENV-1 infection (post-primary DENV-1 samples),  
124 10 post-primary DENV-2 samples, 40 post-secondary DENV-2 samples, and 20 post-primary  
125 DENV-3 samples were used in neutralization assays. Vietnamese plasma samples used for  
126 neutralization tests were from tetanus patients admitted to the Hospital for Tropical Diseases in  
127 1997-1998 (prior to the AA-A1 genotype replacement event; n=25) and 2006-2007 (after the  
128 replacement event; n=27). The scientific and ethics committee of the Hospital for Tropical  
129 Diseases (HTD) in Ho Chi Minh City approved the use of these anonymized, pre-collected

130 plasma samples for infectious disease research. De-identified plasma viremia samples analyzed  
131 were from Vietnamese patients hospitalized in the HTD with dengue in 2011 [37].

132

### 133 **RVP titration and quality control**

134 Raji-DC-SIGN cells (gift from B. Doranz, Integral Molecular), a human B cell lymphoma line  
135 with the DENV attachment factor DC-SIGN [29], were used for the RVP neutralization assay as  
136 described (**Supplementary Figure 1A**) [38]. For each RVP lot, the optimal working dilution  
137 was determined by titration [38]. To ensure that the antibody-RVP interaction only depended on  
138 the neutralization capacity of the antibodies in the serum and was not influenced by the amount  
139 of RVPs used, consistent with the law of mass action [39], we performed neutralization assays  
140 with a polyclonal DENV-positive control (20 pooled sera from Nicaraguan National Blood  
141 Center donors) with concentrations of RVPs above and below the optimal dilution determined  
142 from the titration of each lot. The neutralization curves, all with similar NT<sub>50</sub> values for the three  
143 dilutions, are shown in **Supplementary Figure 1B** [39].

144

### 145 **Neutralization assay**

146 RVPs were diluted in RPMI complete medium (pH 8.0). RVP neutralization assays were  
147 performed as previously described using serial 3-fold dilutions of sera/plasma [38]. Infection of  
148 cells was quantified after 48h by measuring GFP-positive cells via flow cytometry and analyzed  
149 using FlowJo software. Raw data were graphed as percent infection versus the log of the  
150 reciprocal serum dilution, and a sigmoidal dose response curve with a variable slope was  
151 generated using GraphPad Prism 5.0 to determine the antibody dilution at which a 50% reduction  
152 in infection was observed compared to the no-antibody control (NT<sub>50</sub>) [38, 40]. Stringent QC

153 rules, including ensuring that viral particles were neutralized according to the law of mass action,  
154 the absolute sum of squares was  $<0.2$ , and the coefficient of determination ( $R^2$ ) of the non-linear  
155 regression was  $>0.9$ , were used to ensure reproducibility of results. Monoclonal antibodies  
156 (MAbs) were obtained as follows: E76, E87, E60, E28, and E18 (M.S Diamond, Washington  
157 University in St. Louis) [41]; 87.1 and 82.11 (Federica Sallusto and Antonio Lanzavecchia,  
158 Institute for Research in Biomedicine) [23]; 4G2 (ATCC).

159

## 160 **Phylogenetic analyses**

161 The sequence set for phylogenetic analyses consisted of all full-length DENV-2 E genes labeled  
162 as isolates from Vietnam and Cambodia that were available in GenBank as of June 2015  
163 ( $n=261$ ). For the phylogenetic tree, a set that represented DENV-2 genetic diversity was also  
164 included ( $n=13$ ). Phylogenetic relationships were inferred with the maximum likelihood (ML)  
165 method (version 3.0; <http://www.atgc-montpellier.fr/phyml/>) using the general time reversible  
166 (GTR) nucleotide substitution model with four discrete gamma ( $\Gamma$ ) categories of among-site rate  
167 variation, allowing for invariant sites (GTR+ $\Gamma$ 4+I model). The ML tree topology was estimated  
168 using Nearest Neighbor Interchange (NNI) and Subtree Pruning and Regrafting (SPR) branch-  
169 swapping. Trees are unrooted but are drawn with American genotype DENV-2 as the out-group.

170

## 171 **RESULTS**

### 172 **Greater neutralization of A1-160Q compared to AA RVPs by Vietnamese serum samples** 173 **from two different periods**

174 We hypothesized that the A1 genotype may have succeeded in replacing the AA genotype by  
175 acquiring substitutions that allowed it to better escape population immunity. We first generated

176 RVPs representing AA and A1 to analyze their neutralization profiles with population-level  
177 patient sera collected in Vietnam before and after the AA/A1 genotype replacement. Starting  
178 with A1 DENV-2 reference strain 16681, we used site-directed mutagenesis to introduce amino  
179 acid substitutions to generate the consensus of either the A1 or AA genotype, which differ at  
180 thirteen amino acids in E (**Table 1**). We initially constructed an A1 RVP with Q at position 160  
181 (A1-160Q), as it was a major variant in 2006 when AA was almost fully replaced by A1 in  
182 Vietnam. We infected human Raji-DC-SIGN cells with A1-160Q and AA RVPs in the presence  
183 of two sets of Vietnamese plasma samples: 25 samples collected in 1997-98, prior to the A1/AA  
184 lineage replacement, and 27 samples collected in 2006-07, after the lineage replacement. Both  
185 sets were from tetanus patients with unknown prior DENV immune history.

186 DENV neutralization assays can vary from laboratory to laboratory [42]; here, we used a  
187 flow cytometry-based system with human cells, implemented with stringent quality control  
188 measures to ensure reproducibility [38]. As expected, AA RVPs were better neutralized by  
189 Vietnamese sera collected after the major DENV-2 epidemic (2006-07) than before (1997-98),  
190 suggesting that years of intense AA transmission increased the magnitude of the neutralizing  
191 antibody response against the AA genotype (**Figure 1A**). No significant difference in NT<sub>50</sub> titers  
192 was observed when A1-160Q RVPs were tested with 2006-07 compared with 1997-98  
193 Vietnamese patient sera (**Figure 1B**). However, when we compared the neutralization titers of  
194 the A1-160Q relative to the AA RVPs, we found A1-160Q RVPs were better neutralized by both  
195 the pre- (**Figure 1C**) and post- (**Figure 1D**) DENV-2 epidemic Vietnamese sera. This  
196 observation raised the unusual possibility of a virus with an apparent fitness disadvantage arising  
197 naturally in an endemic setting.

198

199 **Post-primary DENV-2 AA infection sera neutralize A1-160Q and AA equally, but post-**  
200 **secondary DENV-2 AA sera neutralize A1-160Q better than AA**

201 We further probed the difference between A1 and AA DENV-2 genotypes by titrating the RVPs  
202 against a panel of sera from the Nicaraguan Pediatric Dengue Cohort Study, which has been  
203 ongoing for 12 years and provides continuous monitoring of all DENV infections that occur in  
204 the cohort [43, 44]. This allows for identification of the infecting DENV serotype in primary as  
205 well as secondary infections [38]. Coincidentally, all DENV-2 viruses circulating in the  
206 Nicaraguan cohort were AA genotype, enabling us to test the role of primary AA and secondary  
207 AA immunity against the A1 and AA lineages. With primary DENV-2 sera, we did not observe  
208 significant differences between neutralization of genotypes A1-160Q and AA (**Figure 2A**).  
209 However, post-secondary DENV-2 infection sera better neutralized A1-160Q compared to AA  
210 RVPs (**Figure 2B**). This unexpected observation suggested that A1-160Q viruses may be better  
211 neutralized by serotype cross-reactive antibodies.

212

213 **Changes in prevalence of A1-160K, A1-160Q, and A1-160M following the AA/A1 genotype**  
214 **replacement**

215 We estimated the phylogenetic and temporal relationships among all DENV-2 E genes listed as  
216 from Vietnam and Cambodia in GenBank and identified two distinct lineages with variation at E-  
217 160 that arose in Vietnam in 2006: one with A1-160Q and another with A1-160M (**Figure 3**).  
218 The proportion of A1 isolates with 160Q or M increased until 2008, at which point DENV-1  
219 genotype I viruses were the dominant serotype (2007-2010) and no DENV-2 was sequenced  
220 from clinical cases, although DENV-2 did circulate at low levels during this period. When  
221 DENV-2 re-emerged as the dominant serotype in 2011, the majority of A1 sequenced in Vietnam

222 contained 160Q (65%), with a smaller number of A1-160M and K viruses still in circulation  
223 (**Table 2**).

224 While the A1-160Q/M substitution arose in Vietnam, a distinct lineage of A1-160M  
225 simultaneously emerged in Cambodia. Although fewer sequences were available on GenBank  
226 from Cambodia, all isolates of A1 in Cambodia before 2005 contained 160K. However, in 2007,  
227 a lineage of A1 emerged containing 160M, and by 2008, when DENV-1 genotype I also  
228 dominated in Cambodia, A1-160M was more commonly isolated than A1-160K (**Table 2**).  
229 Although few isolates are available on GenBank after 2008, virological data from Cambodia  
230 indicates that A1-160M continued to be isolated in 2010 and 2011 (Philippe Buchy, personal  
231 communication). Thus, based on analyses of the available sequences in GenBank, it appears that  
232 as DENV-1 genotype I became dominant in both Vietnam and Cambodia, A1 DENV-2 viruses  
233 evolved two different amino acids substitutions at E position 160 in three independent lineages.

234

### 235 **Post-secondary DENV-2 and post-primary DENV-1 and DENV-3 sera neutralize A1-160Q** 236 **and A1-160M better than A1-160K**

237 The physiochemical properties of the variants at position 160 differ; the initial lysine (K) is  
238 positively charged, while glutamine (Q) is polar uncharged and methionine (M) is hydrophobic.  
239 Position 160, located in a valley on the surface of EDI (**Supplementary Figure 2A**), is a contact  
240 residue of two potently neutralizing type-specific DENV-1 human antibodies, 1F4 [45] and  
241 HM14c10 [46], and is adjacent to a site shown to substantially alter DENV-1 type-specific  
242 immunity [31]. In DENV-3 viruses, position 160 is adjacent to the site of amino acid deletions  
243 (E157 and E158 in DENV-1, -2, and -4 are absent in DENV-3).

244 To investigate whether the difference in serotype cross-reactive neutralization by  
245 human sera was due to amino acid variation at E-160, we generated A1-160K and A1-160M  
246 RVPs and compared their neutralization by Nicaraguan sera from post-primary DENV-1 and  
247 post-primary DENV-3 infections, as well as post-secondary DENV-2 infections. Interestingly,  
248 the high neutralization titers to A1-160Q RVPs were significantly reduced when the A1-160K  
249 RVPs were tested with Nicaraguan cohort sera from post-secondary DENV-2 infections (**Figure**  
250 **4A**,  $p < 0.0001$ ), post-primary DENV-1 infections (**Figure 4B**,  $p < 0.0001$ ), and post-primary  
251 DENV-3 infections (**Figure 4C**,  $p < 0.0001$ ). Like A1-160Q, A1-160M RVPs were also  
252 significantly better neutralized by post-secondary DENV-2 infection sera than A1-160K RVPs  
253 (**Figure 4D**,  $p = 0.0369$ ). Thus, A1-160Q, and to some extent A1-160M, changed the  
254 neutralization profile of polyclonal sera to A1 RVPs, making them significantly better neutralized  
255 by serotype-cross-reactive sera.

256

#### 257 **Substitution at E-160 does not result in an overall change to virion structure**

258 Amino acid substitutions may affect antibody binding by directly modifying the corresponding  
259 epitope, but they can also affect distant sites by causing a global change to virion structure or  
260 affecting the number of epitopes exposed by the virion through “breathing” [47]. To test whether  
261 the 160Q and 160M substitutions modified cross-reactive antibody binding by inducing a global  
262 change to virion structure, we tested the neutralization profiles of A1-160Q and A1-160K RVPs  
263 using a panel of MAbs. We tested MAb 87.1 and E76 (which target the EDIII A strand, a cryptic  
264 viral epitope only accessible with viral breathing or global changes to virion structure), E87  
265 (which targets the EDIII C-C loop in the lateral ridge), and MAbs E60, 82.11, E28, E18, and 4G2  
266 (which target the EDII fusion loop) against A1-160Q and A1-160K RVPs, but did not find

267 significant differences in their NT<sub>50</sub> titers (**Supplementary Figure 2B**). The target of E76 in the  
268 EDIII A strand is a temperature-dependent epitope, but we observed similar E76 neutralization  
269 profiles of A1-160Q and A1-160K at two different temperatures (4°C and 23°C)  
270 (**Supplementary Figure 2C**). These data provide preliminary evidence that the substitution at  
271 position 160 does not alter the overall virion structure and suggest that heterologous antibodies  
272 sensitive to the 160 substitutions may directly target an epitope that includes position 160.

273

274 **Individuals infected with A1-160Q have significantly higher viremia than those infected**  
275 **with A1-160K**

276 We hypothesized that Q and M at position 160, rather than K, must have some in vivo fitness  
277 advantage to explain their evolutionary success, despite apparently being better neutralized by  
278 polyclonal sera. We compared plasma viremia data for 70 Vietnamese adults infected with A1  
279 viruses in 2011. Of these, 70% were secondary, 11% primary, and 19% indeterminate DENV  
280 infections. Primary and secondary DENV infections were classified as previously described [37].  
281 The majority (67%) were drawn on day 3 of illness, with 24% on day 2 and 8% on day 4. Adults  
282 infected with A1-160Q/M were statistically more likely to have secondary immune responses  
283 than those infected with A1-160K (83% versus 43%, 2-sample test for equality of proportions  
284 with continuity correction,  $p < 0.002$ ). The day of viremia measurement did not differ  
285 significantly between groups (0.17 days,  $p = 0.23$ , two-sided t-test).

286 On average, individuals infected with A1-160Q/M had 4-fold higher viral titers than  
287 those infected with A1-160K (A1-160Q/M=8.05  $\log_{10}$ (RNA copies/mL), A1-160K=7.42  
288  $\log_{10}$ (RNA copies/mL), difference in  $\log_{10}$ (RNA copies/mL)=0.63;  $p = 0.03$ , as measured by  
289 linear regression). The difference in viremia between A1-160Q/M and A1-160K remained

290 significant when controlling for day of illness (difference in  $\log_{10}(\text{RNA copies/mL})=0.59$ ,  
291  $p<0.05$ ) and only modestly decreased when also controlling for immune status (difference in  
292  $\log_{10}(\text{RNA copies/mL})=0.50$ ,  $p=0.12$ ). **Figure 5** shows the cumulative distributions of viremia  
293 titers for those infected with A1-160K compared with A1-160Q/M, along with the raw viremia  
294 data. Thus, although A1-160Q and A1-160M were better neutralized by serotype cross-reactive  
295 sera in vitro, viruses with these substitutions achieved higher viremia levels in vivo and were  
296 more often observed to cause secondary infections, providing a possible explanation for their  
297 increasing rate of detection in clinical cases in Vietnam and Cambodia.

298

## 299 **DISCUSSION**

300 Here we report a naturally occurring single substitution in E that significantly alters polyclonal  
301 neutralization. We observed that A1 DENV-2 lineages circulating in both Cambodia and  
302 Vietnam underwent an amino acid substitution at E position 160, making the viruses more  
303 susceptible to in vitro polyclonal antibody neutralization, yet more evolutionarily successful.  
304 Based on available DENV-2 E gene sequences, three separate lineages, two with 160M and one  
305 with 160Q, arose simultaneously in Vietnam and Cambodia in 2006-2007, and in both countries  
306 increased in relative rate of isolation over time. Further, individuals infected with A1-160M and  
307 A1-160Q viruses had significantly higher early viremia levels than those infected with A1-160K  
308 isolates and were more likely to occur in secondary infections. Our findings suggest that A1-  
309 160Q and A1-160M substitutions confer a fitness advantage, which allows them to overcome the  
310 fitness cost of being better neutralized by serotype cross-reactive sera. However, the specific  
311 causal mechanisms underlying the evolutionary success of the A1-160M and A1-160Q lineages  
312 remain elusive.

313 One scenario is that A1-160Q, and possibly A1-160M, are more successful at replicating  
314 in the presence of poorly neutralizing heterotypic antibodies by taking advantage of antibody-  
315 dependent enhancement. Globally, DENV-2 is more often isolated from secondary infections  
316 [48], and based on our findings, it is plausible that A1-160Q and A1-160M replicate better in  
317 DENV-immune individuals than A1-160K. An alternate scenario is that the substitution at  
318 position 160 results in an intrinsic fitness advantage in humans and possibly mosquitoes,  
319 improving viral replication and dissemination independent of pre-existing anti-DENV antibodies  
320 [7, 17].

321 It is possible that another mutation in the genome explains the fitness advantage. We  
322 searched for other variants in E, but position 160 was the only highly variable position; the next  
323 most variant site, position 201, was 96% conserved. Full genomes are not available for the 70  
324 viremic adults we studied. However, for all full-length sequences of Vietnamese DENV-2 Asian  
325 1 viruses in GenBank (n=127), E position 160 was the only major variant (>20% variation) in  
326 the E gene. Two positions in the NS5 gene (one in the methyltransferase and one in the  
327 polymerase) were major variants, but distinct amino acids at these positions did not directly  
328 correlate with E-160 variants.

329 In conclusion, the successful emergence and expanded circulation for multiple years in  
330 Vietnam and Cambodia of viruses with a substitution in the E protein (K160Q, K160M) that  
331 induces increased susceptibility to cross-neutralization calls for an expanded view of the  
332 mechanism(s) of selection driving DENV evolution.

334 **Supplementary Data**

335 Supplementary materials are available at The Journal of Infectious Diseases online  
336 (<http://jid.oxfordjournals.org>). Supplementary materials consist of data provided by the author  
337 that are published to benefit the reader. The posted materials are not copyedited. The contents of  
338 all supplementary data are the sole responsibility of the authors. Questions or messages regarding  
339 errors should be addressed to the author. Preliminary data were presented at the 63<sup>rd</sup> Annual  
340 Meeting of the American Society of Tropical Medicine and Hygiene, November 2-6, 2014, New  
341 Orleans, LA, poster 190, and at the Fourth Panamerican Dengue Research Network Meeting,  
342 October 20-22, 2014, Belém, Brazil.

#### 343 **Notes**

344 ***Acknowledgments.*** The authors would also like to thank Shayna M. Cave, Molly OhAinle,  
345 Claire Quiner, Lisha Wang and Ignacio Salas for their contribution to generating the AA and A1  
346 RVPs, David Burke for sharing code for assisting with generation of phylogenetic trees, and  
347 Philippe Buchy for providing sequence information about recent Cambodian DENV-2 isolates.  
348 We also thank Michael Diamond for MAbs E76, E87, E60, E28, and E18, and Federica Sallusto  
349 and Antonio Lanzavecchia for MAbs 87.1 and 82.11. We thank Angel Balmaseda and the  
350 Pediatric Dengue Cohort Study team at the Centro de Salud Sócrates Flores Vivas, the  
351 Laboratorio Nacional de Virología of the Centro Nacional de Diagnóstico y Referencia at the  
352 Nicaraguan Ministry of Health, and the Sustainable Sciences Institute-Nicaragua for providing  
353 the serum samples from the Nicaraguan cohort study.

354 ***Author contributions.*** E.H. and C.P.S contributed the samples and clinical data; C.W., L.C.K.,  
355 and E.H. conceived and designed the experiments; C.W., M.M.C, and K.D.T.H. performed the

356 experiments; C.W., L.C.K., M.M.C., and E.H. analyzed the data; and C.W., L.C.K., and E.H.  
357 drafted the manuscript; all authors reviewed the manuscript.

358 **Financial support.** This work was supported by the Bill and Melinda Gates Foundation and the  
359 Instituto Carlos Slim de la Salud (FIRST Program); the Nicaraguan Pediatric Dengue Cohort  
360 Study was supported by the Pediatric Dengue Vaccine Initiative grant VE-1 (to EH) and R01  
361 AI099631 (to Dr. Angel Balmaseda). LCK was supported by a Gates Cambridge Scholarship and  
362 the NIH Oxford-Cambridge Scholars Program.

363 **Potential conflicts of interests.** All authors: No reported conflicts. All authors have submitted  
364 the ICMJE Form for Disclosure of Potential Conflicts of Interest. Conflicts that the editors  
365 consider relevant to the content of the manuscript have been disclosed.

380

381 **Figure 1. Neutralization titers to A1-160Q RVPs and AA RVPs in Vietnamese serum**  
382 **samples from two different periods, 1997-98 and 2006-07.** RVPs were incubated with 3-fold  
383 serial dilutions of serum from Vietnamese samples. The RVP-serum mixture was then used to  
384 infect Raji-DC-SIGN cells, and after 48 hours, GFP expression was recorded by flow cytometry  
385 and used to calculate the percentage of infection. The NT<sub>50</sub> was calculated, and the log<sub>2</sub> of the  
386 NT<sub>50</sub> value were plotted on the Y-axis. Prism Graphpad was used to compare the NT<sub>50</sub> between  
387 **(A)** AA RVPs: Vietnamese serum samples from two different periods, 1997-98 and 2006-07; **(B)**  
388 A1-160Q RVPs: Vietnamese serum samples from two different periods 1997-98 and 2006-07;  
389 **(C)** A1-160Q RVPs and AA RVPs for Vietnamese serum samples from 1997-98; and **(D)** A1-  
390 160Q RVPs and AA RVPs for Vietnamese serum samples from 2006-07.

391

392 **Figure 2. Neutralization titers to A1-160Q RVPs and AA RVPs in serum samples from the**  
393 **Nicaraguan Pediatric Dengue Cohort Study.** Neutralization assays were performed as  
394 described in the legend for Figure 1. Neutralization titers were compared between A1-160Q  
395 RVPs and AA RVPs using **(A)** Nicaraguan post-primary DENV-2 infection sera; **(B)** Nicaraguan  
396 post-secondary DENV-2 infection sera.

397

398 **Figure 3. Phylogenetic tree of Vietnamese and Cambodian DENV-2 isolates.** Maximum  
399 likelihood phylogenetic tree of the ancestral relationships among full-length DENV-2 E gene  
400 sequences from Vietnam and Cambodia, and 13 DENV-2 reference sequences. Strain names are

401 colored by amino acid at position 160. The background of the tree is shaded to indicate genotype  
402 and country for relevant lineages. A time-series (right) shows the year of virus isolation.

403

404 **Figure 4. A1-160Q, A1-160M and A1-160K RVP variants were tested against Nicaraguan**  
405 **serum samples from the Pediatric Dengue Cohort Study (2004 to present).** Neutralization  
406 assay were performed as described in the legend to Figure 1. Neutralization titers were compared  
407 between A1-160Q RVPs and A1-160K RVPs using (A) Nicaraguan post-secondary DENV-2  
408 infection sera; (B) Nicaraguan post-primary DENV-1 infection sera; and (C) Nicaraguan post-  
409 primary DENV-3 infection sera. (D) Neutralization titers were compared between A1-160M  
410 RVPs and A1-160K RVPs using Nicaraguan post-secondary DENV-2 infection sera.

411

412 **Figure 5. Viremia levels of 70 Vietnamese patients infected with A1-160K, Q, and M in**  
413 **2011.** (A) Cumulative density plot of  $\log_{10}(\text{RNA copies/mL})$  for infected with A1-160K or M  
414 ( $n=23$  and  $n=2$ , respectively), A1-160Q ( $n=45$ ). Linear regression shows the effect of infecting  
415 virus (A1-160Q/M vs. K) on viremia levels: black line corresponds to the difference in viremia  
416 levels (a significant difference,  $p=0.03$ ) and average values for those infected with A1-160Q/M  
417 and A1-160K are printed adjacent to the line. (B) Jitter plot of  $\log_{10}(\text{RNA copies/mL})$  in  
418 individuals infected with A1-160K or A1-160Q/M.

547 **Supplementary Figure 1. RVP flow cytometry-based neutralization assay.** (A) Experimental  
548 design for the flow cytometry-based neutralization assay. RVPs are incubated with serial  
549 dilutions of the serum/antibody mixture, and then the RVP-serum mixture is used to infect Raji-  
550 DC-SIGN cells. After 48 hours, GFP expression is recorded by flow-cytometry and used to obtain  
551 the percentage of infected cells. (B) Neutralization curves of two representative preparations of  
552 Vietnamese AA (left panel) and A1-160Q (right panel) RVPs. Three concentrations of RVPs  
553 were used to infect Raji-DC-SIGN cells in the presence or absence of 3-fold serial dilutions of  
554 pooled Nicaraguan polyclonal sera (NPS). The percentage of cells expressing GFP was calculated  
555 relative to that without NPS to calculate the relative percentage of infection.

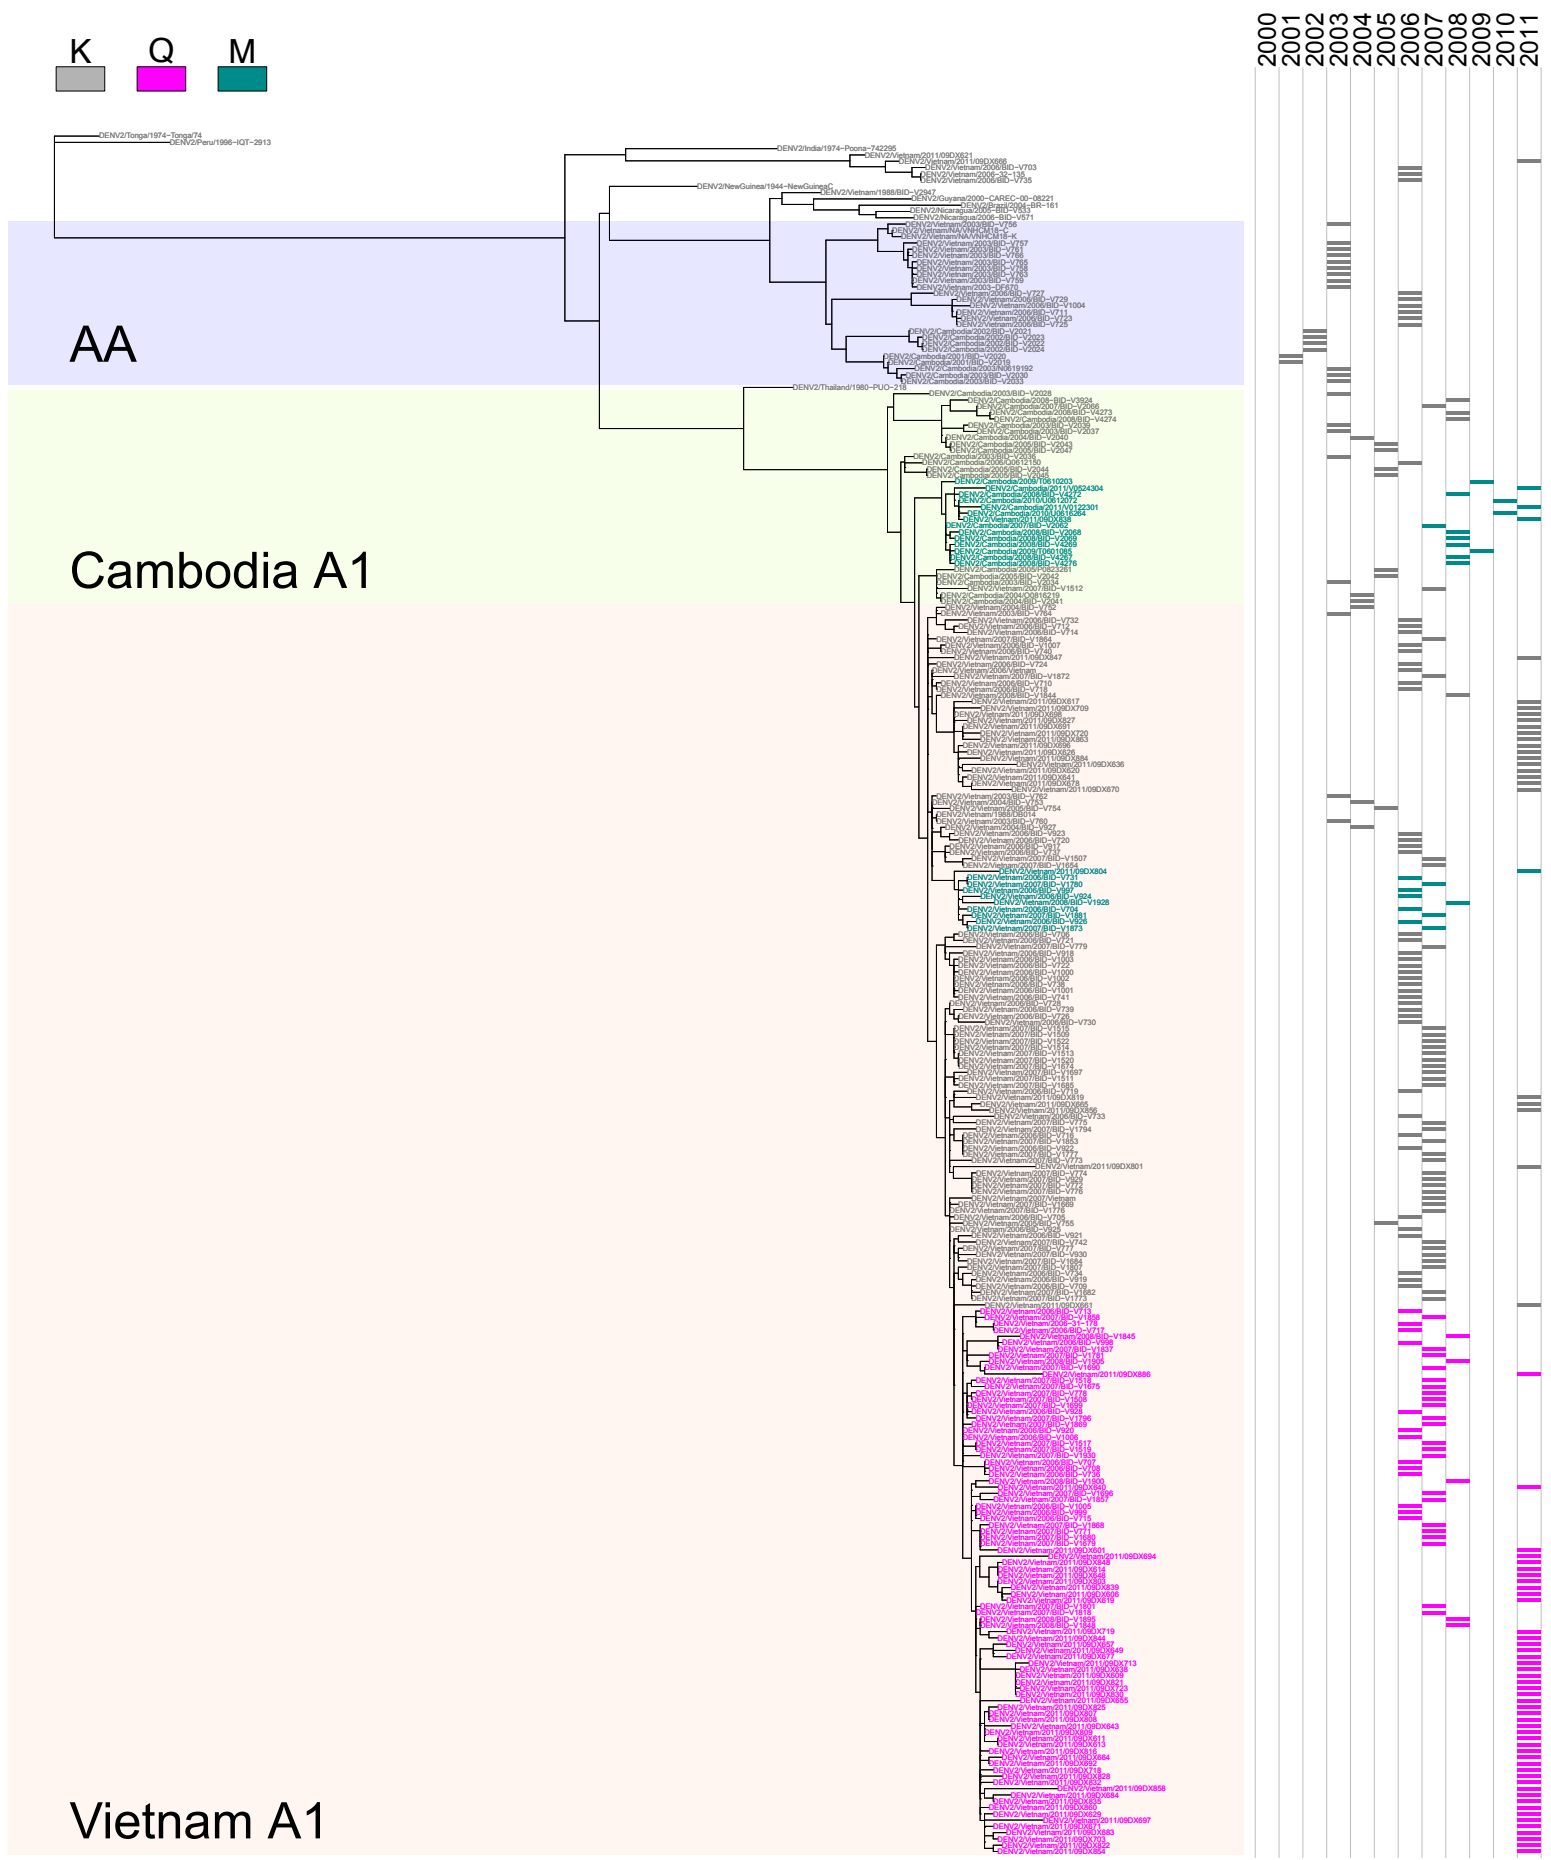

556

557 **Supplementary Figure 2. Substitution at E protein position 160 does not result in an overall**  
558 **change in virion structure.** (A) PyMOL structural analysis reveals that aa160 is located in a  
559 valley on the surface of E (Domain I; EDI) based on the crystal structure of DENV-2 E protein  
560 (1OAN). EDI is shown in red, EDII in yellow, EDIII in blue, and the second monomer in the  
561 dimer is shown in cyan. Arrows indicate the residue of interest highlighted in green. The top  
562 panel is the cartoon representation, while the bottom panel shows the surface of the E dimer. (B)  
563 Similar neutralization profile of A1-160Q and A1-160K as tested by a panel of monoclonal  
564 antibodies, including MAbs 87.1 and E76 (which target the EDIII A strand), MAb E87 (which  
565 targets the EDIII C-C loop in the lateral ridge), and MAbs E60, 82.11, E28, E18, and 4G2 (which  
566 target the EDII fusion loop). (C) Similar neutralization profile of MAb E76, which targets the  
567 temperature-dependent A strand epitope on EDIII, against A1-160Q and A1-160K RVPs at two  
568 different temperatures (23°C and 4°C).
