Abstract

With the high risk and cost in fielding High Energy Laser (HEL) weapon systems, the development process must include computer simulation models of weapon system performance from the engineering level up to predicting the military worth of employing specific systems in a combat scenario. This research effort focuses on defining how to measure lethality for HEL weapons in an Advanced Tactical Laser (ATL) scenario. In order to create an effective measure for direct comparison between the emerging laser weapon system and existing conventionally delivered weapons, lase time in seconds is presented as a measure comparable to rounds required to cause the desired effect at the target. An examination of input parameters which influence the output power of the laser at the target and thus the required lase time is presented with particular attention being paid to atmospheric conditions and vulnerable bucket size. Results include output tables providing the lase time required for melt-through of a set of generic truck-type vehicular ground target aimpoints.

Acknowledgments

First and foremost I would like to thank God Almighty for the strength and determination to undertake this work, and for his allowing me to stay here and finish this work after my unfortunate motorcycle mishap last summer. I would also like to like to express my sincere appreciation to my faculty advisor, Dr. J.O. Miller, for his stalwart support and ever diligent guidance of this thesis effort, and his recommendation that I not attempt to join the professional dart tour. The directive yet not dictative oversight was exactly the stimulus I needed to improve my ability to self-motivate and get this thing done. I would like to express my undying gratitude to Lt Col Moshier and Maj Wiley, for their aid and support of my wife during my recovery. Finally, I would like to thank my wife for her love and support during my medical ordeal and for putting up with me as I completed this work.

TITLE

I. Introduction

Background

In October 2004 the Joint Munitions Effectiveness Manual Effects (JMEM/FX) lethality working group held a meeting concerning a number of lethality issues for multiple weapons systems. Among these were the Advanced Tactical Laser (ATL), the Airborne Laser (ABL), and other lethal and non-lethal directed energy weapon systems. As these technologies mature, we are drawing closer to the coming paradigm shift in weapon engagements and to the realization of effects based operations. Lasers offer significant advantages over conventional systems, including speed of light delivery to distant targets immediately upon detection, with constrained enemy evasion and limited collateral damage (Perram, 2004).

Though they offer advantages, laser weapons are fundamentally different from conventional kinetic-energy based weapons. Along with the aforementioned speed of light delivery comes degradation in effective power with distance. Unlike a dumb bomb or a missile which carries all its energy from the launcher and then 'exerts' that energy at or in the vicinity of the target, a laser's power diminishes proportionally with increased distance between the launcher and the target. This reduction in power necessitates a different approach in developing planning tools for laser weapons, as this effect must be captured in such a way that the planner is able to understand and effectively utilize those tools.

Research Objectives/Questions/Hypotheses

The objective of this research is to develop a methodology for production of JMEM type data for the Advanced Tactical Laser platform. An examination of relevant input factors must be presented, and analysis of which factors may be necessary for consideration in vulnerability prediction must be performed. Relevant questions include: Which input factors are significant in predicting the laser output? Which output measures are most directly applicable to use in calculating target vulnerability? Finally, how does the predicted vulnerability vary with those input factors determined to be significant? It is hypothesized that the major driver in power output prediction will be the distance to the target, given the physical properties of the engagement scenario. It is also hypothesized that the various atmospheres tested will affect the output power, however no predictions are made at this point as to whether various atmospherics will increase or decrease the output power.

Research Focus

This research will focus on the issues surrounding laser weapons and their utilization, specifically propagation through the atmosphere, target and platform engagement geometry, predicted laser power output, and vulnerability based on target thresholds. A number of output measures will be examined in order to determine the best

2

or most representative measure for reliable damage prediction and weapon system comparison.

Methodology

The methodology employed for this research will include data generation by a physics based model, which will output a number of measures of laser energy at the target. The data will then be analyzed in order to assure that the output follows expectation based on the physics of the scenario. The input factors will be analyzed against the outputs to determine which are the driving factors, and then linear regression will be used to predict that output. Finally, target vulnerability will be examined through the use of laser test data, which will be used in conjunction with the predictive model output to generate vulnerability tables for use by the weaponeering community.

Assumptions/Limitations

This research assumes that the ATL system will be fielded as initially projected, and bases the system capability on unclassified system characteristics obtained from the System Program Office (SPO). The propagation model used assumes perfect laser tracking, and median atmospheric characteristics (summer, 50th percentile relative humidity) for each of the atmospheres utilized in laser output calculations.

Implications

The results of this research will be applicable to system effectiveness for the ATL, and will present a capabilities profile for the system. This profile will be usable by a JMEM end user for ATL mission planning, and by a SPO analyst for exploration of ATL Concept of Operations (CONOPS) determination. The applicability of the research conclusions will be limited by the assumptions listed above, but the research results will be extensible through the utilized methodology when considerations for exploration beyond the initial assumptions are included.

II. Literature Review

Introduction

In order to perform meaningful research for this project, a review of the applicable unclassified literature needs to be performed. One interesting note is that though there may be additional information available in a classified medium, this research is limited to the open source unclassified information available. It is understood that due to the nature of a new weapon system still in development, there are a number of performance characteristics which will be classified until the system is fielded, and some which will remain classified even after the system is operational. It is important therefore to perform a thorough review of the available literature, in order to examine all relevant issues as accurately as possible.

Department of Defense Modeling and Simulation

Modeling and Simulation (M&S) is defined as "The process of designing a model of a system and conducting experiments with this model for the purpose either of understanding the behavior of the system or of evaluating various strategies for the operation of the system" (Shannon). M&S is done within the Department of Defense (DoD) as a means to save resources, such as time, money, personnel, or any combination thereof. Modeling and simulation can be performed when it would be expensive or dangerous to use the real systems. Additionally, a system may be simulated because there is enough inherent variability in the system's processes that an analytic solution to the question being asked may be very messy, extremely taxing computationally, or completely intractable. A model is a representation of a system and a simulation is a utilization of a model; however, for the remainder of this thesis, these two terms are used interchangeably.

Model Hierarchy

Within the realm of DoD M&S, models and simulations are classified by the level of warfare they model. This classification is traditionally depicted as a pyramid, with the higher fidelity, higher resolution models concerned with lower levels of warfare at the bottom, and the strategic level models at the top.

Figure 1: DoD M&S Pyramid

At the bottom are the mathematical models, which are used to explicitly describe processes, e.g. physics equations describing the ballistics of a projectile in flight. Examples of models at this level are Newton's laws of motion, and the like. The second level consists of engineering level models which combine a number of mathematical

models to describe a series of events where the level of warfare is at the system vs. system level. An example of this would be the interaction of a given rifle round with a particular type of body armor. Next on the way up the pyramid are the Engagement level models, which move from system vs. system to platform vs. platform, with each platform consisting of a number of individually described systems. At this level, the physics equations for a round being fired may be reduced to a simple muzzle velocity, which suffices for a description of the firing process at this level of resolution. These models operate at the operational level of warfare, where tactics, techniques, and procedures are modeled using rule sets governing the behavior of systems with regard to events within the simulation. At the fourth level are the mission level models which move from 1 vs. 1 to Many vs. Many with regard to numbers of platforms involved. At the top of the pyramid are the campaign level models, which describe operations at the theater and strategic levels of warfare. These models utilize inputs concerning the actions of large groups of systems and their interaction within the framework of a large battlespace. In general, the aggregation increases as one moves up the pyramid, and fidelity increases as one moves down, but this is not always the case. The primary model used in this research effort, the High Energy Laser End to End Operational Simulation (HELEEOS), is primarily an engagement level model, and will be described in detail later in this literature review.

7

Joint Munitions Effectiveness Manual

Now that we have explored the range of models available for analyst evaluation of operational scenarios, it is important to understand the specific output required by the end user in the field. Planners and targeteers operate in an environment where the use of a combat model to give a point prediction for weapon effectiveness, or the time required to perform a large number of replications in order to form a tighter prediction are not conducive to completing work in a timely manner. The operational environment for a planner requires that any estimates they use for targeting purposes are as simple as looking a value up in a table given the scenario for a particular target engagement. This requires that a great deal of work has been done by the analysis community to accurately populate those tables, and to make sure that the tables are based on the correct factors for the scenarios involved.

Manual Basics

The Joint Munitions Effectiveness Manual (JMEM) comprises a series of Field Manuals (FM) which describe the capabilities of weapons systems against different targets based on the profile by which the weapon is delivered. Unfortunately for the academic, these documents are classified due to the nature of the data they contain. Additionally, very little information is available in the unclassified arena concerning the generation, formatting, and use of this data. However, one can establish a methodology for developing the data, and through the use of unclassified or notional data, can verify and validate that methodology as an acceptable data production tool. With the validated methodology in hand, one can produce relevant output once the 'correct' inputs are

8

linked up with the tool. In order to generate this methodology, it is necessary to identify exactly the area of combat to which the data will be applied, and to present the data in as similar a format to existing data for that field as is possible.

Lethality, Probability of Kill

For the purposes of this thesis we define the Probability of Effectiveness (P_{eff}) as the probability that the given set of input criteria will produce a result such that the desired effect is reached. Traditionally in the directed energy forum, there has been a misconception about JMEM in that there is some mythical P_k or Probability of Kill whereby the targeteer is able to divine the required number of weapons to utilize in order to effectively neutralize the chosen target. In actuality, the primary measure of effectiveness used in JMEM data is the ability to cause one of the following desired effects: Delay, Disable, or Destroy. Modelers have had to develop rulesets for engagements and in order to capture the effect of a near-miss have created the concept of mobility kills, firepower kills, and catastrophic kills. This modeling construct has unfortunately bled back over into the community's perception of the real world data.

Though the set of Measures of Effectiveness (MOEs) for Lasers may be similar to or contain some of the same elements as those for kinetic weapons, they have not as yet been defined. As has been previously mentioned, laser power decreases over distance. This is one of the fundamental differences between kinetic and beam weapons, and therefore demands that we include it in our discussion of MOEs. Where there are a single set of values for damage given by a kinetic weapon, the dependence on a direct hit and associated dwell time may dictate a graduated list of values for lasers, based on lase time as an analog to the number of rounds used in a traditional kinetic scenario.

Little work has been directed toward developing and circulating a methodology for determining lethality or the thresholds for differing levels of non-lethal effects. While kinetic weapons may deliver their full energy in the vicinity of their target and thus cause less than complete kill effects, a laser shot is either a hit or a miss. The laser however can hit the target and 'quit' delivering energy when a specified level of damage has been administered, allowing for tailored effects through the use of the same weapon. (Dial-a-Damage, as was opined by one of the JMEM/FX meeting attendees). This research will attempt to establish an initial methodology for development of lethality data for use in planning and modeling tools.

Laser Issues

We cannot adequately discuss the use of lasers in combat without reviewing the literature on the initial development of lasers and their subsequent advancements toward weaponization. We must cover both the work done to develop lasers with more output power and with better propagation characteristics. Additionally, we need to cover the development of optics used in the aiming and targeting of laser systems, as these developments have a significant impact on the applicability of laser systems to military objectives.

Weaponized lasers

The LASER, which stands for Light Amplification by Stimulated Emission of Radiation, was originally developed by Shawlow and Townes at Bell Labs in 1958 as an extension to MASER (Microwave Amplification by Stimulated Emission of Radiation) technology developed a few years earlier. The acronym for a LASER has become part of common speech, with the Merriam-Webster dictionary defining a laser as "a device that utilizes the natural oscillations of atoms or molecules between energy levels for generating coherent electromagnetic radiation usually in the ultraviolet, visible, or infrared regions of the spectrum".

The US Navy has been working on High Energy Laser (HEL) technologies since the early 70's, with the advent of Deuterium Fluoride (DF) lasers. Earlier developments in CO₂ lasers offered a laser which did not propagate in the sea-level maritime atmosphere nearly as well as the newly developed DF lasers (Albertine, 2002). The Navy-ARPA Chemical Laser (NACL) was successful at engaging and destroying highsubsonic TOW missiles in flight in March of 1978. Citing DoD over-emphasis on long wavelength IR laser technology, Congress cancelled the Sea Lite program under which the NACL and the follow-on Mid-Infrared Advanced Chemical Laser (MIRACL) in 1983. Congress failed to notice that for projected laser engagement scenarios (sea level, <10km range) the propagation for the IR lasers was better than the Chemical Oxygen-Iodine Laser (COIL) systems. Laser integration with a tracking system was continued in order to gain the engineering experience with an established laser while waiting on the development of newly directed technology. This integration culminated with the successful shootdown of a VANDAL supersonic missile by the MIRACL system in 1989, and follow-on testing to improve weapon accuracy through improved beam aiming systems and jitter reduction.

The Air Force Weapons Lab has also been working on HEL technology, with early work beginning in the 1970's. The Air Force Research Lab (AFRL) first demonstrated a COIL in 1977 (Perram 2004). The military applicability of airborne lasers was first championed in 1967 by Edward Teller. His idea culminated in the development of the Airborne Laser Laboratory (ALL) which was a KC-135 Aircraft modified to carry a carbon dioxide gas dynamic laser. This system succesfully shot down two towed drones and a number of sidewinder air to air missiles at the White Sands Missile Range, New Mexico in May of 1981 (Boeing, 2001).

In November 1996, Congress authorized Boeing, Northrop Grumman, and Lockheed Martin to begin development of the successor to the ALL, the Airborne Laser (ABL). Based on the much larger 747-400 and using a COIL laser much more powerful than the ALL's gas dynamic laser, the ABL was developed to intercept and destroy theater ballistic missiles in their boost phase. A smaller COIL laser system has also been developed for Special Operations Command (SOCOM), for use in support of ground operations. The ATL system carries a one-hundred kilowatt laser in the fuselage of a C-130 aircraft, and projects the beam from a turret mounted underneath the aircraft. A more detailed description of this system follows later, as it is the weapon selected for study in this research effort.

Propagation

As has been stated above, one of the primary concerns with evaluating the effectiveness of a laser system is the proportional loss of system power with increasing distance from the platform to the target. There are a number of ways of determining this

resultant loss in power, each having its advantages and disadvantages. Captain Azar's (2003) work used a first order brightness equation scaled by a factor of $1/R^2$ where R is the distance from the target. This gave a resulting power reaching the target in watts per square meter. There are currently a number of much more detailed sets of calculations known as wave optics codes which use detailed physics equations for optics and the propagation of light to represent the travel of a laser beam through various atmospheric effects. Among these are Science Applications International Corporation's (SAIC's) Atmospheric Compensation Simulation (ACS) code and MZA Associates Corporation's WaveTrain code. Both of these represent the current pinnacle in laser propagation fidelity and accuracy; however they both have extremely high computational overhead, with runs taking on the order of several hours. This amount of time for propagation calculation will definitely not be available to the operator in the field, thus we need a faster way to describe the 'flyout' of the laser. Though they are not developed with the same level of fidelity as the wave optics codes, scaling law models such as HELEEOS are orders of magnitude faster with run times on the order of seconds instead of hours.

Developed by the Air Force Institute of Technology Center for Directed Energy under the sponsorship of the HEL Joint Technology Office (JTO), HELEEOS is being designed to provide reasonable fidelity in predictions of energy delivered to a target for a wide range of militarily applicable input parameters (HELEEOS User's Guide). The output from HELEEOS has been benchmarked and tuned to match up with the output of the ACS code at a number of design points. This assists in validating the output of HELEEOS by assuring the user that for a given set of inputs, the output of the scaling law model will reasonably match up with the output of a higher fidelity model. Currently the HELEEOS model has a number of limitations, such as the lack of adaptive optics and a 'top hat' profile for beam intensity. However, since the area of laser weapon adaptive optics is still a developing field, and this work is concerned with the intensity over time and not specifically at any given point, neither of these are identified as limiting factors with regard to this research effort. The model does support dynamic engagements where the platform and target move relative to each other over the course of the laser engagement. Since the scenario used for this work will implement C-130 Gunship employment methodology, the relative geometry should remain almost constant for the duration of any given engagement.

Targeting

One problem associated with the implementation of an ultra-precise weapon system on board an aircraft in flight is the ability to accurately designate and lock onto targets at an extended distance. Though the projected laser system can project lethal fluence to distances somewhere in excess of 20 kilometers, the ability to accurately pick out a target and aim the laser at that distance is lacking. This is analogous to a readily understandable and well established ground based kinetic weapon problem. The standard issue M1903 Springfield battle rifle used during WWI by U.S. troops was accurate at ranges out to 1000 yards, but until the addition of optical sights, the effective range of the weapon was only 600 yards. Just as the .30-06 round accurately carries a lethal amount of energy beyond the ~600 yard sight range of the common soldier, the ATL beam still retains sufficient brightness to effect damage out past the range of the current sighting optics. This also means that with improved sighting optics and aiming components, it may be possible to also extend the effective range of the ATL as was done with the M1903.

Another problem arising from the addition of laser weapons to an arsenal stems from their stark contrast to the traditional kinetic weapon systems which operators are trained on and familiar with. The ATL will at least initially come online as a Special Operations Command (SOCOM) weapon, filling a new niche very close to that currently occupied by the UC-130 Spectre gunship. The instantly apparent difference in these two systems is the level of operator feedback involved in their associated weapon systems. While the Spectre provides instant feedback in the form of rounds visibly striking (or missing) a target, and the resultant payload reaction (high explosive, incendiary, etc), the ATL may not provide this level of feedback. At extended engagement ranges, the operator will have to be able to trust that the system performed as desired, and will have to be able to do so automatically. It is beyond the capability and outside the job description of a weapons officer to require them to calculate necessary fluence on target and the corresponding amount of lase time required to attain that level of fluence. This functionality will need to be built into the targeting computer system, such that the operator will simply select the target from a pre-loaded list and when the trigger is pulled, the appropriate lase time will occur automatically. Also, since SOCOM is well known for 'inventive' uses of systems, the targeting computer will need a large collection of generic targets for an operator to choose from in order to deal with emergent situations.

15

Design of Experiments / Linear Regression / ANOVA

In order to evaluate the data output from the model, we can use any one of a number of analysis techniques. Because no one technique is the be-all, end-all tool for data analysis, it is advisable to look at the data using at least a few of the most applicable techniques for the particular data set.

Design of experiments (DOE) refers to the particulars of an experiment, including the treatments, experimental units, rules and procedures for assigning treatments to experimental units, and measurements on the experimental units following treatment application (Neter, 1996). In general, DOE is most concerned with the rules and procedures portion of the aforementioned list, in order to maximize efficiency. Sir R.A. Fisher introduced the concept of randomization for experimental treatment application as a means of eliminating bias. By randomly selecting the order in which the treatments are applied, any systemic or subjective bias is effectively reduced or removed. This randomization is only necessary to remove unknown bias from the system, and is not necessary in the case of deterministic computer models, as each run is independent of run order, and will produce the same output whether the run is first, last or anywhere in the middle of a large run set.

Linear regression is the method of using a number of input variables and their relationship to an associated response variable to construct a linear model with which the output or response variable can be predicted based on a given set of inputs. As an example, for this particular problem we know that the output power of the laser decreases with increased distance, so the an increase in the distance input variable would have a negative impact on the power output response. The end result is a fixed equation into which the input variables are substituted in order to predict the output with negligible computational expense.

ANOVA stands for Analysis of Variance, which is another method of studying the relation between a response variable and the associated input or explanatory variables. ANOVA models do not require any statistical assumptions about the nature of the explanatory variables, nor do they require those variables to be strictly quantitative. Again, as an example, given that the geographic factor for laser output power is a qualitative variable, it follows that an ANOVA model would be developed in order to aid in the construction of the regression model. Should two levels of the geographic factor be shown to be statistically different, it would follow that they should use different regression equations to model the power output. On the other hand, should they be shown to not be statistically different, then we would be justified in using the same regression model for both of the factor levels.

Advanced Tactical Laser System

Overview

The Advanced Tactical Laser weapon system consists of a C-130 aircraft containing a sealed-exhaust Chemical Oxygen-Iodine Laser (COIL) with a laser turret mounted underneath the fuselage. The turret will be retractable for takeoff and landing in order to avoid modification of the landing gear. The current development contract is held by Boeing and though a variant system was originally being envisioned for use with the MV-22 Osprey airframe, the current incarnation of the system is limited to the C-130. The system is limited in output by the airlift capacity of the chosen airframe. In comparison, the 747-400 based Airborne Laser (ABL) has a much larger payload capacity, and thus it carries a larger laser, with power output in the megawatt class.

Concept of Operations

The ATL is one of the first in a new class of ultra-precision weapon systems which will change the face of the modern battlefield. The ability to interdict over long range with pinpoint accuracy brings a large capability to the fight. In addition to the weapon platform itself, the system brings a highly capable intelligence gathering tool in the form of the laser sighting optics. The ability to maintain a laser spot on a target at range is predicated on the capability to see and distinguish targets at range. This long range 'observer' role is a force multiplier for the special operations arena where the ATL could be initially fielded.

Previous Research

In order to better understand the situation in the arena of high energy laser (HEL) modeling and simulations, it is necessary to examine the work previously accomplished in the field. Two previous AFIT theses developed the area of laser simulation by examining the way in which HEL weapons were being modeled. Captains Maurice Azar and Michael Cook established a framework for evaluating the ATL in combat simulations which this thesis should attempt to expand upon in the area of target lethality

Research of Captain Maurice Azar

Assessing the Treatment of Airborne Tactical High Energy Lasers in Combat Simulations by Maurice C. Azar (2003) examined the current state of system modeling

for the ATL in a scenario set up in the Extended Air Defense Simulation (EADSIM). Captain Azar's scenario utilized a single ATL as a point defense against nine cruise missiles launched from random launch sites within a specified launch area. In order to populate the vulnerability inputs for EADSIM, Captain Azar utilized Tyson's 1st order Brightness equation to determine the power being delivered to the target. From there he worked out a value for radiant flux density and using assumptions about material properties he determined a probability for the delivered energy to destroy the target. He used the populated tables to initialize his scenario and gain insight into the performance of the system. EADSIM uses one table for propagation, which he populated through the use of the brightness equation, and a second table for lethality. He determined the entries for the vulnerablility table through the use of an equation governing the energy required to vaporize a material, and indexed the table by 'survivability percentile'. He concluded that EADSIM version 9.0 was not the most applicable model with which to evaluate the effectiveness of laser weapons, due to the lack of assessment of the variability of the atmosphere, as well as lacking logic for dealing with terrain obscuration of the target after the initiation of the laser engagement. He did however conclude that viable inputs to a campaign level model such as THUNDER could be generated by a mission level model like EADSIM, and included the number of targets killed per engagement and total laser firing time for an engagement. Results from numerous runs would most likely be rolled into a distribution for use by the stochastic campaign model.

Research of Captain Michael Cook

Captain Michael Cook's (2004) thesis, Improving the Estimation of the Military Worth of the Advanced Tactical Laser through Simulation Aggregation used output data from HELEEOS to populate propagation tables for input into EADSIM in order to better examine the evaluation of the military worth of the ATL. This input was used to initialize a number of runs of a scenario in EADSIM designed to measure the effectiveness of the ATL as a military system. For the EADSIM vulnerability tables, Capt Cook used generic levels for radiant flux density (fluence), and indexed the tables using a similar scheme to the one used by Capt Azar. One of the major findings of this work was the observation that HELEEOS and EADSIM (along with other models) exclude non-lethal damage due to the lack of criteria for evaluating 'varying degrees of non-lethal data' (Cook, 04). This partially stemmed from the fact that target vulnerabilities were not well enough developed to evaluate the effect of non-lethal actions taken against them.

Summary

In this chapter we have discussed the modeling hierarchy and identified the level at which the primary model used in this work operates. A description of the Joint Munitions Effectiveness Manual was provided, specifically noting the difficult nature of developing unclassified methods due to the lack of unclassified information about the JMEM. A list of laser issues was laid out, including a history of the DoD development of weaponized lasers, the fundamental problem with laser power falloff over a distance, and an example of the targeting issues associated with distinguishing and designating targets at the ranges involved. A description of the ATL system was provided, and the previous research efforts of Captain Azar and Captain Cook were summarized.

III. Methodology

General Methodology

The purpose of this chapter is to lay out the methodology for conducting this research effort. The specific scenario will be laid out, along with any assumptions which accompany it. A description of HELEEOS, the primary model used in this effort, will be presented, including the specified input being passed to the model, the development of input scripting, and the expected output data. An examination of the Design of Experiments used in this research will be discussed, with an emphasis on factor analysis, ANOVA, and regression techniques.

Scenario

As has been stated previously, the scenario for this research consists of a single ATL system engaging a single ground target. The model for this engagement is patterned after the Concept of Operations (CONOPS) for the UC-130 Spectre Gunship. The target is a stationary generic truck, in the $\frac{1}{2}$ - 1 ton pickup class. The ATL circles the target on a constant radius, similar to the flight path for a gunship engaging ground targets. This allows the ATL to minimize the slewing of the turret over the course of the engagement.

Figure 2: Scenario Geometry

This geometry will also allow the assumption of constant angle of incidence for the duration of the engagement. Given that the ground target is stationary, the slant range is the shortest tested range (2000 meters), and the platform is moving at the maximum tested velocity (129 m/s), the accompanying change in incident angle is 18.3 degrees, with all other engagement geometries resulting in a smaller delta in incident angle.

HELEEOS

Scenario setup will require the specification of a number of inputs for use by the model in the propagation calculations. HELEEOS has a set of inputs which are designated as default and can be loaded by the user via either the Graphical User Interface (GUI) or at the Matlab command line. Some of these values, such as Target Threshold Damage, are used by HELEEOS for p_k calculations, and as such will be irrelevant for this research effort. The model assumes a single aimpoint, and calculates the p_k relative to the user input Target Damage Threshold and Standard Deviation with

either a Lognormal or Normal distribution. While this is assumed to be a valid method for determining the probability of kill for a particular aimpoint, one of the purposes of this research is to further investigate options for confirming this method or developing a more applicable method by which to evaluate weapon system performance. It must be noted that HELEEOS assumes perfect tracking (Bartell, 2005), which in reality is impossible. Through the examination of varying target vulnerability parameters such as bucket sizes, and the introduction of jitter, the effect of imperfect tracking can be effectively studied. However, for the purposes of this research, the perfect tracking in HELEEOS will suffice, as what is being developed is not the entire list of factors to be fed to the end table calculations, but the methodology for producing table calculations. An examination of all applicable factors needs to be presented, and any relevant factors not examined for this research need to be noted, for the purposes of completeness.

The following table outlines the initial parameters for HELEEOS. The italicized entries are not varied in this research effort, while the bold entries are those parameters which will need to be either adjusted to match the scenario, or varied for evaluation.
| Parameter | Initial Setting |
|--------------------------------------|-----------------------|
| Scenario Type | Static Engagement |
| Slant Range | 9000m |
| Platform Altitude | 3000m |
| Target Altitude | 0m |
| Dwell Time | 1 sec |
| Platform Velocity Parallel to LOS | 0 m/s |
| Platform Velocity | 0 m/s |
| Perpendicular to LOS | |
| Target Velocity Parallel to LOS | 0 m/s |
| Target Velocity Perpendicular to LOS | 0 m/s |
| Relative Azimuth | 00 |
| Susceptible Target Length | 0.05m |
| Susceptible Target Width | 0.05m |
| Angle of Incidence | 90 ⁰ |
| Target Damage Threshold | $50,000,000 J/m^2$ |
| Target Damage Threshold STD | $1,000,000 J/m^2$ |
| Laser Type | COIL Laser (High Alt) |
| | 1.31525 μm |
| Exit Aperture | 0.5m |
| Relative Obscuration | 0.3 |
| Power | 50,000 W |
| Beam Quality | 1.3 |
| Wavefront Error | 0 |
| Total System RMS Jitter | 0 |
| Magazine Depth | 1 sec |
| Aerosol Type | Rural Aerosols |
| Atmosphere Type | U.S. 1976 Standard |
| | Atmosphere |
| Ground Wind Velocity | 4 m/s |
| Perpendicular to LOS | |
| Ground Wind Velocity Parallel to | 0 m/s |
| LOS | |
| Turbulence Multiplier | 1 |
| Turbulence Profile | HV 5/7 |

Table 1: HELEEOS Standard Settings

Input Requirements

For the purposes of this research we seek to evaluate the performance of the ATL system over a range of engagement conditions by varying selected inputs to the HELEEOS model described above. The model can be run from a GUI where all of these inputs can be selected as required. This does require user interaction via the keyboard and mouse between model runs, which is not conducive to completing the number of runs required for exhaustive analysis. The model can be run via the Matlab command line, which allows for scripting of repeated runs. The user can specify that the standard inputs are loaded first, and then can adjust any individual input via the command line before initiating a model run.

Factor Levels

In an experimental design, the input parameters which are to be varied are referred to as factors. Some of the input parameters listed in bold in Table 1 are not to be varied, but need to be adjusted from the default setting in order to match the scenario. Table 2 below contains the bold entries from Table 1, with their corresponding corrected values or range of values.

| Tuble 2. TIELEE of Seenano Settings | | | | | |
|-------------------------------------|------------------------------|--|--|--|--|
| Parameter | Scenario Settings | | | | |
| Slant Range | 2000m | | | | |
| Platform Altitude | 2000 - 12000m | | | | |
| Dwell Time | 1 - 5 sec | | | | |
| Platform Velocity Perpendicular | 150 - 250 kts | | | | |
| to LOS | | | | | |
| Susceptible Target Length | 0.05 - 0.1m | | | | |
| Susceptible Target Width | 0.05 - 0.1m | | | | |
| Laser Type | COIL-ATL Simplified High End | | | | |
| | Power – 40s Run Time | | | | |
| Laser Power | 100,000 W | | | | |
| Beam Quality | 1.1 | | | | |
| Magazine Depth | 5 sec | | | | |
| Aerosol Type | Described in Text | | | | |
| Atmosphere Type | Described in Text | | | | |

Table 2: HELEEOS Scenario Settings

For each of the parameters in Table 2 we will now describe the significance of that factor, as well as the reasoning for adjusting or varying it for this scenario. As a general rule, the adjustments are made in order for the input parameters to match the

latest projected performance characteristics for the ATL system, while the factors to be varied are those factors which would be loaded into a targeting computer at the time of engagement, and would therefore be directly relevant to required lase time calculations in the field.

Slant Range

For the purposes of this research, the viable slant range over which engagements could take place is 2000 to 12000 meters. The range input vector for slant ranges in meters is as follows:

 $slantRng = [2000\ 3000\ 4000\ 5000\ 6000\ 7000\ 8000\ 9000\ 10000\ 11000\ 12000]$ This represents the range of geometries from the platform firing straight down from the nominal altitude of 2 kilometers to the platform firing at a ground target ~10 km ground distance away. This researcher believes that this will be one of the driving factors in determining projected engagement lase times, since as has been discussed, beam power falls off with increased distance from the platform to the target. Also, given that the nominal scenario altitude is 2000 meters, this geometry covers the range of engagements from straight down from 2000 meters out to a ground distance of approximately 11,800 meters

Platform Altitude

Platform altitude is set at 2000 meters in order to facilitate the range of engagements required within the Slant Range factor range of values. It is understood that this choice is somewhat arbitrary, but is valid for the scenario as developed. The CONOPS for this scenario differ from previous research efforts in that a ground target is

being engaged, while in the work of both Capt. Azar and Capt Cook, the chosen target was a set of multiple targets, resulting in a series of laser engagements. Capt Azar's work used nine cruise missiles in flight, launched from random locations within a specified launch area. For that setup, it would be more appropriate for the ATL to fly at a higher altitude so that engagement ranges could be extended by lessening the target obscuration by the aerosols present in the lower atmosphere. Capt. Azar's EADSIM lookup tables contained data for slant ranges out to 15300 meters while the platform altitude was fixed at 15000 meters. While this geometry provides better visibility for the aircraft to detect and engage airborne targets, it restricts the ground range from the platform to ~ 3000 meters. Capt. Cook's scenario involved engaging ground targets which were simulated by zero velocity cruise missiles placed at zero altitude. He also utilized longer slant ranges (out to 15000m), but also varied the altitude between 1000, 4500, and 8000 meters. While it may be possible for the laser to deliver lethal fluence at these ranges, it was noted at the DEPS conference that it may not be possible for the targeting optics to effectively discern and designate targets at these ranges. The chosen scenario altitude allows the platform the option of engaging targets out toward the limit of the targeting optics (DEPS Conference, 2005). Additionally, the 2000 meter engagement altitude is above the 1525 foot boundary layer, below which most of the atmospheric aerosols are contained (Bartell, 2005) Without further evidence to the contrary, this altitude and slant range pairing will allow engagements within the performance envelope of the ATL and may allow insight into viable maximum engagement distance parameters.

Dwell Time

While lase time will be the 'knob' by which desired p_{eff} will be 'dialed' within the analysis portion of this work, a reference set by which this factor can be evaluated must be varied within the experimental design. The vector for lase time in seconds is as follows:

$$dwellTime = \begin{bmatrix} 1 & 1.5 & 2 & 2.5 & 3 & 3.5 & 4 & 4.5 & 5 \end{bmatrix}$$

The projected laser magazine for the ATL is currently 100 seconds of lase time (Boeing, 2005), and the scenario defined 1-5 second lase time will allow for between 20 and 100 engagements per sortie. It may be determined that longer lase times will be required for extended distances near the upper edge of the slant ranges defined. This may be a factor which will determine the correct engagement ranges over which the laser would be used in normal operating conditions.

Platform Velocity

In order to determine the correct CONOPS for any airborne platform, consideration must be given to airspeed. The vector for platform velocities, converted from knots to meters per second is as follows:

The C-130 is capable of flight in excess of 250 knots, but for the purposes of this scenario, we will limit the airspeed to 250 knots. HELEEOS uses velocity measured in m/s, which for the stated scenario range of 150 to 250 knots translates to 77 to 129 m/s. As was stated before, this should not violate the assumption of constant incident angle for the laser at the target, as the maximum change in incident angle is obtained at the shortest

engagement slant range and is only 18.7⁰ given the aircraft is traveling at the maximum velocity of 129 m/s for a full 5 second engagement.

Susceptible Length/Width (Bucket Size)

The Susceptible Length and Width parameters are used to describe the 'bucket' into which energy can be deposited on the target in order to cause damage. The vector for the bucket size parameter in meters is as follows:

$$spotSize = [.01 .02 .03 .04 .05 .06]$$

When the input is made, the Length factor and Width factor are varied symmetrically (Length = Width), and the resultant levels are simply each of the six listed levels squared. This factor is varied to simulate the variance in target vulnerability by aimpoint or desired effect. It may be determined that for a particular aimpoint it is less important that the spot be maintained in a small area. As an example, in order to light the vehicle interior on fire, it may not be as important to maintain a fixed spot as it is to burn a hole in the hood or fuel tank. This may allow the former as a viable aimpoint at a greater range than the later two, as spot point maintenance becomes more difficult with increasing range. An interesting note from the screening runs is that for bucket sizes above $.0025 \text{ m}^2$, (.05 m * .05 m), the power in the bucket did not vary, meaning that the entire beam spot was contained in the bucket. Given that result, the initial levels from .05m to .1m were changed to the levels listed above. The .06m level was retained in order to attempt to replicate the observation from the screening runs and to possibly account for beam spread at longer engagement ranges than were used in the screening runs.

Laser Type

HELEEOS supports a number of laser types and wavelengths, each with their appropriate atmospheric absorption and scattering characteristics. For this research, we will implement the High Powered ATL COIL Laser defined in the model's laser types. This is a COIL laser with a wavelength of $1.317\mu m$. Within the model this laser type is denoted as laser type seven.

Laser Power

The current projected Initial Operational Capability (IOC) for the ATL power output is 100kW (Boeing, 2005). Previous research has used either 50kW or 50kW and 100kW laser output levels. Since we are attempting to replicate the currently projected system as it will be fielded, this research uses a fixed laser output power of 100kW.

Beam Quality

One of the optical characteristics of a laser beam is Beam Quality. A 'perfect' Gaussian beam is given a value of 1, with beam qualities typically falling in the 1.1 - 1.5 range (as seen by the author). This rating is a measure of the focusability of the laser and governs the distribution of the laser spot across the surface of the target. The current projected ATL system lists a beam quality of 1.1 (Boeing, 2005).

Magazine Depth

For the currently projected system IOC, the magazine depth is listed as 100 seconds of lase time. Though lase times for this scenario are limited to 5 seconds, and there is no tracking of total lase time between scenario engagements, the magazine depth must be at least 5 seconds. This is because each run consists of a single engagement

where previous work has looked at multiple engagements within a single model run. In order to match the system as closely as possible, the magazine will be set to 100 seconds.

Aerosol Type

HELEEOS contains data for a number of different aerosol type profiles. Aerosols are the fine matter particulates in the air which are more prevalent in the lower atmosphere. As was noted above, these particulates are for the most part contained in the atmosphere below 1525 feet. These particulates impede the propagation of a laser beam by absorbing energy and diffracting the beam. These will be adjusted within the scenario to match the last factor, Geographic Area, in order to replicate the specified atmospheric environment.

Geographic Area

Within this scenario, geographic area is varied over 5 regions: Average Weather, Mid Latitude, Coastal, Rugged Terrain, and Chaparral. The current Boeing system assumptions lists these five environments as the atmospheric conditions of interest to the development of ATL modeling. Within the HELEEOS model, these regions will be represented by the 1976 Average atmosphere, Mid Latitude atmosphere, and the Expert Atmospheric data for Langley, Nellis, and Davis-Monthan, respectively. All calculations are made at a 50th percentile value for relative humidity, and are based on the summer data numbers (where summer and winter settings exist).

Input Script Development

In order to adjust the input parameters to the specified levels and to vary the experimental factors, a Matlab script with a nested looping structure has been developed. Capt Cook used a script with two loops in order to vary platform altitude and slant range over his scenario values in order to develop a propagation table for input into EADSIM. This script was modified in order to perform further variations and gain additional insight into the laser propagation over a larger range of input values, to adjust parameters to this scenario, and to calculate additional outputs. Appendix A contains the script along with the relevant code comments.

Output Data

Within the input script, the output for each design point is fed into a data array, and after all model runs have been completed, the array is written out to a comma separated text file for import in to Microsoft Excel or other software package for data analysis. The outputs initially gathered are as follows: Peak Irradiance (W/m²), Average Irradiance (W/m²), Fluence based on Peak Irradiance (J/m²), Fluence based on Average Irradiance(J/m²), and Power in the Bucket (W). The fluence numbers are calculated based on the reported numbers for irradiance because in the course of performing screening runs, it was discovered that the fluence number being output by the model was a number of orders of magnitude larger than should have been expected, given the geometries and lase times. The fluence numbers are calculated using the following equation:

Fluence = *Irradiance* × *Lase Time*

Energy in the Bucket is also listed, and is calculated as follows:

Energy in the Bucket = Power in the Bucket x Lase Time

It is hoped that additional insight can be gained by examining this larger number of outputs, in an attempt to find a measure by which the laser can be accurately and effectively evaluated. A number of preliminary screening runs are being performed in order to confirm that the input variation of the factors works as intended, and to see if there are any issues which may arise from large data output. One initial run consisted of 11881 design points, and took 1.65 hours to complete computation running on an Athlon64 2800+ system with 1 gigabyte of memory. From this initial effort we can see that scalability of the input factors in number and number of levels is limited only by our ability to capture and analyze the data. For the sake of simplicity and portability, we will limit the number of design points to the number of data row elements which we can capture in a spreadsheet tool for manipulation. Current Microsoft Excel 2003 worksheets are limited to 65,533 data rows, thus an additional factor with 5 levels could be explored without exceeding our imposed limit. Given that the processing time required to complete these runs is directly proportional to the number of runs being performed, we should expect a computing time of approximately 9 hours if the full data output capability is utilized.

Design of Experiments

This effort will use a full factorial experiment design, where every factor is varied across every available level of every other factor. This is generally the least computationally efficient method, but considering the length of any given run is on the order of seconds, full enumeration of all factor levels outweighs the minimal time

required to do so. Additionally, a number of replications for each treatment (or set of factor levels) is generally run. The output from HELEEOS is deterministic, and therefore additional replications for each treatment gain nothing in terms of statistical significance. Also, because the model is deterministic, as was mentioned in Chapter 2, the model runs do not need to be randomized in their order because the model output is deterministic and is independent of time or run order.

The initial expected end-product for this research will consist of a tool to be used for development of JMEM type data. The tool will be based on a linear regression model which will be constructed to predict the output power of the laser system given a set of inputs and will be adapted to 'tune' the output to the required level by adjusting one of the input variables.

ANOVA stands for Analysis of Variance, which is another method of studying the relation between a response variable and the associated input or explanatory variables. ANOVA models do not require any statistical assumptions about the nature of the explanatory variables, nor do they require those variables to be strictly quantitative. Given that the geographic factor for laser output power is a qualitative variable, it follows that an ANOVA model would be developed in order to aid in the construction of the regression model. Should two levels of the geographic factor be shown to be statistically different, it would follow that they should use different regression equations to model the power output. On the other hand, should they be shown to not be statistically different, and then we would be justified in using the same regression model for both of the factor levels.

Factor Analysis

In order to better understand the influence of each of the input variables on the power output given by the model, a number of multivariate analysis techniques will be applied to the data. Multivariate analysis is the application of methods that deal with large numbers of measurements made on each object simultaneously (Dillon, 1). Objects in this case are individual design points, and the measurements are the individual factor levels for each output observation. These techniques move away from univariate and bivariate analyses which concentrate only on individual or pairwise analysis of variables and looks at the covariance between three or more variables simultaneously. While this may prove overkill given the number of input factors identified for this study, it is important to initially explore all options for analysis which seem relevant to the area of analysis.

Vulnerability Assessment

The vulnerability assessment portion of this work is where the largest change from previous efforts occurs. While the previous work used vulnerability en-route to some other higher level output factor as a MOE, this research is restricted to an exploration of the vulnerability assessment itself. The intention is to fill out and solidify the concepts and methodology for developing and presenting this vulnerability data in order to create a product which a current JMEM user would find familiar and easy to use. Using empirical test data instead of theoretical values for required radiant flux density, as well as evaluating multiple aimpoints, will aid in more accurately evaluating the vulnerability of targets to interdiction by a laser system.

Materials Assessment

The data for required radiant flux densities was obtained from AFRL/DE by specifying particular thicknesses of steel, painted steel, and rubber which correspond to the aimpoint configuration for the designated target for this scenario. The data returned lists the required flux density in joules per square centimeter required to burn a hole in the specified material. The following is a list of the specified materials, thicknesses and the energy required to realize the desired effect.

| Material | Thickness | Energy Required to Melt | Irradiance | Critical Irradiance |
|--------------------------------|---|-------------------------|-----------------------|----------------------|
| Primed and Painted Steel | 0.080" | 2500 J/cm ² | 500 W/cm ² | 50 W/cm^2 |
| Primed and Painted Steel | 2 Layers, 0.080" (Second layer bare) | 5000 J/cm ² | 500 W/cm ² | 50 W/cm ² |
| Primed and Painted Steel | 0.160" | 5000 J/cm ² | 500 W/cm ² | 50 W/cm ² |
| Primed and Painted Steel | 2 Layers, 0.160" (Second layer bare) | 9900 J/cm ² | 500 W/cm ² | 50 W/cm ² |

Table 3: Vulnerability Data

Table 3 notes that for any given target point, there is a Critical Irradiance level, which represents the threshold above which the laser output power at the target must remain in order to accumulate the required energy to melt the target material. This level is the level of input energy below which the target will just 'get hot' instead of accumulating enough energy to begin the process of melting. For reference, the .080" thickness represents 14-gauge steel, and the .160" thickness is 8-gauge steel, both common thicknesses used in vehicle construction. The body panels on a light truck would be represented by the 14-gauge sample, while a heavy duty truck may incorporate the thicker 8-gauge sample in some components. Though the scenario calls for a single ground target, since the target has been previously defined as a pickup truck in the $\frac{1}{2}$ - 1 ton class, these samples encompass the range of viable target aimpoint materials for this class of target.

At this point it makes sense to review the process of imparting a desired effect to a target via energy deposited by a laser beam. The laser beam imparts energy to the surface until, assuming the energy is being added at a wattage level above the critical irradiance threshold described above, a number of effects may take place. The material can transition to liquid form (melt), vaporize, or ignite and burn or char. For the purposes of this research, we will be concentrating on the melting of the material, and will 'hand wave' the energy lost to the vaporization and burning phenomena by the adjustment of the vulnerability threshold. Additionally, for the data obtained, these represent the worst case scenario for each of the target configurations. What is meant by worst case is that this configuration assumes the worst case for any of the given inputs for target characteristics. Specifically, for the two layer samples, there may be portions of the target surface where the layers are separated by some distance (assumed up to and including 1cm). This configuration is common in vehicle construction, such as in the support rib sections underneath the hood of our fictional truck. In this separated configuration, the second bare layer would absorb the energy from the laser better than in the non-separated case, and would therefore require less energy to melt through both layers while separated (as opposed to non-separated). The painted surface for the

samples was assumed to be white paint, which has the lowest absorption rate for any paint color. Any darker color would absorb at a faster rate and again require less energy to be deposited in order to attain melt-through (Thompson, 2005). Thus, this data set represents the 'hardest' target within this class by assuming white paint color, and worst specific particular aimpoint characteristics by assuming there is a second metal layer nonseparated from the surface layer.

To compensate for the variation in target construction material, the damage threshold for this work will be ten percent higher than the figures listed in Table 3. It is understood that this adjustment is rather arbitrary, but is relevant as a correction factor for the purposes of real world planning calculation replication. The critical irradiance threshold will be maintained at the same level, as it is assumed there may just be up to ten percent of extra material or material energy absorption capability which would simply require the additional energy deposited at the original threshold for accomplishment of melt-through.

Concept of Operations Considerations

As was mentioned above, the basic concept of operations for the ATL has been assumed to be similar to that of the current UC-130 Spectre gunship. The expected model output should contain sufficient data to perform an initial survey of viable engagement parameters for the operation of the ATL. By evaluating the relation of various input factors to the power output of the laser at the target, a clearer picture of which factors may be ignored and which factors may warrant further investigation. As an example, it may be found that platform velocity has such a small influence on power output within a given range of other inputs as to recommend that the CONOPS for flight speed be set according to fuel consumption rather than laser output. On the other hand, the exact opposite may be true, and flight speed should be set so as to utilize some characteristic of a particular speed. All of the viable alternatives warrant initial investigation Care should taken that previous research given similar data is examined and contrasted, while at the same time gaining additional insight from the addition of design points.

Summary

The methodology chapter provided an explanation of the general research plan for the remainder of this work. The scenario was laid out, including the background justification for engagement geometry. The primary model, HELEEOS, was described, and a detailed explanation of all pertinent input factors was provided. The input scripting process was outlined, and initially gathered output responses were defined. The design of experiments used in this research was reviewed, concluding that the full factorial experiment used, though not computationally efficient, is the most applicable for exploration of factor analysis. Finally, a description of the vulnerability portion comprising the greatest advance of this research over previous work was discussed, with special attention paid to the examination of target vulnerability assessment.

IV. Analysis and Results

Chapter Overview

This chapter contains the core of the analysis work done and will build from initial data verification analysis to ANOVA and factor influence analysis. It will conclude with an investigation of viable weapon system engagement profiles and presentation of system performance in a tabular format. Initial data verification will investigate the model output and will attempt to confirm that physical phenomena which are expected based on the scenario setup are correctly represented in the data. The ANOVA will attempt to determine which of the factors are the most significant to power output. Finally, we will present a regression model to predict peak power output, which can then be used to evaluate inputs against the vulnerability thresholds for a given aimpoint.

Results of Simulation Scenarios

The final experimental design contained an additional two atmospheric types, giving a total of seven atmospheres, nine lase times, five values for platform velocity, six bucket sizes, and eleven slant ranges, for a total of 20,790 design points. For each of these points, output was recorded for peak irradiance, average irradiance, fluence based on peak irradiance, fluence based on average irradiance, and power in the bucket. After the data was recorded, a unit conversion was performed. HELEEOS outputs for irradiance and fluence are in W/m² and J/m² respectively, and the vulnerability data obtained from AFRL/DE is in W/cm² and J/cm², so the first four outputs were multiplied by a factor of 1/10,000 to convert from $1/m^2$ to $1/cm^2$. This allows direct comparison

between the unit converted data and the data acquired for the purposes of vulnerability assessment.

For each of the inputs, there is an expected relationship with the output power which is based on the physics involved with the scenario. For example, we expect both the peak and average intensity to increase as slant range decreases, as the laser is passing through less of the atmosphere. These relationships can be seen by plotting the output data against the inputs to see if the expected pattern appears. We will investigate all the inputs against the output data in their input order: slant range, lase time, platform velocity, atmosphere type, and bucket size.

For the slant range, as stated above, the researcher expects the power at the target to fall off as distance to the target increases.

Figure 3: Peak Irradiance vs. Slant Range

Figure 3 shows the unit converted peak irradiance values plotted against slant range. We can see that the power at the target does indeed fall off with increased slant

range, but there is some stratification of the data at each range, meaning there is another factor involved, and we would initially identify atmosphere as a possible culprit.

Figure 4: Average Irradiance vs. Slant Range

Figure 4 shows the unit converted average irradiance values plotted against slant range. As expected, power does fall off with increased range, but the variance in the data suggests that there is something in addition to our initial guess of atmospheric stratification as a reason for variance, as the values for even the closest range fall off almost to zero, and there appear to be a number of widely distributed groups within that one range. On initial investigation, it appears that the bucket size is the factor involved here, and it did not appear in the peak values above because bucket size affects the average irradiance, but not the peak. This will be explained and expanded on in the section on bucket size later in this section. For the lase time factor, we expect energy deposited to increase as lase time increases. This should be apparent in the plots of both peak and average fluence over lase time.

Figure 5: Peak Fluence vs. Dwell Time

Figure 6: Average Fluence vs. Dwell Time

Figures 5 and 6 show the linear increase of fluence at the target with increased dwell time. There again seems to be a stratification based on atmosphere, slant range,

and bucket size. The reason all three of these factors are identified as interactions is as follows: since irradiance falls off with increasing range, the fluence at each dwell time value will contain the values for all slant ranges. Also, since there are different levels of irradiance for the varying atmospheres, this will also cause multiple irradiances for each dwell time level. Finally, as bucket size increases, the average irradiance decreases, and again causes multiple fluence levels for each dwell time level.

Next, as platform velocity increases, we expect an increase in the peak irradiance at the target, and a subsequent increase in fluence and PIB, due to the mitigation of the effects of thermal blooming caused by the laser more rapidly slewing though the atmosphere.

Figure 7: Peak Irradiance vs. Platform Velocity

Figure 7 shows that although there is a difference in the output performance of the laser, it is very slight across all the levels tested. From the JMP output for this plot, the linear fit for peak irradiance is as follows:

$$Peak(W/Cm^2) = 7966.33 + 14.03 Platform Velocity$$

This means that for the increase from 77 to 129 meters per second, the average for peak irradiance increased 729.56 W/cm², or 9.16%. Since the maximum efficient cruising speed of a C-130 is 177 m/s, and this speed is well above the values tested for this work, we will from this point forward use only the output values corresponding to the maximum tested platform velocity of 129 m/s.

For the atmospheric factor, we made no assumption about the difference which each of the atmospheres would have on the output data, but expected to see some variance, based on the physical properties of the atmosphere at each of the chosen geographic locations. If you will recall from Chapter III, the seven atmospheric types are: the 1976 Average data, Mid-Latitude data, and the HELEEOS ExPERT data for Langley, Nellis, Davis-Monthan, Hail (Saudi Arabia), and the Gibraltar Civilian/Military airfields. After performing a one-way ANOVA for this factor using JMP, it was discovered that three of the levels were not statistically significantly different.

| Level | | | Peak Irradiance | | |
|---|---|---|-----------------|--|--|
| Gibraltar | А | | 11953.125 | | |
| Langley | В | | 9727.992 | | |
| Hail | В | | 9652.636 | | |
| Davis Monthan | В | | 9652.636 | | |
| Nellis | | С | 9195.436 | | |
| 1976 Standard | | D | 8682.046 | | |
| Mid Latitude | | E | 7018.191 | | |
| Levels not connected by the same letter are | | | | | |
| significantly different | | | | | |

 Table 4: Atmospheric Means Analysis

Table 4 lists the mean peak irradiance for each of the atmospheric factor levels, and the center column shows to which mean group the level belongs. JMP determines this statistical significance using the Tukey-Kramer HSD test. Given that the Gibraltar data and the Langley data are both from coastal regions, while the Hail data and Nellis data were both considered chaparral, it is apparent that the initial assumption about these outputs being similar was incorrect. It has instead been shown that the Langley, Davis-Monthan, and Hail outputs are statistically the same, and all other atmospheric levels are different. This means that when a regression is developed to attempt to predict laser output, the inclusion of atmosphere as a predictor should only contain five statistically differing estimates for regression coefficients.

Finally, we expect to see a decrease in average fluence for a given slant range as the bucket size increases. This is because as the bucket size increases, there is more area over which we are averaging the beam strength, while at the same time we are capturing more of entire beam spot. However, we should also see a limit to this pattern, because once the entire beam has been captured, we are then averaging the energy being deposited over a larger and larger area. Power in the Bucket should be the output measure by which this phenomenon should be most readily discernable, because unlike the average, the PIB number does not fall off after the entire beam spot has been captured, as it is an integration of the energy deposited over the area of the spot, rather than of the bucket. Thus, as the bucket increases, PIB should also increase, but only until the entire spot has been captured, at which point the PIB output should remain constant. From the screening runs we noted that for all the bucket sizes investigated, the PIB number remained almost constant, meaning the buckets were too large for the increasing PIB with bucket size phenomena to be observed, as we were already capturing the entire

spot. For the screening runs, the bucket sizes ranged from $(5\text{cm})^2$ to $(10\text{cm})^2$, and since we noted the lack of change in PIB, the bucket sizes for the production runs were changed to $(1\text{cm})^2$ - $(6\text{cm})^2$. With this information in hand, an analysis of PIB over slant range was performed for a single atmospheric level and platform velocity level.

Bucket Size Effect on PIB (1976 Atmosphere)

Figure 8: Bucket Size Analysis

Figure 8 shows that as the bucket size increases, the corresponding PIB also increases, but is limited by the size of the spot at a given range. It can be seen that at the minimum range of 2000 meters, the entire spot energy has been captured in the 9cm² bucket, and as the range becomes larger and the spot size increases, the full energy is not captured until the larger bucket sizes. Since during the screening runs it was observed that the PIB output did not increase significantly between bucket sizes out to 4000 meters, it was assumed that the entire spot was being captured for these larger bucket sizes, and the decision was made to change to the set of smaller buckets. After performing the analysis on the production data, there is still some question as to the proper bucket size to use for targeting purposes. After discovering the pattern displayed in Figure 8 above, the same analysis was run on the screening data for the same atmosphere and platform velocity, and a similar pattern was discovered.

Figure 9: Screening Run Bucket Size Analysis

We can see that as the slant range increases, there is a significant difference in the amount of energy being deposited depending on the bucket size. While this is indeed an interesting result, though the PIB output increases with bucket size, the average irradiance continues to fall off for the larger buckets, and is especially distorted at close ranges. For example, at a 2000 meter slant range with a $.01m^2$ bucket, the average irradiance is 775 W/cm² and the peak is 50900 W/cm², while with a $.0036m^2$ bucket, the average irradiance is 2150 W/cm² with the same peak. Thus it is apparent that we need to choose a spot size large enough to capture the majority of the beam profile, but not so much that the peak value is 'washed out' over the large bucket area. This suggests picking a value toward the smaller end of the screen run bucket sizes, but on the upper side of the production runs. We therefore will restrict further investigation to the 36 cm² bucket size, both to capture the entire spot size, and to limit the area over which we are attempting to cause the desired effect.

Predictive Model

After the initial screening of the data, in order to formulate a predictive model for the output, linear regression techniques were applied to the data. The number of design points was reduced by limiting the bucket size to the 36cm² level and the platform velocity to the 129m/s level. The original set of factor levels was [7 9 5 6 11] resulting in a total of 20,790 design points. The reduced set of factor levels is [7 9 1 1 11], giving a total of 693 design points.

In order to most accurately predict the number of seconds of dwell time required to exceed the threshold criteria for each aimpoint in Table 3, we have determined that it would be most applicable to consider the average irradiance across our chosen bucket size. According to the Intermediate Value Theorem from calculus, we know that for any continuous function on a closed interval [a,b] where *c* is between f(a) and f(b), there is some x^* on [a,b] such that $f(x^*)=c$ (Mendelson, 114). Additionally, we know that if c is the mean value for the function over [a,b], f(x) decreases monotonically over [a,b], and that $f(b) < f(x^*) = c$, then it is necessary that $f(a) > f(x^*)=c$. We know that the irradiance falls off with distance from the center of the laser spot, and does so monotonically. The short explanation of all the previous math is to explain that if we are concerned with satisfying a energy threshold within a given aimpoint, and calculate the amount of time required to reach that threshold based on the average irradiance across the spot, then if we satisfy that threshold on average, we have more than exceeded the threshold at the peak irradiance at the center of the spot and have therefore most definetly satisfied the threshold somewhere within the aimpoint bucket.

From the nature of the physics involved, we can see that except in cases of extreme thermal blooming, the irradiance at the spot is independent of dwell time, and we therefore can not include that factor as a regressor. This leaves the atmospheric type and slant range as our inputs for a regression model. Since we have already determined that not all of the scenario atmospheres are statistically different, we should expect that the betas for the regression for each of these levels should be very similar or identical. We will however initially use all of the levels as predictors in order to confirm this result before combining atmospheres. Additionally, it makes sense to go ahead and predict the unit converted average irradiance, as linear regression will produce identically comparable models when predicting any output and any linear transformation of that input. Since the unit conversion involves only a linear transformation (dividing by 10,000), the transformation will not interfere with the predictive capability of the model.

In order to be sure of the correct prediction based on atmospheric level, six binary dummy variables were coded, with atmosphere 1 representing the baseline, and each of the other atmospheric levels represented by a binary variable. This ensures that the betas output by JMP[®] are coded correctly. Using the minimum mean sqare error method of linear regression, the model for predicted average irradiance using all levels of the atmospheric factor and slant range as regressors, JMP[®] outputs the following for the model:

| | Summary of Fit | | | | | | | |

Figure 10: Linear Regression Model Including All Atmospheres

From the parameter estimates in Figure 10 we can see that according to the regression, atmospheric levels five and six are identical since they have the exact same beta value. This was expected, as this was evidenced in the Tukey-Kramer HSD test

performed in Table 4 above. However, from this test we expected that atmospheric level three should also be associtiated with levels five and six. It is apparent in the reduced data set that there is some difference in the means across the atmospheric factor levels. In order to confirm this, the Tukey-Kramer HSD was re-run on the reduced data set, and is displayed in Table 5.

| Table 5. Tukey-Klainel HSD for Keduceu Data | | | | | |

| Langley | D | 864.8182 | | | |
| Levels not connected by same letter are | | | | | |
| significantly different | | | | | |

Table 5: Tukey-Kramer HSD for Reduced Data

This re-evaluation of the data in the reduced set indicates that for some reason, the third atmospheric level now has the lowest mean, and that only levels five and six are strictly related. Level two straddles the five/six group and level four, and should thus have a beta value between the values for these level groups. A review of the information in Figure 10 shows that this is indeed the case. Since we only have data for one replication, this test will only detect larger differences in the means. Using only three replications of the data, the means separate into six distinct levels. The Davis-Monthan and Hail data remains identical, and we therefore can combine the atmospheric levels for these two atmospheres. This is accomplished by coding a new binary dummy variable which contains a 1 in the rows where the atmosphere equals either Davis-Monthan or Hail, and zero otherwise. This variable is then added to the model, while the variables

for atmospheric levels five and six are removed. This substitution will result in a reduction in the number of degrees of freedom used in the model, without any reduction in the predictive power of the model as represented by the value for R^2 not being reduced. Additionally, during recoding and further investigation it was observed that the slant range squared is also a significant factor for prediction and was added to the model. Using this new coding scheme, the model was re-run and the following results were observed:

| | _ | | | | | |

Figure 11: Regression Results with Consolidated Atmospheres for Reduced Data

Figure 11 shows that all levels are significant because all of the Prob>|t| values are much less than the commonly accepted cutoff of .05. This regression gives the following equation for estimating average irradiance (W/cm²)output:

Equation 1:

$$Irradiance (W / cm2) = 2448.5134 + (-192.6364 \times Atm 2) + (-335.1818 \times Atm 3) \\ + (-249.0909 \times Atm 4) + (-132.9091 \times Atm 5 / 6) \\ + (64.4545 \times Atm 7) + (-0.1871 \times Slant Range) \\ + [(Slant Range - 7000)2 \times 0.00000611]$$

Where the Atm variables represent the atmospheric type, and are equal to 1 if the atmosphere is of that type, and are zero otherwise.

As an example, we will evaluate this equation for a sample design point. Given the input factor levels given in Table 6, we will perform the regression and determine the approximate value for the average irradiance from HELEEOS given in the last column of the table.

| Table 6: Example Regression Calculation Data | | | | | | |
|--|------------------------------------|-----|---|--------|------|--|
| Slant | Slant Dwell P Vel Atmos Spot Irrad | | | | | |
| 2000 | 1 | 129 | 1 | 0.0036 | 2154 | |

Substituting these values into Equation 1 gives:

Equation 2: Example Regression Calculation

Irradiance
$$(W / cm^2) = 2448.5134 + (-192.6364 \times 0) + (-335.1818 \times 0)$$

+ $(-249.0909 \times 0) + (-132.9091 \times 0)$
+ $(64.4545 \times 0) + (-0.1871 \times 2000)$
+ $[(2000 - 7000)^2 \times 0.00000611]$
= 2227.12

This gives an error of -77.12 or -3.39% for this data point. Using this percentage based error, the error remains relatively small until the slant ranges reach the 10,000m range, where the extreme error appears to be limited to the Langley atmosphere. Plotting the percent error against slant range, the following pattern emerges:

Figure 12: Percent Error by Slant Range

We can see that the percent error versus slant range plot in Figure 12 exhibits a sinusoidal pattern, and by examining the Durbin-Watson autocorrelation score, we can see that there is definetly some issue with correlation between the responses. What is interesting is that the highlighted points in Figure 12 are all from the Langley atmosphere, and the three points directly below those highlighted points are from the Nellis atmosphere. The highest point is for the Langley atmosphere where actual average irradiance is 179 W/cm² and the predicted average irradiance is 21.04 W/cm². This indicates that there is some interaction over slant range which was not apparent when the

lower platform velocities and smaller bucket sizes were still included. One possible explanation is that the effects of thermal blooming are mitigated more in the closer ranges for the Langley atmosphere due to the nature of a coastal/maritime atmosphere, and there is a stronger interaction between these factors as range increases. Adding all of the interactions between slant range and the coded variables scales the percent error closer to zero, but does not at all mitigate the sinusoidal pattern exhibited in Figure 12.

Figure 13: Error by Slant Range Including Interactions

Based on p-values, the Mid-latitude atmosphere interaction with slant range is not significant, and based on the betas for the other interactions, we are well enough off without any of these additional interactions included. The sinusoidal pattern in Figure 12 continues in Figure 13, simply scaled toward zero across the slant ranges. This points to an area for further study, as it seems that some unknown underlying factor is influencing the output as slant range increases. However, the model is not grossly under-estimating

the output until the extreme ranges of the scenario, where based on the level of irradiance it would not be possible to effect damage within the imposed five-second per shot time limit. We will therefore press forward using the model as established in Equation 1 and will now begin the process of producing predictive output for a JMEM like data table.

Vulnerability Assessment

Now that the predictive model has been established, we will begin the process of evaluating the laser against the chosen target evaluation criteria. If the reader will recall, Table 3 listed the vulnerability data provided by AFRL/DE; however it was decided that this data would be scaled upward by ten percent in order to account for manufacturing inconsistencies and general conservativeness.

| Aimpoint | Material | Thickness | Energy Required to Melt | Critical Irradiance |
|----------|------------|-------------|-------------------------|---------------------|
| 1 | Primed and | .080" | 2750 J/cm^2 | 50 W/cm^2 |
| | Painted | | | |
| | Steel | | | |

| | Painted | .080" | | |
| | Steel | (Second | | |
| | | layer bare) | | |
| 3 | Primed and | .160" | 5500 J/cm ² | 50 W/cm^2 |
| | Painted | | | |
| | Steel | | | |
| 4 | Primed and | 2 Layers, | 10890 J/cm^2 | 50 W/cm^2 |
| | Painted | .160" | | |
| | Steel | (Second | | |
| | | layer bare) | | |

Table 7: Scaled Vulnerability Data

Note that Table 7 does not contain the column for irradiance from Table 3. This column has been excluded as this value will be determined by the output from Equation 1, and will be used to determine the number of seconds of dwell time required in order to cause the desired effect. Additionally, it is important to note that though the output from

Equation 1 does predict values for irradiance below the critical irradiance threshold, the actual data never drops below this level. In either case, these data points reside at the longest slant ranges and due to the level of irradiance both produced and predicted, the energy required for melt-through would not be reached due to dwell time limit as opposed to not meeting the critical irradiance requirement.

With these pieces of information in hand, we can now proceed to develop vulnerability tables for our target, with entries for each of the aimpoints described in Table 7. Because the linear regression equation is valid for points within the range of the data for which it was originally developed, we can confidently interpolate slant ranges between those entered in the original design. The entire range of resulting tables are listed in Appendix C, but for the purposes of discussion we will examine a table for Atmosphere 5/6, which the reader will recall are Davis-Monthan and Hail, Saudi Arabia. The reduction of Equation 1 for this atmosphere is as follows:

$$Avg (W / cm^{2}) = 2448.5134 + (-192.6364 \times (0)) + (-335.1818 \times (0)) + (-249.0909 \times (0)) + (-132.9091 \times (1)) + (64.4545 \times (0)) + (-.1881 \times Slant Range) + [(Slant Range - 7000)^{2} \times 0.00000611]$$

From this equation we can use the slant range column of the table to predict irradiance, and then can determine the number of seconds required to melt through the chosen aimpoint. Number of seconds required for melt-through is generated from the following function:

$$Seconds \operatorname{Re} quired = \begin{cases} \frac{Threshold}{\operatorname{Pr} edicted \ Irradiance} & if \frac{Threshold}{\operatorname{Pr} edicted \ Irradiance} \leq 100\\ N/A & Otherwise \end{cases}$$

| Aun | olant Range | Inadiance | | | | |

Table 8: Predicted Time to Melt-Through for Atmosphere 1

From Table 8 we can see a fall-off in the ranges at which the ATL is capable of inflicting the required amount of damage as the threshold moves up across the selected aimpoints. This limit is of course arbitrary, and is based on our prescribed CONOPS limit of five seconds for any particular shot. The tables listed in Appendix C are built
such that this arbitrary restriction is removed, and only the critical irradiance criteria is checked. Thus the maximum time for the listings in those tables is the hard limit of 100 seconds of lase time as dictated by the current projected ATL system capabilities.

Figure 14: Required Lase Time Over Slant Range, by Aimpoint, for Atmosphere 1

Figure 14 shows the increasing lase time required for melt-through, with the original five second time limit depicted as a horizontal line across all the ranges. Note that for the 'hardest' aimpoint, the lase time limit cuts all but the very first point. This indicates that this aimpoint would not be a viable selection for the given CONOPS. However, for this atmosphere, irradiance never falls below the critical irradiance value, so for a high-value target there is enough irradiance at longer ranges to effect melt-through, given clearance to exceed the shot time limit. This also assumes the target will

remain in the same relative geometry with the ATL over the entire course of the engagement. This assumption may cause issues with thermal blooming, as the model was only run out to times of five seconds, but this is unknown to the researcher at this time. This pattern exhibited in Figure 14 exists across all atmosphere types. However in the third and fourth atmospheric types, there are a number of points for which there is not enough irradiance to meet the critical irradiance threshold or not enough time within the hard limit of 100 seconds to cause melt-through.

Summary

This chapter has reviewed the results of the simulation and examined the outputs to validate the data based on the researcher's understanding of the physics involved with the problem. A number of the outputs were examined after being plotted vs. various inputs, and insight was gained into the 'shape' of the data. The bucket size input was examined, and after examination was limited to the 36 cm² level. Similarly, the platform velocity was also examined, and based on the flight characteristics of the C-130, was limited to the 129 m/s level. A regression equation was then developed for use in population of vulnerability tables. After re-statement of the adjusted vulnerability characteristics for each of the aimpoints, the tables were developed and analyzed.

V. Conclusions and Recommendations

Chapter Overview

This chapter summarizes the results of this research effort, and will attempt to draw conclusions from the scenario output. Deviations from the original research plan will be listed and explained. It will expand on and explain the significance of the results and will make recommendations for action based on the results as presented. Though Chapter 4 contains the bulk of the analysis of the data, this chapter will highlight areas where further exploration is warranted. It will then conclude with suggestions for future research in the field.

Evolution of Research Plan

There were a number of areas in which the research evolved from the original and intermediate plans, one due to time constraints, one to researcher inexperience with programming in Matlab, and one to a lack of available data. First, multivariate factor analysis was listed in Chapter 3 as one of the techniques which would be used to investigate the influence of any underlying factors on the inputs which would in turn influence the outputs. It first appeared as this technique would be unnecessary, as all of the apparent physical phenomena were being explained through exploration of the inputs themselves without regard for any possible underlying factors. Only after the development and examination of the linear regression model for output prediction did any indication that additional influences were at work appear. The outputs were considered good enough to press on, as the anomalies were out at the furthest ranges examined, where the reduction in overall output power caused the laser to run out of magazine before causing the required level of damage. Further multivariate analysis may be justified in order to find the source of this behavior.

Second, two additional atmospheric types were computed through Matlab user miscoding on the part of the researcher. The original vector for the atmospheric type was coded as ['na' 'na' 147 190 71]. When a call is made to return the third, fourth, and fifth elements of this vector, [n], [a], and [147] are returned. Since the evaluation uses the numeric value for the characters, the returned values became [110], [97], and [147]. The input listing for geographic sites lists Hail, Saudi Arabia as entry 110, and the Gibraltar Civ/Mil Air Station as entry 97. It was determined that this data should not be wasted, given the computational expense of having calculated the outputs for these atmospheres, and they were therefore recoded as atmospheres 6 and 7, respectively. The script was then corrected and re-run in order to confirm that the coding error was as discovered, at the expense of having to re-calculate the outputs for atmosphere 3. When the corrected outputs for atmosphere 3 matched the previously recorded values for atmosphere '5', the coding error was considered correctly diagnosed, and the data output for atmospheres 6 and 7 were appended to the corrected run output.

Finally, data was not able to be obtained for the generic 'tire' aimpoint for reasons undisclosed to the researcher. The original request for information contained a ¹/4" thickness rubber target, which would have been used to represent a sidewall shot on a tire for the truck. This data would have to have been restricted on the slant range factor, because in most cases the tires are not targetable in the geometry of the closest slant ranges, as the angle of attack prohibits line of sight to the aimpoint. This aimpoint data was requested for the specific purpose of simulating a particular aimpoint for which the resulting p_{eff} could be directly linked to the delay or disable categories of the JMEM data picture. The researcher understands that AFRL/DE is time and manpower restricted, and is grateful that the four other aimpoint data requests were filled expediently. It is our opinion that this data may be available at the classified level, but was not able to be obtained in unclassified form within the time restriction imposed by the researcher's graduation date. This lack of vulnerability data will be brought up again in the areas for further research section below.

Conclusions of Research

From the vulnerability tables produced in Chapter 4, it is apparent that given the projected capabilities of the ATL system, there are limits to the applicability of those capabilities based on range to target, atmospheric profile, and target vulnerability characteristics. It has been shown in previous research that there are a number of other factors which can influence the irradiance reaching the target, such as jitter, atmospheric relative humidity, and others. The purpose of this research was not to create a complete picture of all the factors which influence irradiance at the target, but was to develop a methodology for creating JMEM type outputs for the ATL weapon system. Given that goal, we have created a straightforward lookup table based on atmosphere and slant range which returns the number of 'rounds' of lase time (in seconds) which are required to effect the required damage at a number of different aimpoints. This framework is extensible by later considering other output influencing factors in the development of the

65

regression equations, or by evaluating the predicted output against additional aimpoint vulnerabilities. Additionally, the output from a model such as HEELEOS could be used to predict irradiance for a more accurate estimate of actual lase times required. The advantage of the regression approach is that given the input levels, the required output can be calculated by hand if necessary. While this may not necessarily be an advantage for an individual calculation, any calculation that can be done manually can also be done en-masse in a spreadsheet, which is where the real advantage lies.

The vulnerability tables produced for Appendix C show the increase in required lase time without regard for the artificially constructed per-shot time limit of five seconds established as a part of this scenario. These tables allow a planner to evaluate the cost in terms of magazine percentage utilized to achieve the effect of melt-through at the aimpoints given for the scenario's generic truck target. These tables represent an assumed one hundred percent p_{eff} for either delaying or disabling the target. This assignment to the delay and disable categories is arbitrary, as the researcher is not a JMEM user by trade, and the researcher would defer to the judgment of a more experienced end user for p_{eff} classification.

The listing of the vulnerability threshold surpassing point as seconds of lase time is not arbitrary, and was done so that the most logical comparison between a laser weapon and a similarly targeted conventional weapon could be performed. Because the capacity of the laser magazine is listed in seconds of lase time, it seems most appropriate to list the required 'number of munitions' to effect damage as lase time in seconds as well. This allows the JMEM end user to make an evaluation as to the worth of 1 second

66

of lase time in a given delivery profile against the worth of a conventional weapon delivered similarly.

Significance of Research

For any developmental weapon system, it is necessary to explore initial capabilities and to compare those capabilities with currently available weapon systems. It is especially important in the case of laser weapons, as this comparison must be done thoughtfully, and with regard for the inherent differences between laser and conventional weapons. This research has presented a coherent view of the issues involved with predicting and producing damage with laser weapons, and has laid the groundwork for extension by the laser vulnerability community. The propagation and target vulnerability profiles utilized are directly applicable to questions about the initial capability of the ATL weapon system. Finally, the output tables produced can be used not only for initial baseline comparisons, but are applicable to the development of the CONOPS for the ATL, as they can be used in tradeoff analysis for mission effectiveness based on maximum allowable per-shot lase time.

Recommendations for Action

This document and the associated data is being forwarded to members of the JMEM/FX lethality working group in hopes that it will have sufficiently moved the discussion about this topic forward to justify expansion of this work vice replication. The JMEM/FX Chairperson has requested that the output data, analysis, and conclusions be forwarded to their office for review and possible expansion.

67

Recommendations for Future Research

- Given the nature of laser effects research being done at the classified level, it is recommended that this research be passed on for evaluation given 'better' vulnerability data.
- The researcher was unable to obtain data for the generic tire aimpoint. This additional work would be directly applicable to evaluation for delaying or disabling this specific target type, as well as other wheeled vehicles.
- Additional HELEEOS exploration of the lase time and bucket size input factors would help clarify whether extended lase times for this scenario would cause issues with the thermal blooming phenomena, and whether increased bucket size would be more applicable at extended ranges, respectively.
- Tradeoff analysis for CONOPS consideration should be performed in order to determine the correct cutoff for per-shot lase time, in order to maximize military utility given the currently projected magazine limit of 100 seconds.

Summary

This work presented the problem of the necessity for development of JMEM type data for the ATL weapon system. A review of the available unclassified literature was performed, exploring the issues associated with the problem. Some of these issues include modeling of laser propagation, previous assumptions about target vulnerabilities,

and the inherent differences between laser and conventional weapons. A methodology was laid out, using the output from a validated physics based model to produce a linear regression equation for predicting average irradiance, and from that predicted value, generating a lase time required to meet various vulnerability thresholds. The output from the HELEEOS model was analyzed to confirm that the data appeared as expected, and to determine which of the input factors were significant, or could be limited to specific levels for use in the development of the regression model. The regression model was constructed, and an analysis of the predictive capabilities of the model was performed. It was discovered that there was some unseen factor underlying the output, as there was a distinct sinusoidal pattern in the residual data. This discrepancy was determined to be small enough, and located far enough toward the extreme ranges of the system for the developed predictive model to be applicable for the predominant range of projected engagements. The model was then used to develop predicted outputs for a set of scenario points, and those predictions were used to populate vulnerability tables. Through the use of actual AFRL/DE laser test data instead of theoretical energies required to cause the effect, the researcher attempted to more accurately predict the required lase time to cause the specified effects. Deviations from the original research plan were then listed, and were followed by the conclusions reached by the researcher. Finally, recommendations were made for future research in the field, and specifically for application to this problem.

| The public reporting burden for this collection of information is estimated to average 1 hour per response, including the time for reviewing instructions, searching existing data sources, gathering and maintaining the data needed, and completing and reviewing the collection of information. Send comments regarding this burden estimate or any other aspect of the collection of information, including suggestions for reducing this burden to Department of Defense, Washington Headquarters Services, Directorate for Information Operations and Reports (0704-0188), 1215 Jefferson Davis Highway, Suite 1204, Arlington VA 22202-4302. Respondents should be aware that notwithstanding any other provision of law, no person shall be subject to an penalty for failing to comply with a collection of information if it does not display a currently valid OMB control number. PLEASE DO NOT RETURN YOUR FORM TO THE ABOVE ADDRESS. | | | | | | | | | |
