## Acknowledgments

I would like to express my sincere appreciation to my faculty advisor, Major Robert Graham. There is no way this thesis would have been done this well without his guidance. Also, I would like to thank the members of my committee, Dr. Richard Raines and Dr. Henry Potoczny, for their support and assistance. Finally, I would like to acknowledge Dr. Sylvan Pinsky, my sponsor from NSA. The trips to Baltimore and California proved very valuable in my understanding of the whole Strand Space Theory.

## Abstract

When Roger Needham and Michael Schroeder first introduced a seemingly secure protocol [24], it took over 18 years to discover that even with the most secure encryption, the conversations using this protocol were still subject to penetration. To date, there is still no one protocol that is accepted for universal use. Because of this, analysis of the protocol outside the encryption is becoming more important. Recent work by Joshua Guttman and others [9] have identified several properties that good protocols often exhibit. Termed "Authentication Tests", these properties have been very useful in examining protocols. The purpose of this research is to automate these tests and thus help expedite the analysis of both existing and future protocols.

The success of this research is shown through rapid analysis of numerous protocols for the existence of authentication tests. The result of this is that an analyst is now able to ascertain in near real-time whether or not a proposed protocol is of a sound design or whether an existing protocol may contain previously unknown weaknesses. The other achievement of this research is the generality of the input process involved. Although there exist other protocol analyzers, their use is limited primarily due to their complexity of use. With the tool generated here, an analyst needs only to enter their protocol into a standard text file; and almost immediately, the analyzer determines the existence of the authentication tests.

# AUTOMATING SECURITY PROTOCOL ANALYSIS

## I. Introduction

### 1.1 Background

When Roger Needham and Michael Schroeder first introduced a seemingly secure protocol [24], it took over 18 years to discover that even with the most secure encryption, the conversations using this protocol were still subject to penetration [9]. To date, there is still no one protocol that is accepted for universal use. Because of this, analysis of the protocol outside the encryption is becoming more important. Recent work by Joshua Guttman and others [5] has identified several properties that good protocols often exhibit. Termed "Authentication Tests", these properties have been very useful in examining protocols. The purpose of this research is to automate these tests and thus help expedite the analysis of both existing and future protocols.

### 1.2 Problem Statement

Numerous security protocols have been proposed [29]. They utilize both asymmetric and symmetric cryptography and employ characteristics such as trusted and non-trusted third parties. Chapter 2 covers these concepts in great detail. The problem is that analysis of these protocols is normally done either through tedious pen and paper proofs or by realizing weaknesses after the fact. This research is intended to reduce the burdensome task of evaluating protocols from a theoretical pen-and-paper method to a more automated method that incorporates techniques understood to prove certain

correctness properties of a protocol. Although there are other methods to evaluate protocols, this research focuses on the methods developed by Guttman et al [5].

### 1.3 Summary of Results

The Security Protocol Analyzer (SPA) successfully shows that automated tools can be highly valuable in the performance of protocol analysis. In particular, the SPA is able to determine when and where outgoing, incoming and unsolicited tests occur within a protocol run. Using string comparisons vice type comparisons requires specific values be given and does limit the application to analysis based on completed static runs. However, putting together numerous protocols in generic text files proves much easier than individual protocol development as noted in other protocol analyzers [11, 27]. It also allows for much quicker analysis of the protocol because it does not have to dynamically create a search tree; instead it only examines the post-run state of the protocol as entered in the input text file. The SPA takes any protocol as input in a standard text file and generates accurate output that shows occurrences of authentication tests. Detecting authentication tests is done in very short time.

### 1.4 Thesis Overview

The remainder of this thesis consists of four chapters.

- Chapter 2 – This chapter is intended to give the reader an understanding of the theoretical aspects of what this thesis intends to accomplish. This chapter focuses primarily on background literature and other work done in the field of protocol

analysis. It introduces concepts such as authentication tests, test components and different types of encryption methods.

- Chapter 3 – This chapter lays out how the protocol analysis is accomplished. It describes the inner workings of an automated analysis tool developed specifically for this research and gives the reader an understanding of how the results of the protocol analysis tool are to be interpreted.
- Chapter 4 – In this chapter, numerous protocols are executed using the analysis tool. The output is described and the importance of certain functionality, in relation to the tool, is laid out for the reader.
- Chapter 5 –This is the summary chapter. Here, the determination about the effectiveness of the tool is given. It also lays out the groundwork as to where future work in the field of protocol analysis should go.

# II. Literature Review

## 2.1 Chapter Overview

This chapter's purpose is to give the reader a basic understanding of strand spaces and authentication tests. First, an introduction into the basic forms of encryption, symmetric and asymmetric, is given. This is necessary to ensure the reader understands basic cryptographic principles that are discussed throughout this chapter. Next, a brief introduction of what strand spaces are and how they are a means of representing protocols within the context of graph theory is given. Particularly, this chapter shows how strand spaces are used to model current protocols, such as Needham-Schroeder-Lowe [9] and Kerberos [13]. It also introduces the various authentication tests, which are derived from the theory of strand spaces. Authentication tests are a means of ensuring a protocol is designed well enough to withstand common capabilities of penetrators, such as those represented in the Dolev-Yao threat model [26].

Next, this chapter gives a brief introduction into automated modeling tools that represent potential candidates for automating the tests. The purpose of automating strand space analysis is to show whether or not potential weaknesses exist within a given protocol. If successful, this approach can provide a method for alleviating the tedium and inaccuracy associated with pen-and-paper proofs. Finally, related work in the field of strand space automation is discussed and their general results summarized.

## 2.2 Symmetric/Asymmetric Cryptography

A brief review of symmetric/asymmetric cryptography is warranted since there is frequent mention of 'keys' belonging to different parties throughout the remainder of this thesis.

### Symmetric Cryptography

With the advent of the Caesar cipher over 3000 years ago, symmetric cryptography was established as the first form of encryption. It is the use of a single key to perform both encryption and decryption of messages. The concept works as follows:

If Bob wants to send Alice a message, they have an agreed-upon key, which they will use for encryption/decryption purposes. This key is most likely a mathematically generated prime number, which when applied to an algorithm will generate cipher text (the encrypted message). Alice or Bob can then take the cipher text, along with the same key, plug it into the same algorithm and generate the original plain text (the unencrypted message). Symmetric cryptography has the advantage of requiring only one key for both encryption and decryption, but if compromised, all messages encrypted with that one key are now in danger of being read by unintended parties!

### Asymmetric Cryptography

Asymmetric encryption utilizes two keys, a private and public key to encrypt/decrypt a message. The public key is the receiver's key that is freely made available to all potential senders. The private key is the key owned by the receiver that is never shown to anyone else. In this case, Alice has a private key, which only Alice knows, and Alice has a public key, which is available to anyone. Similarly, users will entrust their public key

to Alice and keep their private key to themselves. Because Alice has another user's public key, Alice can encrypt a message with that public key. Once the message is sent, only the owner of the corresponding private key can decrypt it. Asymmetric cryptography has the advantage of guaranteeing that only the intended recipient of a message can read that message, and does not require sharing private keys with anyone. (This assumes one's private key is not compromised.) However, asymmetric keys are normally mathematically larger than symmetric keys so it is quite common for asymmetric cryptography simply to be used to encrypt symmetric keys that are distributed to intended recipients. Another more recent use for asymmetric keys is digital signing. By encrypting only a portion of the message (e.g. hash of the message) with my private key, then enclosing the total message in a symmetric key, I guarantee non-repudiation of its origin. This means that whoever opens the message is assured of its origin if the sender's private key is not compromised because at this point, only the sender's public key opens the inner encrypted portion.

### 2.3 Strand Spaces and Security Protocols

A strand space is a graph-theoretic representation of a security protocol. A security protocol is the handshaking that occurs between different parties, within the context of computer networks. The intent of the handshaking is to ensure authenticity of each party to the others, that authorized persons only view a message's content, and possibly to generate and/or distribute session keys. Session keys are used temporarily for encryption during time-sensitive conversations. Their advantage is that they expire; and if they are not compromised, intercepting a message from one session is not mathematically

equivalent to a message from another session regardless of the contents in the message. Their disadvantage is that they need to be generated for each new session. So, if there is a weakness in the protocol, a penetrator might be able to ascertain how session keys are being created. This very flaw is exploited in Needham-Schroeder [9].

Authentication tests stem from an understanding of strand spaces. Therefore, the first topic covered is strand spaces. Once it is shown how graphs are used to represent protocols, the next logical step is to show how messages are formed and represented along these graphs. This is where the concept of a test component is introduced. Then it is explained how outgoing, incoming and unsolicited tests are derived from test components and thus result in the formulation of the authentication tests.

### 2.3.1 Strand Spaces – Brief Overview

To start, let's assume for now that a protocol only consists of two parties communicating with each other. Communication consists of a series of discrete events. For example, Party A sends some sort of message to Party B. Party B receives that message and maybe sends another back, etc. This process continues for whatever length of time that given protocol requires. A *strand* is the sequence of events that occur involving only one of the parties (A's strand for this protocol: A sends a message, A receives a message, A sends another message etc). A *regular strand* is identified as a legitimate party's strand. A *strand space*, shown as $\Sigma$, is the collection of all strands, or sequences of events, that can occur between communicating parties. It is these 'strand spaces' which form the basis of authentication tests [2]. The authentication tests are a

means of verifying whether a given protocol can successfully ensure proper (intended) and secure communication between the parties.

Messages that can be exchanged between communicating parties in a protocol are called *terms*. Terms are elements of the set of messages, called *A*, which can be sent between communicating parties. The set *A* is freely generated from two disjoint sets: *T,* which represents text (nonces, names etc) and *K,* which represents keys. The generation of *A* from these sets occurs through encryption, concatenation or both. We show transmitted terms as being preceded by a positive (+) sign and received terms as being preceded by a negative (-) sign. To further illustrate this, we'll use *t* to represent a term being sent then received by party A from our example above. In the above case, we represent A sending the term as: + *t* and A receiving the term as: - *t*. Also, a term *t* is said to be a subterm of *t*', written as $t \subset t'$, if one can arrive at *t*' by "repeatedly concatenating [t] with arbitrary terms and encrypting with arbitrary keys." [8] Encryption of a term is written as: $\{ t \}_{Ka}$ . If we want to show encryption from the use of a particular party's key, we write this as: $\{ t \}_{Ka}$ meaning the term is encrypted with A's public key. A's private key is denoted $K_a^{-1}$. To represent symmetric cryptography, encryption with a key shared by A and B is shown as $\{ t \}_{Kab.}$

Strand spaces are based on graph theory (Figure 2.1). A graph consists of edges and vertices. The vertices represent communication events, also called *nodes*. If *s* is a strand, then we represent the $i^{th}$ node along that strand as $n = \langle s, i \rangle$. There are two kinds of edges: successive events (nodes) within a strand (shown with the double arrow: $\Rightarrow$) and communication between nodes on two separate strands (shown with the single arrow:

$\rightarrow$). The graph will be acyclic since events cannot go back and precede events that have already occurred. The relation between nodes on the same strand is represented as n $\Rightarrow^+$ n' where n = $<s, i>$, n' = $<s, j>$ and $j > i$. The relationship between inter-communicating nodes, meaning nodes from separate strands, is denoted as n $\rightarrow$ n' where term(n) = $+t$ and term(n') = $-t$. Finally, a *bundle* is defined as a section of the strand space that is large enough to represent a full protocol exchange. Figure 2.1 demonstrates an example of a bundle, although in this case, the bundle consists of essentially the protocol itself.

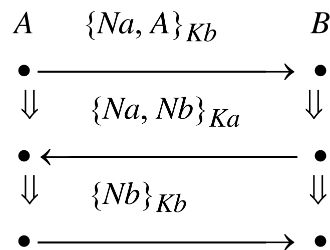

Figure 2.1 - Needham-Schroeder Protocol

This brief introduction into the notation used in strand space analysis suffices to demonstrate how a protocol is represented. Later in this chapter, this notation is used to show the Kerberos protocol (Figure 3) in detail. Next, incoming and outgoing tests are described. These tests are the foundation of the authentication tests.

### 2.3.2 Understanding the Penetrator

First, to help understand why the authentication tests are important, it is now necessary to explain what the tests help protocol designers guard against. The penetrator is understood to be the person(s) who is trying to perform any unwanted action during an exchange. Dolev-Yao [26] have formalized what are understood to be widely accepted

capabilities of the penetrator. This formalization is termed the Dolev-Yao threat model. Because the focus here is not on the mathematical soundness of encryption, it is understood that the penetrator is actually a legitimate party on the network simply out to do no good, so we term this person: Malice. What can Malice do?

- Malice can obtain any message passing through the network
- Malice is a legitimate user and can initiate conversations, and is expected at one time, to be a recipient of an initiated conversation
- Malice can impersonate any principal and thus send messages on their behalf to any other principle on the network

Dolev-Yao also explicitly state what Malice can not do:

- Malice cannot guess a random number (i.e. the mathematics of the encryption is assumed to be ideal)
- Malice cannot decrypt properly encrypted messages without possessing the proper key; Malice cannot generate encrypted text on behalf of a user without his or her proper key
- Malice cannot ascertain the correct corresponding private key of any other user's public key

### 2.3.3 Authentication Tests

Now that we understand what we are guarding against, we can move onto the authentication tests themselves. To understand the authentication tests it is necessary to understand three simple tests: outgoing, incoming and unsolicited [4]. It is these three tests that form the foundation of the authentication tests.

The key component that these tests work with is called a test component. The formal definition of a test component is shown below [4]:

**Definition**: $t = \{h\}_k$ is a test component for $a$ in $n$ if:

1. $a \subset t$ and $t$ is $a$ component of $n$;
2. The tem $t$ is not a proper subterm of a component of any regular node $n' \in \Sigma$.

What this states in laymen's terms is that a principal generates some *a,* and it is *a*'s existence in a component that differentiates between a routine component and a test component. The transmission or reception of this test component is how we ascertain whether an incoming, outgoing or unsolicited test occurred.

An "outgoing test for *a* in *t*" is when a test component *t* that contains a uniquely originating value *a* is sent out and *a* is received back in cryptographically altered form called *t'* (Figure 2.2); (cryptographically altered form means that the initial message is decrypted by someone possessing the proper key and subsequently altered) the conclusion is that an authorized recipient received the message, decrypted it, extracted the value *a* and transmitted it back. This conclusion relies on the assumption that the decryption key, $K^{-1}$, is safe, or not compromised by an attacker, and therefore only a regular (authorized) user could perform the decryption. The uniquely originating value, in this case *a,* which is a very large randomly generated number, has very little chance of being guessed by another party. The uniquely originating term is indicated by the * and

we represent the outgoing test as: $\{\ldots a \ldots\}_K \sim \ldots a \ldots$ where $a$ is the uniquely originating value.

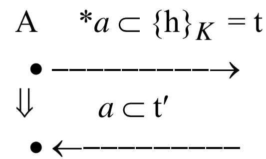

Figure 2.2 - Outgoing Test

Coincidentally, the creation of this unique number is very common. A regular use of this unique value is as a nonce or numbers once; because of their size and randomness, they are commonly used as session keys. The unaltered portion of the message is this uniquely created value because it is possible that the intended recipient concatenates other values to the original message. With regard to the graph representation, the part of a strand that receives $a$ and sends it back altered is referred to as a *transforming* edge. The part of a strand that sends $a$ out and receives it back altered is referred to as a *transformed* edge. A transformed edge containing a uniquely originating term in the sending node is called a *test*.

The incoming test works in a similar fashion. Given some $a$ transmitted in either plain or encrypted form, if it is received back unaltered but within a test component properly encrypted by an uncompromised symmetric key, we conclude that a regular recipient performed the encryption. We write this as: $\ldots a \ldots \sim \{\ldots a \ldots\}_{Kab}$. The unsolicited test is inherently weaker in nature. It states that whenever a test component $\{ \mathrm{t} \}_K$ is received, assuming that symmetric key $K$ is safe, then the term could only have originated on a *regular* strand. Since the graphical representation of the protocol is acyclic, this

originating node is located somewhere before the reception node. We show this as: ~ $\{\ldots a \ldots\}_{Kba}$. These three tests provide the groundwork for understanding how the authentication tests work. Since the purpose of this research is to generate a tool that automates security protocol verification, the following are the formal definitions for authentication tests and are drawn directly from [2]:

**Authentication Test 1**: Let $C$ be a bundle with $n' \in C$, and let $n \Rightarrow + n'$ be an outgoing test for $a$ in $t$.

1. There exist regular nodes $m, m' \in C$ such that $t$ is a component of $m$ and $m \Rightarrow + m'$ is a transforming edge for $a$.

2. Suppose in addition that $a$ occurs only in component $t1 = \{h1\}K1$ of $m'$, that $t1$ is not a proper subterm of any regular component, and that $K1^{-1} \notin P$. Then there is a regular node with $t1$ as a component.

**Authentication Test 2**: Let $C$ be a bundle with $n' \in C$, and let $n \Rightarrow + n'$ be an incoming test for $a$ in $t'$. Then there exist regular nodes $m, m' \in C$ such that $t'$ is a component of $m'$ and $m \Rightarrow + m'$ is a transforming edge for $a$.

**Authentication Test 3**: Let $C$ be a bundle with $n \in C$, and let $n$ be an unsolicited test for $t = \{h\}K$. Then there exists a positive regular node $m \in C$ such that $t$ is a component of $m$.

### 2.3.4 Tests Applied to Needham-Schroeder

This section shows how these tests are visible in an actual Protocol. Although the Needham-Schroeder is described later on in great detail, it serves as a good tool to further understand how the tests work.

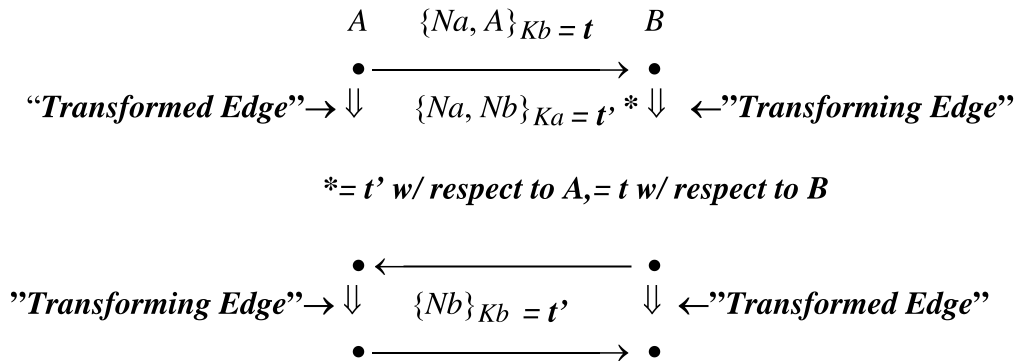

Figure 2.3 – Annotated Needham-Schroeder

Working from Figure 2.3, in the first line, A is sending his test component out. The message {A Na}Kb is valid as a test component for reasons described in Section 2.3.3. (The *a* in this example is represented by *Na*.) The component is received by B, who then transforms the term through decryption, alteration and re-encryption (only the end result is shown). With respect to the SSM, this constitutes the transforming edge. A's receipt of this new component, with respect to the SSM, is the transformed edge. The receipt of this new component in this protocol represents two actions: The first is the completion of A's outgoing test and the second is B's transmission of his own test component. Because A has received his test component back altered, only through proper decryption, he can infers a proper principal performed the transformation thus completing his outgoing test. A then takes over the role as 'transforming edge' with respect to B's test component: {Na

Nb}Ka, with the *a,* for B's test component, represented as *Nb*. A decrypts, alters and re-encrypts B's test component, then retransmits the new component back to B. Once B receives his new component back, he goes through the same evaluation proofs as A and thus concludes a proper principal performed the transformation and concludes an outgoing test has occurred.

### 2.4 Security Protocol Examples

The strand space methodology enables the modeling of security protocols as graphs. This section describes two security protocols represented in the context of strand spaces. The two protocols are: Needham-Schroeder [2] and Kerberos [13]. However, in an effort to illustrate the use of strand spaces with a particular protocol, more emphasis is placed on the Needham-Schroeder protocol as this protocol is routinely studied and analyzed in the context of strand spaces [2, 4 and 5].

#### 2.4.1 Types of Protocols

Clark and Jacob identify basic categories that protocols fit into: Symmetric or Asymmetric cryptography, employing either trusted third parties or simply two communicating principals [29]. For the purpose of this research only the main three protocol types are reviewed. They are: Symmetric Key with Trusted Third Party, Symmetric Key without Trusted Third Party and Public Key. Symmetric key with trusted third party is demonstrated in the Kerberos protocol. In this protocol, the session keys are generated by a server and then distributed to the requesting parties. There exists an

understanding that each party has its own secure symmetric key for use when communicating with the server.

The symmetric key without trusted third party is best demonstrated in challenge-response protocols. The way Needham-Schroeder is shown in Figure 2.1, it could be construed as a challenge response protocol had the keys been symmetric vice asymmetric. The reason is, had the keys been symmetric, it would imply that the communicating parties each had prior knowledge of the key they intend to use with no server generating it for them. However, Needham-Schroeder does use asymmetric cryptographic techniques with a trusted third party.

### 2.4.2 Needham-Schroeder Protocol

The Needham-Schroeder [24] public key protocol is represented in Figure 2.1. Later in Chapter 4, this protocol is shown with the server. A description of the protocol represented in Figure 2.1 is as follows: The parameters $A$ and $B$ represent communicating principals. The parameter $N$ represents a nonce. The letter following $K$ is indicating which node's public key is used. In the Needham Schroeder protocol, $A$ sends $B$ a nonce encrypted with $B$'s public key. Along with this, $A$ sends $B$ his signature; in this case a signature is simply some agreed upon identifier which each party can use to know who they are speaking to. Node $B$ decrypts the message and replies by sending $A$ the original nonce along with a new nonce generated by $B$, all encrypted with *A's* public key. Node $A$ decrypts the message and sends $B$ his nonce back, encrypted with *B's* public key. Once these events happen, it is now understood that $A$ and $B$ are communicating. However, it is not implied that this is a secure sequence of events. In fact, it is shown [9,

2 and 5] that strands termed *penetrator strands* are capable of infiltrating a session. The *penetrator strand* represents an unauthorized party who has infiltrated a session. The effect of infiltration varies significantly based upon the importance or sensitivity of the session.

### 2.4.3 Penetration of Needham-Schroeder Defined

The penetration of the Needham-Schroeder occurs as follows [Figure 2.4]: Assume that *A* wants to talk to another party. In this case, we'll call that party *P*. *A* then initiates a conversation with *P*, who then encrypts/forwards *A*'s information over to party *B*. Party *B*, thinking *A* initiated a conversation with him, will then answer the challenge with a reply, and also issue his own challenge. *A* receives this message and assumes it came from *P* and then replies to *P* with the correct response. *P* then encrypts/forwards this new information over to *B* who sees it as the correct information.

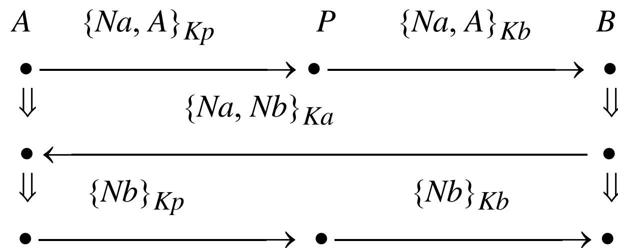

Figure 2.4 - Needham-Schroeder Penetrated

Now, both parties are convinced they are talking to their intended audience. However, *P* now has the nonces from each party and is able to eavesdrop on a conversation between *A* and *B* or simply converse with *B* while impersonating *A*. In [9], Lowe proposes that *B*'s reply contain his identifier: ( $\{ Na, Nb, B\}Ka$ ). This will allow *A* to see that

somehow his information is going to an unintended party and deduce that *P* is probably malicious.

### 2.4.4 Kerberos

Kerberos is an authentication service for open network systems first proposed by Miller and Neuman [14]. It involves three principals: user, client and server. The basic process works as follows. A user desiring a service or program contacts the client. The client can be anything from a program to a person. The client then contacts the server on behalf of the user. Kerberos, using private key encryption, derives a private key from the users' password. This key, along with all other users' keys, is stored in a Kerberos-managed database. Any network service requiring authentication is registered with Kerberos. Also important to note, Kerberos maintains a list of registered clients, which corresponds with a particular key. What is evident here is that Kerberos acts as the middleman between registered clients. Another role Kerberos plays is the generation of session keys. Unlike the private keys, session keys are only temporary keys used within a limited timeframe, as stated earlier; nonces are often used for session keys.

It is now demonstrated how Kerberos handles a request for communication between two parties. *A* first requests a session key from the authentication server that it can then use to communicate with *B*. The session key is a uniquely originating key, which is ideally used for only one session. First, *A* sends the authentication server, *AS*, its identity and the identity of whom it wants to communicate with. *AS* then generates a symmetric session key, it encrypts the session key and *B*'s identity with *A*'s key. It then encrypts the session key and *A*'s identity with B's key (Figure 2.5). It then sends both encrypted

messages to *A*. At this point, *A* decrypts the session key encrypted with *A*'s key, generates a time stamp, encrypts the time stamp with the newly acquired session key and sends both packages off to *B*. Now, *A* and *B* are able to communicate in a secure fashion.

With respect to the authentication tests, Kerberos uses the incoming and unsolicited tests. This determination is made by the fact that *A* sends out plaintext and receives it back properly encrypted. This is an example of the incoming test. With respect to incoming tests, sending something out plain and receiving it back encrypted does not imply symmetric cryptography; if that protocol uses asymmetric cryptography then any party can encrypt a plain message with a public key and one cannot conclude an incoming test occurred because you cannot be sure who did the encrypting. However in Kerberos, *A* shares a symmetric key with *AS* therefore we conclude the *AS* did the encrypting. *B* receives an un-requested message properly encrypted by *A*; this is an example of an unsolicited test. This protocol does not contain any outgoing tests, but it is not a requirement that all tests be represented in a protocol. The presence of these tests also does not guarantee that Kerberos is a 'good' protocol. The original Needham-Schroeder contained outgoing tests with respect to both parties but still demonstrated a serious flaw due to the contents of the messages themselves.

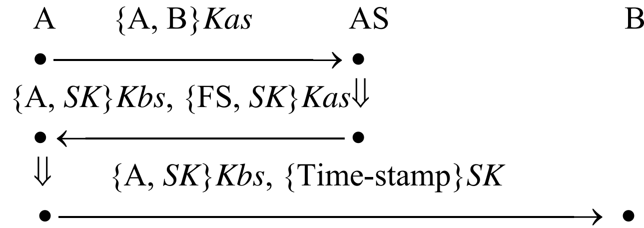

Figure 2.5 - Kerberos Communication Initialization

## 2.5 Related Work in the Automation of Security Protocol Verification

Automating security protocol verification allows for quicker determinations of the weaknesses and strengths of a particular protocol. Numerous researchers [11] have proposed applying formal proof techniques towards the analysis of security protocols. The next sections briefly cover key work that has been successful in the automation of security protocol verification.

The techniques employed in protocol analysis, covered in this review, typically fall into two categories. They are model checking and theorem proving. In the model checking approach, one searches for desired states by modeling the protocol and executing it in every possible way. In the theorem proving approach, one creates a search tree and checks for the existence of the theories in that tree at some state. The Multi-Set Rewriting and Failure Divergence Refinement [22] checking typically fall into the model checking camp. The Athena approach [11] falls into the theorem proving camp. The approach in this research falls into the theorem approach because it automatically identifies where the authentication test theorems can be applied.

### 2.5.1 Failure Divergences Refinement Checker

Lowe [9] successfully analyses the Needham-Schroeder protocol using the Failure Divergences Refinement Checker (FDR), which is a model checker for Communicating Sequential Processes (CSP) [25]. CSP is a language that allows easy representation of pattern interaction. Using CSP, Lowe tests whether a protocol achieves authentication. In the case of an attacker being discovered [9], Lowe is also able to show that the fixed protocol is secure.

### 2.5.2 Process Calculus

In [1], Blanchet uses an extension of pi-calculus to represent protocols. Pi-calculus is "a 'process algebra' in which channel names can act both as transmission medium and as transmitted data" [23]. His results show promise in that automated protocol verification can be done in less than one second. The user needs only to correctly code whatever protocol they intend to evaluate. The tool, OCaml 3.04 [1], translates the protocol into Horn clauses and then executes it against rules based on whatever that particular protocol defines as a rule. This is obviously much faster than traditional methods of hand proving. Blanchet also permits an unbounded number of sessions within the test, whereas previous work has limited the number of session due to infinite state systems. On rare occasions the algorithm will not terminate and it can even fail on correct protocols. However, it is Blanchet's conjecture that it will terminate for a large class of protocols.

### 2.5.3 Athena

Athena is an automated checking algorithm that analyzes security protocols [12]. Athena implements a specialized logic for expressing security properties such as authentication, secrecy and properties related to electronic commerce [12]. Athena works by terminating and providing a proof on well-formed formulas or generating a counter example on well-formed formulas that evaluate to false. Although there are other formal techniques for analyzing security protocols [11], Athena differs in the sense that it can directly evaluate the strand space model without succumbing to the state space explosion [11, 2.5.1]. State space explosion occurs whenever there is an unbounded number of initiators/responders and sessions thus creating an unreachable theorem [18]. Athena uses 'unreachability theorems' to 'prune' the state space, thus reducing the number of states and increasing the probability of terminating [12]. Another method Song uses to reduce the state space is that of the Strand Space Model (SSM) [28]. By using the causal relationships developed by Guttman in the SSM, Song is able to further prune the state space. Song shows that although limited due to its inability to allow certain terms to be encrypted, Guttman and Thayer's tests are still effective in reducing the state space.

### 2.5.4 Security Modeling in Maude

Object modeling software is another effective way to model protocol transactions. One example of automated modeling software is Maude [19]. Maude was the intended language for this research, but Java proved very effective. However, for future research it is highly recommended that using Maude to automate authentication tests be performed, as this is now explained. Developed primarily at the University of Illinois

and Stanford Research Institute, Maude's purpose is stated as follows: "…supporting formal executable specification, declarative programming, and a wide range of formal methods as means to achieve high-quality systems in areas much as: software engineering, networks, distributed computing, bioinformatics, and formal tool development." [19].

Specifically, Maude is a "high-performance reflective language, which supports both equational and rewriting logic specifications" [19]. Being a reflective language means that Maude can program or manipulate itself [20]. Rewriting logic allows for concurrent state computations. Although a protocol is pre-defined at run time, concurrent state computations allows for rules or equational rewrites to occur simultaneously.

In [27], Denker and Meseguer show how protocols can be effectively modeled using object-oriented specification in Maude. The purpose of his work is to show that Maude's ability to perform rewritable logic and concurrent execution is helpful in uncovering security flaws in protocols. The paper uses the Needham-Schroeder public key protocol as the case study. Meseguer implements a bounded depth first search on multiple instances of protocol runs. The depth first search shows efficient searching of possible attacks on the multiple run is an effective means of ascertaining a weakness on a given protocol. In this case, the weakness discovered by Lowe [9] is found using a depth first search. In this example we see Maude being used as a model checker. However, Maude can also be used for theorem checking. Because Maude is powerful enough to handle either method of use, it allows for multiple means in which modeling the authentication tests can be done.

### 2.5.5 Multi-Set Rewriting

In [22], Cervesato et al. use multi-set rewriting to provide a means to specify 'finite length' protocols. In his work, Cervesato uses the multi-set rewriting to extend the strand space formalism. Through this he is able to model penetrator capabilities, as defined by Dolev-Yao, and then relate the intruder theory to penetrator strands as defined within the context of strand space modeling. This particular work serves as a means to further understand the Dolev-Yao threat model.

## 2.6 Summary

This chapter outlines what a strand space is and how it is represented using graph theory notation. It then shows how this notation is used to represent a security protocol. The Needham-Schroeder and Kerberos protocols were used to illustrate the use of strand spaces. Next, three authentication tests were defined from [5]. There are three tests—outgoing, incoming and unsolicited—and each has a theorem describing the guarantees it provides. Finally, previous work in automating aspects of security protocol analysis has been discussed.

# III. Methodology

## 3.1 Chapter Overview

The purpose of this chapter is to introduce the methods that are employed in automating the authentication tests developed by Guttman et al [2, 5]. This chapter describes the Security Protocol Analyzer (SPA) tool developed for the purpose of this research. The chapter also shows SPA's analysis of a representative set of known protocols and basic examples in order to establish a baseline of reliability. In Chapter 4, a much more diverse set of protocols is analyzed.

This chapter is laid out in the following manner:

- Problem Review
- Overview of software used
- Java based protocol analysis
- Demonstration of tests in the following environments:
    - Numerous one and two pass tests
    - Needham-Schroeder
- Summary

## 3.2 Problem Review

The problem that this research addresses is the effective automation of security protocol analysis, and in particular, the automatic recognition of authentication tests as defined by Guttman et al. Guttman et al have developed three authentication tests that greatly simplify the tedious pen-and-paper proofs normally required to show if a security

protocol has certain correctness properties. This research takes the next step and automates aspects of their work. In the previous chapter, these tests and correctness properties have been defined and now the focus will shift to how occurrences of these tests are automatically identified using a tool developed in Java.

### 3.3 Software Overview

The Java-based protocol analyzer was developed using the Java development environment TogetherSoft® version 6.0. This application was executed on a Windows® 2000 operating system. The version of Java that TogetherSoft® 6.0 employs is 1.3.1.

### 3.4 Java Based Protocol Analysis

The protocol analyzer uses a traditional software development approach of object-oriented programming. The analyzer uses dynamically created objects to represent different component classes, such as Principals, Messages and Text. The next few sections outline the algorithm and the specific techniques used in the creation of the tool.

#### 3.4.1 Layout of Java Program

The Java-based program, called Security Protocol Analyzer (SPA), can be divided into two portions. The first portion is the parsing portion. The second portion is as the analysis portion.

Table 1 – Brief Description of SPA classes

| **Class:** | **Brief Description:** |
|---|---|
| ProtocolAnalyzer | Main driver of program. Contains m*ain*(). |
| Encryption | Checks encryption of messages against receiver and sender. Ensures proper parties are viewing messages. |
| Protocol | This is the root node of an abstract syntax tree representing a protocol. It contains a list of Messages. |
| Message | An instance of message is instantiated as each message is read in from the input file. A message consists of a sender, a receiver and the term sent. |
| Sequence | Since messages exist as concatenations of terms, we call this a sequence. This class contains an iterator which is traversed during analysis on instances of Sequence. |
| Term | The primary abstract class that enables Text, Encryption, and Sequence to generically create functions for recursive use. Two key methods for analysis, GetReadableText() and GetTextObj(), are established here. |
| Text | This class represents individual instances of each text. If tagged with a * in the input file, a flag condition is set to show its new/fresh characteristic. |
| Parser | This class checks the syntax of the input file and verifies if it is legal or not. It also builds an abstract syntax tree rooted at an instance of the Protocol class. |
| Principal | For each occurrence of a party within a protocol transaction, an instance of principal is generated. Within it, the test conditions are checked within the addnonce() method as components get passed. |

The main role of the parsing portion is to retrieve a file and import the contents into "iterators" that the analyzer steps through and analyzes. It also builds the abstract syntax tree (AST), which is traversed during the analysis portion. The parsing method could have been done numerous ways therefore not much attention is given to the specifics in this thesis but the authentication tests are strictly defined and hence that is where our focus lies. Table 1 lays out brief descriptions of key classes in the SPA. Sections 3.4.2

and 3.4.3 go into detailed specifics of the more important operations and give a more thorough description of the key classes as seen in the SPA class diagram, Figure 3.1.

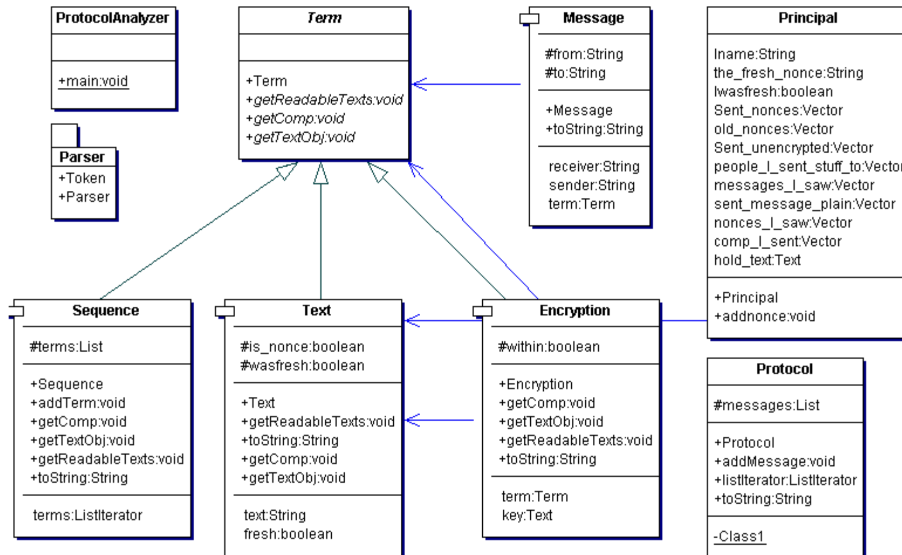

Figure 3.1 – Class Diagram of SPA

### 3.4.2 Description of Parsing Operation

The parsing of the SPA is performed as follows: An input file (Figure 3.2) is parsed line by line into an abstract syntax tree with a Protocol object as the root. A Protocol consists of a list of Message objects. Each Message contains three portions: *from*, *to* and the *message* itself. It is this list of messages that we walk through during the analysis portion.

A -> B : {A *Na1}Kb
B -> A : {Na1 *Nb1}Ka
A -> B: {Nb1} Kb

Figure 3.2 – Needham-Schroeder Protocol Input File

Figure 3.3 shows an example of the abstract syntax tree created during the initial parsing of a message. As seen in Figure 3.3, whenever a message is broken down, an instance of Sequence, Encryption or Text is created. Due to the recursive structure of message terms, within Encryption and Sequence lie further instances of Sequence, Encryption or Text. The breakdown process continues recursively until individual Text instances are all that remain. The parsing of the input file into AST's completes the initial run of the SPA with respect to the input file. The next operation performed is the analysis portion.

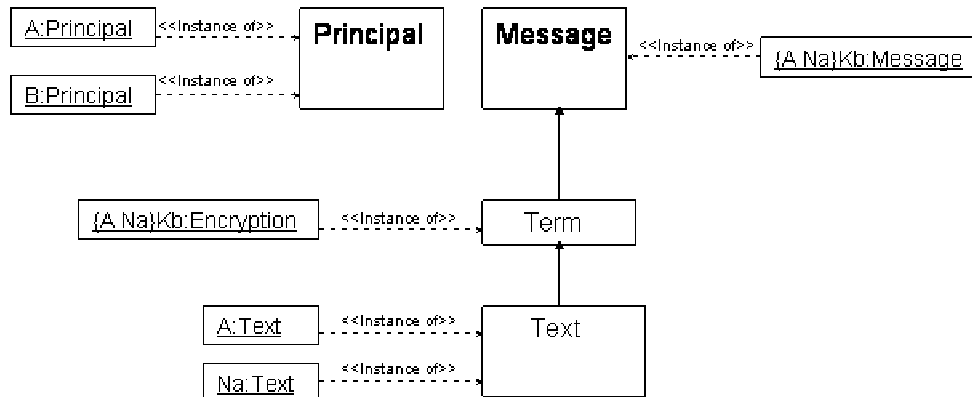

Figure 3.3 – UML of Message Breakout

### 3.4.3 Description of Analysis Operation

This section covers the key classes that perform the main analysis. The ProtocolAnalyzer, Principal and Term classes are what drive the analysis portion of the

program. The ProtocolAnalyzer class contains the *main()* function and hence is the driver for the program. The program makes several passes through the list of messages during the analysis portion.

The first pass through the message list checks for potentially disqualifying conditions. For instance, one of the more common conditions is occurrence of an encrypted term within another encrypted term, thus negating the inner one's use as a test component in accordance with criteria outlined by Guttman [5] and described in Chapter 2. The SPA takes this encrypted term and stores it in a vector with any other disqualified encrypted terms. If an encrypted term is not disqualified it is stored in another vector which contains potential test components. Later on, these vectors are viewed to determine if a component received by a Principal is disqualified as a test component or not.

The second pass through the message list creates instances of the Principal class and stores them in a vector. Recall that during the parsing process, each line of the input file generates a *from, to* and *message*. The *from* and *to* are used to create these instantiations of Principal. For example, using the example in Figure 3.2, in Figure 3.3 A and B are created as different instances of Principal. However, the parser first checks to make sure a previous existence of that Principal does not exist, that way only one instantiation per principal occurs. By having individual instantiations for each participant in the protocol, this allows each party to know what terms and components it has sent and received.

The third pass is where actual analysis of individual terms occurs. Using Figure 3.2 as an illustration, whenever the first line is analyzed, individual terms A and Na (parsed into an AST as described earlier), are stored individually in a sent items vector of A's

instantiation of Principal. B's instantiation of Principal will store them in a received items vector. As the SPA iterates through the list of messages, each principal, depending on its role as sender or receiver, checks its vectors of sent and received items and then applies the rules of the tests against that item. With respect to Figure 3.2, the SPA output generated is shown in Figure 3.4. This serves as a good overview regarding the analysis operation but there are two key functions that allow this to operate so effectively.

The first key function is the *GetReadableText*() function. The analyzer calls the *GetReadableText*() function initially in *main*() to initiate the third pass, but as described shortly, the SPA actually traverses the tree through recursive calls of *GetReadableText*(). This recursion happens because the *GetReadableText*() function is an abstract function stemming from abstract class Term. In order to allow more effective analysis without duplication of functionality, Term was developed as an abstract class from which Encryption, Text and Sequence are all extended. As the analyzer starts at the top of the AST, based on whatever instantiation lies at that particular node, the SPA knows what class' *GetReadableText*() function to call. From within this Term, it steps down to the next node and the SPA then calls that particular instance of *GetReadableText*(). This is especially important for encrypted terms. If the analyzer is on an encrypted node, it will determine if the receiver can view the message through string comparisons on the key and Principals identity (For example: Ka is viewable by A only). As the analyzer steps further down the tree, based on the results of whether a Principal can read the encrypted portion or not, the analyzer will know which information to pass into that Principals instantiation, thus, a received item, if not readable, will not be entered into a receiver's

vector of received terms! (The actual addition of individual text into a principals' relevant vectors is done through the *addNonce*() function, described shortly.) Once the end node of the AST is reached, we know from earlier that this will be an instance of an individual Text. At this point, when *GetReadableText*() is called, the values of the arguments at this point are now ready to be added directly into each Principal's relevant vectors.

Within the Text class' *GetReadableText*() function is called the other key function: *addNonce*(). *AddNonce*() is a method of the Principal class that is only called from within each individual instance of Text. In *addNonce*(), the following arguments get passed in: the vectors of bad test components, good test components, the name of the individual Text currently being analyzed, as determined by being at the bottom of the AST, and whether or not the sender/receiver can read the individual Text. *GetReadableText*() of that particular instance of Text will traverse the vector of Principals then whenever sender and receiver get matched, that particular Principal has its *addNonce*() function called. It is within *addNonce*(), since we are getting all the key information at this time for this particular Text, that the existence of the tests with relation to this particular Text are determined. The determination of the existence of tests follows strictly the criteria defined by Guttman [5] and covered extensively in Chapter 2.

### 3.5 Specific Protocols analyzed using Java

In this section, the SPA is tested with simple input to demonstrate its ability to find examples of the authentication tests under a variety of basic conditions. For example, simple one-pass and two-pass runs are performed using both asymmetric and symmetric

cryptography. The chapter then culminates with the SPA running the Needham-Schroeder protocol in both a normal setting and a setting with intentional flaws. Once these tests are completed, a reliable baseline is established for use of the SPA in identifying occurrences of outgoing, incoming and unsolicited tests in unfamiliar protocols.

### 3.5.1 Verifying Presence of Tests

In the first example, A executes an incoming test. A sends out plain text and receives it back properly encrypted with a symmetric key, thus completing an incoming test. The layout for all tests is similar in nature. The SPA shows encryption keys used then proceeds to identify the existence of any tests or errors.

```
File Contents:
A -> B : *Na1 A
B -> A : {Na1 B}Kab

<Parties> : <Message> >> A -> B : *Na1 A
Sender may be attempting to initiate an incoming test by transmitting Na1 in the clear.

<Parties> : <Message> >> B -> A : {Na1 B}Kab
Encrypt term(s) < Na1 B > with key Kab is readable by both sender/receiver.
The unencrypted/fresh nonce Na1 has been received back in new component: {Na1 B}Kab
Incoming test for A because fresh term Na1 was sent out earlier in < Na1 >
```

In this example, a simple two-pass run of an outgoing test is demonstrated:

```
File Contents:
A -> B : {*Na1 A}Kab
B -> A : Na1 B

<Parties> : <Message> >> A -> B : {*Na1 A}Kab
Encrypt term(s) < *Na1 A > with key Kab is readable by both sender/receiver.
Sender may be attempting to initiate an outgoing test by transmitting Na1 in encrypted form.
Unsolicited test for B because of nonce Na1 within test component < {Na1 A}Kab >

<Parties> : <Message> >> B -> A : Na1 B
The encrypted/fresh nonce Na1 has been received back in new component: Na1
```

**Outgoing test for A because fresh term Na1 was sent out earlier in < {Na1 A}Kab >**

In the first pass, the SPA identifies what key is used for encryption and states which parties can view that part of the message. Then, it states that the sender may be initiating an outgoing test. Also, based on the use of symmetric cryptography, as indicated by the key format, it also indicates the presence of an unsolicited test from B's perspective. B transforms the message through decryption, once again, assuming the key is safe, then retransmits it back to A. Finally, it shows A completing an outgoing test because he is receiving his fresh nonce back in altered form.

In the below example, a simple case of nested encryption is used to demonstrate another example of an outgoing test. In this case, A's fresh nonce is inside an encrypted term, which is itself encrypted. On the first pass, the SPA shows both terms' encryption keys and states how A is attempting to initiate an outgoing test. On the second pass, the SPA verifies that A has completed his outgoing test. Notice on this pass there is no unsolicited test because the communicating parties are using asymmetric cryptography, as indicated by their key format. Recall from Chapter 2, all public keys are assumed to be compromised. Also, although not shown by the SPA, the validity of this test depends on B's private key not being compromised.

**File Contents:**
**A -> B : A {{*Na1}Ka}Kb**
**B -> A : {Na1}Ka**

**<Parties> : <Message> >> A -> B : A {{*Na1}Ka}Kb**
**Encrypted term(s) < {*Na1}Ka > with key Kb is readable by recipient only.**
**Encrypted term(s) < *Na1 > with key Ka is readable by sender only.**
**Sender may be attempting to initiate an outgoing test by transmitting Na1 in encrypted form.**

**<Parties> : <Message> >> B -> A : {Na1}Ka**
**Encrypted term(s) < Na1 > with key Ka is readable by recipient only.**

**The encrypted/fresh nonce Na1 has been received back in new component: {Na1}Ka**
**Outgoing test for A because fresh term Na1 was sent out earlier in < {{Na1}Ka}Kb >**

The next example is a more common example of what one would expect during a routine transaction using symmetric cryptography. In the example, it shows the unsolicited test that exists due to the symmetric cryptography used, as indicated by the key format used, but more importantly because of the valid test component received by B. The only thing to note here is the phrase incoming/outgoing test. This is not a new test. Recall from Chapter 2, the outgoing test is sent out encrypted and received back altered, possibly unencrypted; the incoming test is sent out in either format but received back encrypted. Therefore, this example fulfills the requirements of both tests and could be called either, thus it is termed an outgoing/incoming test!

**File Contents:**
**A -> B : {*Na1 A}Kab**
**B -> A : {Na1 B}Kab**

**<Parties> : <Message> >> A -> B : {*Na1 A}Kab**
**Encrypt term(s) < *Na1 A > with key Kab is readable by both sender/receiver.**
**Sender may be attempting to initiate an outgoing test by transmitting Na1 in encrypted form.**
**Unsolicited test for B because of nonce Na1 within test component < {Na1 A}Kab >**

**<Parties> : <Message> >> B -> A : {Na1 B}Kab**
**Encrypt term(s) < Na1 B > with key Kab is readable by both sender/receiver.**
**The encrypted/fresh nonce Na1 has been received back in new component: {Na1 B}Kab**
**Outgoing/Incoming test for A because fresh term Na1 was sent out earlier in < {Na1 A}Kab >**

In this next example, it appears as though there should be a simple incoming test. However, this is not the case. A sends out an unencrypted fresh term and receives it back encrypted. The SPA indicates that principal A may be attempting to initiate an incoming test; however, because everyone knows public keys, A cannot be sure who encrypted his plain text. The SPA's adherence to the notion of compromised public keys, as discussed in Chapter 2, disallows a completed incoming test.

**File Contents:**
**A -> B : *Na1 A**
**B -> A : {Na1 B}Ka**

**<Parties> : <Message> >> A -> B : *Na1 A**
**Sender may be attempting to initiate an incoming test by transmitting Na1 in the clear.**

**<Parties> : <Message> >> B -> A : {Na1 B}Ka**
**Encrypted term(s) < Na1 B > with key Ka is readable by recipient only.**

The final example is very similar to the earlier one in which a term is sent out encrypted and received back altered. This represents an outgoing test for A because test component {*Na1 A}Kb is transmitted to B. B receives the test component, based on the input file composition, transforms the test component into {Na1 B}Ka and transmits it back to A. Since encryption is correct and private keys are assumed safe, we see a valid instance of an outgoing test.

**File Contents:**
**A -> B : A {*Na1 A}Kb**
**B -> A : B {Na1 B}Ka**

**<Parties> : <Message> >> A -> B : A {*Na1 A}Kb**
**Encrypted term(s) < *Na1 A > with key Kb is readable by recipient only.**
**Sender may be attempting to initiate an outgoing test by transmitting Na1 in encrypted form.**

**<Parties> : <Message> >> B -> A : B {Na1 B}Ka**
**Encrypted term(s) < Na1 B > with key Ka is readable by recipient only.**
**The encrypted/fresh nonce Na1 has been received back in new component: {Na1 B}Ka**
**Outgoing test for A because fresh term Na1 was sent out earlier in < {Na1 A}Kb >**

### 3.5.2 Analyzing Needham-Schroeder

The above examples showed different examples of the outgoing, incoming and unsolicited tests. In this section we expand upon this by running an actual protocol through the SPA. The result of normally operating the Needham-Schroeder protocol in the SPA confirms the previously known existence [5] of outgoing tests in the protocol. Figure 3.4 shows the entire output for the original Needham-Schroeder protocol.

```
A -> B : {*Na1 A}Kb
B -> A : {Na1 *Nb1}Ka
A -> B : {Nb1}Kb

<Parties> : <Message> >> A -> B : {*Na1 A}Kb
Encrypted term(s) < *Na1 A > with key Kb is readable by recipient only.
Sender may be attempting to initiate an outgoing test by transmitting Na1 in encrypted form.

<Parties> : <Message> >> B -> A : {Na1 *Nb1}Ka
Encrypted term(s) < Na1 *Nb1 > with key Ka is readable by recipient only.
The encrypted/fresh nonce Na1 has been received back in new component: {Na1 Nb1}Ka
Outgoing test for A because fresh term Na1 was sent out earlier in < {Na1 A}Kb >
Sender may be attempting to initiate an outgoing test by transmitting Nb1 in encrypted form.

<Parties> : <Message> >> A -> B : {Nb1}Kb
Encrypted term(s) < Nb1 > with key Kb is readable by recipient only.
The encrypted/fresh nonce Nb1 has been received back in new component: {Nb1}Kb
Outgoing test for B because fresh term Nb1 was sent out earlier in < {Na1 Nb1}Ka >
```

Figure 3.4 – Output of running Needham-Schroeder in SPA

Although there are no surprises here, it is important that an actual protocol was run. From this, we are now able to move forward and test protocols where outcomes may not necessarily be expected. The final test is to run the Needham-Schroeder protocol in slightly altered form, then using already known results [5], verify that the analyzer generated the correct results.

In this next test we present an altered form of Needham-Schroeder. In Figure 3.5, we see several different erroneous/mischievous activities being performed. The first is principal C trying to resend a previous message. The SPA generates no notice on this because it cannot assume this was intentional. It may simply be acting as a relay. From the legitimate test, it recognizes that A has received his fresh nonce back and therefore won't reregister this as another outgoing test. The next activity is that of B trying to initiate a conversation using A's old nonce; once again no test is registered. These duplicate transactions do occur several more times but to no avail.

```
A -> B : {A *Na}Kb
B -> A : {Na *Nb}Ka
C -> A : {Na Nb}Ka
B -> A : {B Na}Ka
A -> B : {Na}Kb
A -> B : {Nb}Kb
A -> C : {Nb}Kc

<Parties> : <Message> >> A -> B : {A *Na}Kb
Encrypted term(s) < A *Na > with key Kb is readable by recipient only.
Sender may be attempting to initiate an outgoing test by transmitting Na in encrypted form.

<Parties> : <Message> >> B -> A : {Na *Nb}Ka
Encrypted term(s) < Na *Nb > with key Ka is readable by recipient only.
The encrypted/fresh nonce Na has been received back in new component: {Na Nb}Ka
Outgoing test for A because fresh term Na was sent out earlier in < {A Na}Kb >
Sender may be attempting to initiate an outgoing test by transmitting Nb in encrypted form.

<Parties> : <Message> >> C -> A : {Na Nb}Ka
Encrypted term(s) < Na Nb > with key Ka is readable by recipient only.

<Parties> : <Message> >> B -> A : {B Na}Ka
Encrypted term(s) < B Na > with key Ka is readable by recipient only.

<Parties> : <Message> >> A -> B : {Na}Kb
Encrypted term(s) < Na > with key Kb is readable by recipient only.

<Parties> : <Message> >> A -> B : {Nb}Kb
Encrypted term(s) < Nb > with key Kb is readable by recipient only.
The encrypted/fresh nonce Nb has been received back in new component: {Nb}Kb
Outgoing test for B because fresh term Nb was sent out earlier in < {Na Nb}Ka >

<Parties> : <Message> >> A -> C : {Nb}Kc
Encrypted term(s) < Nb > with key Kc is readable by recipient only.
```

Figure 3.5 – Output of NS with duplicate transmission of nonce

We learn from this example that the SPA is not being fooled with repetitive transactions. However, it is catching and printing the existence of the two legitimate outgoing tests that occur. As one can see, there are numerous ways to arrange the order of these tests and the components within, but at this point we can be fairly certain the SPA is capable of finding the tests.

### 3.6 Summary

In conclusion, this chapter covered in detail the basic operation of the SPA. Numerous test cases and the Needham-Schroeder protocol were run and we use them to establish a baseline of reliability. Finally, there was a modification done to the Needham-Schroeder protocol to show that obvious mistakes in a transaction, whether intentional or not, could be captured. As a result of these tests, we've shown that the SPA is capable of detecting instances of incoming, outgoing and unsolicited authentication tests as well as basic improper events occurring during the course of a protocol run. We also introduce something termed outgoing/incoming test, which is the case where a received term meets criteria for both outgoing and incoming tests as described in chapter two. In the next chapter, we will expand upon this and run the SPA against numerous protocols that exhibit numerous characteristics.

# IV. Analysis and Results

## 4.1 Chapter Overview

This chapter demonstrates the results of running the SPA on several regular protocol runs. These tests show if any authentications tests occur in the protocol and where. Following the discussion of normal protocol runs, several more 'incorrect', or seemingly incorrect, protocol runs are investigated. The purpose of creating incorrect protocols is to show that the SPA is capable of discovering erroneous scenarios that may occur in protocols. The means by which these particular scenarios are chosen is discussed later.

## 4.2 Results of Protocol Analyses

This section covers the overall results of running known protocols. As discussed earlier, protocols are grouped into categories. Categories can be broken up into protocols that use symmetric cryptography verse asymmetric cryptography. Another category is protocols which use trusted verse non-trusted third parties. Although there do exist hybrid protocols, the protocols chosen most assuredly fit into the above categories. The layout of the protocols is taken almost directly from [29].

In Chapter 3, outgoing, incoming and unsolicited tests output is shown in great detail. In this section, since testing occurs on large established protocols, previously unseen output is displayed. Although warnings and errors are self explanatory, there is another test condition that is introduced that may not be self-evident. The test is called a pseudo-unsolicited test. This test does not alter the definition of an unsolicited test in any way, but what it does do is show how one party is receiving a challenge from another that it

has previously sent a message to. In other words, because both parties understand the protocol, *A* may expect something back from *B*, in one case, the minimum reply might be *A*'s fresh nonce. However, simultaneously if *B* solicits a challenge of his own, *A* must now reply with the correct answer. The reason for the slight name change is based upon the generic nature of the analyzer. This analyzer is able to review any protocol without knowing how the protocol works. But because of this, it does have to keep track of intercommunicating parties and know who is sending what to whom but does not necessarily know that a reply or request is part of the protocol. Therefore, because a party has sent something to another means receiving something back from the party is not necessarily 'unsolicited'.

### 4.2.1 Wide Mouth Frog Protocol

The wide mouth frog protocol (Figure 4.1) involves the use of symmetric cryptography in conjunction with a trusted third party. In this protocol, the initiating principal generates a temporary session key, along with a timestamp. These are passed to the server, along with the identification of the party in which the initiating principal wishes to communicate. The server then passes the timestamp and session key onto the intended recipient.

The SPA recognizes all known tests. In the first message it correctly identifies the fact that *A* may be attempting to initiate two different outgoing tests. This does not mean they are completed; only that *A* is transmitting a legitimate test component that contains two fresh terms. *S*'s receipt of this valid test component with two fresh terms inside and the use of proper symmetric cryptography mean there exists two unsolicited tests from

*S*'s perspective. In the second pass, *S* has created his own test component containing a fresh nonce and thus may be initiating his own outgoing test. From *B*'s point of view, the receipt of this test component with two fresh terms, one generated by *S* and the other by *A*, means *B* has two unsolicited tests. In this example, the SPA accurately detects all relevant tests that occur as shown in Figure 4.1.

```
A -> S : A {*Na1 B *Kab}Kas
S -> B : {*Ns1 A Kab}Kbs

<Parties> : <Message> >> A -> S : A {*Na1 B *Kab}Kas
Encrypt term(s) < *Na1 B *Kab > with key Kas is readable by both sender/receiver.
Sender may be attempting to initiate an outgoing test by transmitting Na1 in encrypted form.
Unsolicited test for S because of nonce Na1 within test component < {Na1 B Kab}Kas >
Sender may be attempting to initiate an outgoing test by transmitting Kab in encrypted form.
Unsolicited test for S because of nonce Kab within test component < {Na1 B Kab}Kas >

<Parties> : <Message> >> S -> B : {*Ns1 A Kab}Kbs
Encrypt term(s) < *Ns1 A Kab > with key Kbs is readable by both sender/receiver.
Sender may be attempting to initiate an outgoing test by transmitting Ns1 in encrypted form.
Unsolicited test for B because of nonce Ns1 within test component < {Ns1 A Kab}Kbs >
Unsolicited test for B because of nonce Kab within test component < {Ns1 A Kab}Kbs >
```

Figure 4.1 -Wide-Mouth Frog Protocol

### 4.2.2 Yahalom Protocol

In the Yahalom protocol, the SPA starts out by showing how principal *A* is initiating an incoming test by sending out a fresh term. The next message shows how *B* is initiating his own outgoing test and at the same by doing so, an unsolicited test occurs for the server, represented as *S*. Also, an unsolicited test occurs for nonce Na because it is still fresh from *S*'s view and it exists within a valid test component. The next step then shows how *A* gets its nonce, Na, back; thus completing the run of its incoming test. At the same time, it shows an unsolicited test for *A* because of a fresh term within a valid test component from *S*. In this pass, the first warning is generated. *S* has generated one

key and is transmitting it in two separate components. Because of this, if *S* were to get back one of these keys, it can not be certain from whom and therefore they are invalidated as a test component with regard to outgoing tests. The final message sees an unsolicited test for *B* as well as *B*'s receipt of his fresh nonce back completing a run of an outgoing/incoming test.

The significance of running Yahalom in the SPA is that the SPA is challenged with multiple parties, multiple test cases and an encounter with its first negated test component and warning message. The results of the SPA were expected so therefore we conclude that it has successfully completed analysis of this protocol.

**A -> B : A *Na**
**B -> S : B {A Na *Nb}Kbs**
**S -> A : {B *Kab Na Nb}Kas {A *Kab}Kbs**
**A -> B : {A Kab}Kbs {Nb}Kab**

**<Parties> : <Message> >> A -> B : A *Na**
**Sender may be attempting to initiate an incoming test by transmitting Na in the clear.**

**<Parties> : <Message> >> B -> S : B {A Na *Nb}Kbs**
**Encrypt term(s) < A Na *Nb > with key Kbs is readable by both sender/receiver.**
**Unsolicited test for S because of nonce Na within test component < {A Na Nb}Kbs >**
**Sender may be attempting to initiate an outgoing test by transmitting Nb in encrypted form.**
**Unsolicited test for S because of nonce Nb within test component < {A Na Nb}Kbs >**

**<Parties> : <Message> >> S -> A : {B *Kab Na Nb}Kas {A *Kab}Kbs**
**Encrypt term(s) < B *Kab Na Nb > with key Kas is readable by both sender/receiver.**
**Unsolicited test for A because of nonce Kab within test component < {B Kab Na Nb}Kas >**
**Sender may be attempting to initiate an outgoing test by transmitting Kab in encrypted form.**
**The unencrypted/fresh nonce Na has been received back in new component: {B Kab Na Nb}Kas**
**Incoming test for A because fresh term Na was sent out earlier in < Na >**
**Unsolicited test for A because of nonce Nb within test component < {B Kab Na Nb}Kas >**
**Encrypted term(s) < A *Kab > with key Kbs is readable by sender only.**
**Warning: Sender is transmitting nonce Kab in two separate components, invalidating its use as an outgoing test.**
**Sender may be attempting to initiate an outgoing test by transmitting an invalid Kab in encrypted form.**

**<Parties> : <Message> >> A -> B : {A Kab}Kbs {Nb}Kab**
**Encrypted term(s) < A Kab > with key Kbs is readable by recipient only.**
**Unsolicited test for B because of nonce Kab within test component < {A Kab}Kbs >**

**Encrypt term(s) < Nb > with key Kab is readable by both sender/receiver.**
**The encrypted/fresh nonce Nb has been received back in new component: {Nb}Kab**
**Outgoing/Incoming test for B because fresh term Nb was sent out earlier in < {A Na Nb}Kbs >**

Figure 4.2 – Yahalom Protocol

### 4.2.3 Woo-Lam Protocol

In this section, the Woo-Lam protocol is examined. From this point onward, rather than explain line by line each protocol, only key events of the protocol and the SPA's conclusions are discussed. In Woo-Lam, which is already identified to have a flaw [5], the SPA recognizes two tests. The first is the completed incoming test from *B*'s view. The second is the unsolicited test from the servers' point of view. However in Guttman's work, [5], he concludes that their does not exist a legitimate incoming test. This reasoning is based on the notion that another node could produce a received component of the same form. Since the SPA performs tests based on string comparisons, in a test like this, type comparisons would be more beneficial. Hence, a model checking language may prove more effective in this type of scenario.

**A -> B : A**
**B -> A : *Nb1**
**A -> B : {Nb1}Kas**
**B -> S : {A {Nb1}Kas}Kbs**
**S -> B : {Nb1}Kbs**

**<Parties> : <Message> >> A -> B : A**

**<Parties> : <Message> >> B -> A : *Nb1**
**Sender may be attempting to initiate an incoming test by transmitting Nb1 in the clear.**

**<Parties> : <Message> >> A -> B : {Nb1}Kas**
**Encrypted term(s) < Nb1 > with key Kas is readable by sender only.**

**<Parties> : <Message> >> B -> S : {A {Nb1}Kas}Kbs**
**Encrypt term(s) < A {Nb1}Kas > with key Kbs is readable by both sender/receiver.**
**Encrypted term(s) < Nb1 > with key Kas is readable by recipient only.**
**Unsolicited test for S because of nonce Nb1 within test component < {Nb1}Kas >**

**<Parties> : <Message> >> S -> B : {Nb1}Kbs**
**Encrypt term(s) < Nb1 > with key Kbs is readable by both sender/receiver.**
**The unencrypted/fresh nonce Nb1 has been received back in new component: {Nb1}Kbs**
**Incoming test for B because fresh term Nb1 was sent out earlier in < Nb1 >**

Figure 4.3 – Woo-Lam Protocol

### 4.2.4 Neuman-Stubblebine Protocol

The next protocol reviewed is the Neuman-Stubblebine protocol. In this test, two different scenarios are executed. The first (Figure 4.4) puts the * tag on the nonces and session keys generated by the server and the ticket generated by *B*. In other words, anything created fresh and unique is tagged in order to identify all potential tests. The second run (Figure 4.5) shows the analysis done without placing the * on the keys and tickets generated by the different parties. The reason for this is to show that in order to detect the presence of tests, it is important that the analyzers of the protocol know what they intend to use as unique/fresh terms, thus they have more flexibility when doing analysis.

In the first test, numerous examples of unsolicited tests are shown due to the sheer volume of freshly tagged terms. At this point, it is important to note that the SPA does not disqualify any components but does make note of the fact that in step 3 a fresh term (a key) is being transmitted in two components. Although this negates their validity as outgoing tests, the SPA still makes the correct assessment and determines that unsolicited tests involving these components do occur.

**A -> B : A *Na**
**B -> S : B {A Na *tb}Kbs *Nb**
**S -> A : {B Na *Kab tb}Kas {A *Kab tb}Kbs Nb**
**A -> B : {A *Kab tb}Kbs {Nb}Kab**

**<Parties> : <Message> >> A -> B : A *Na**

**Sender may be attempting to initiate an incoming test by transmitting Na in the clear.**

**<Parties> : <Message> >> B -> S : B {A Na *tb}Kbs *Nb**
**Encrypt term(s) < A Na *tb > with key Kbs is readable by both sender/receiver.**
**Unsolicited test for S because of nonce Na within test component < {A Na tb}Kbs >**
**Sender may be attempting to initiate an outgoing test by transmitting tb in encrypted form.**
**Unsolicited test for S because of nonce tb within test component < {A Na tb}Kbs >**
**Sender may be attempting to initiate an incoming test by transmitting Nb in the clear.**

**<Parties> : <Message> >> S -> A : {B Na *Kab tb}Kas {A *Kab tb}Kbs Nb**
**Encrypt term(s) < B Na *Kab tb > with key Kas is readable by both sender/receiver.**
**The unencrypted/fresh nonce Na has been received back in new component: {B Na Kab tb}Kas**
**Incoming test for A because fresh term Na was sent out earlier in < Na >**
**Unsolicited test for A because of nonce Kab within test component < {B Na Kab tb}Kas >**
**Sender may be attempting to initiate an outgoing test by transmitting Kab in encrypted form.**
**Unsolicited test for A because of nonce tb within test component < {B Na Kab tb}Kas >**
**Encrypted term(s) < A *Kab tb > with key Kbs is readable by sender only.**
**Warning: Sender is transmitting nonce Kab in two separate components, invalidating its use as an outgoing test.**
**Sender may be attempting to initiate an outgoing test by transmitting an invalid Kab in encrypted form.**

**<Parties> : <Message> >> A -> B : {A *Kab tb}Kbs {Nb}Kab**
**Encrypted term(s) < A *Kab tb > with key Kbs is readable by recipient only.**
**Unsolicited test for B because of nonce Kab within test component < {A Kab tb}Kbs >**
**The encrypted/fresh nonce tb has been received back in new component: {A Kab tb}Kbs**
**Outgoing/Incoming test for B because fresh term tb was sent out earlier in < {A Na tb}Kbs >**
**Encrypt term(s) < Nb > with key Kab is readable by both sender/receiver.**
**The unencrypted/fresh nonce Nb has been received back in new component: {Nb}Kab**
**Incoming test for B because fresh term Nb was sent out earlier in < Nb >**

Figure 4.4 – Neuman-Stubblebine with Tags on Keys/Tickets

In Figure 4.5, the Neuman-Stubblebine is run on the SPA without attaching the * to the keys or ticket. The only difference here is that it follows more closely with the results made by Guttman [5]. However, it is not incorrect to show a key or timestamp, generated similarly to a nonce, as fresh and denoting it with a fresh identifier as previously shown. Nor does it negate the conclusion of the previous example.

**A -> B : A *Na1**
**B -> S : B {A *Na1 Tb}Kbs *Nb1**
**S -> A : {B Na1 Kab Tb}Kas {A Kab Tb}Kbs Nb1**
**A -> B : {A Kab Tb}Kbs {Nb1}Kab**

**<Parties> : <Message> >> A -> B : A *Na1**
**Sender may be attempting to initiate an incoming test by transmitting Na1 in the clear.**

**<Parties> : <Message> >> B -> S : B {A *Na1 Tb}Kbs *Nb1**
**Encrypt term(s) < A *Na1 Tb > with key Kbs is readable by both sender/receiver.**
**Sender is attempting to intiate a test with an old/invalidated nonce!**
**Unsolicited test for S because of nonce Na1 within test component < {A Na1 Tb}Kbs >**
**Sender may be attempting to initiate an incoming test by transmitting Nb1 in the clear.**

**<Parties> : <Message> >> S -> A : {B Na1 Kab Tb}Kas {A Kab Tb}Kbs Nb1**
**Encrypt term(s) < B Na1 Kab Tb > with key Kas is readable by both sender/receiver.**
**The unencrypted/fresh nonce Na1 has been received back in new component: {B Na1 Kab Tb}Kas**
**Incoming test for A because fresh term Na1 was sent out earlier in < Na1 >**
**Encrypted term(s) < A Kab Tb > with key Kbs is readable by sender only.**

**<Parties> : <Message> >> A -> B : {A Kab Tb}Kbs {Nb1}Kab**
**Encrypted term(s) < A Kab Tb > with key Kbs is readable by recipient only.**
**Encrypt term(s) < Nb1 > with key Kab is readable by both sender/receiver.**
**The unencrypted/fresh nonce Nb1 has been received back in new component: {Nb1}Kab**
**Incoming test for B because fresh term Nb1 was sent out earlier in < Nb1 >**

Figure 4.5 – Neuman-Stubblebine w/o Tags on Keys/Tickets

### 4.2.5 Needham-Schroeder with Server

In this test, the Needham-Schroeder protocol is executed on the SPA again. However, unlike before, the server portion of the protocol is included (Figure 4.6). This protocol is drawn directly from [29]. However, for clarification, the keys Kas and Kbs are used to show when the server is communicating with *A* and *B* specifically. Normal operation of the protocol entails the server using its private key for encryption of these messages and assumes both parties have the servers' public key. The use of this key format does not alter the results of the test.

**A -> S : A B**
**S -> A : {Kb B}KaS**
**A -> B : {A *Na}Kb**
**B -> S : B A**
**S -> B : {Ka A}KbS**
**B -> A : {Na *Nb}Ka**
**A -> B : {Nb}Kb**

```
<Parties> : <Message> >> A -> S : A B

<Parties> : <Message> >> S -> A : {Kb B}KaS
Encrypt term(s) < Kb B > with key KaS is readable by both sender/receiver.

<Parties> : <Message> >> A -> B : {A *Na}Kb
Encrypted term(s) < A *Na > with key Kb is readable by recipient only.
Sender may be attempting to initiate an outgoing test by transmitting Na in encrypted form.

<Parties> : <Message> >> B -> S : B A

<Parties> : <Message> >> S -> B : {Ka A}KbS
Encrypt term(s) < Ka A > with key KbS is readable by both sender/receiver.

<Parties> : <Message> >> B -> A : {Na *Nb}Ka
Encrypted term(s) < Na *Nb > with key Ka is readable by recipient only.
The encrypted/fresh nonce Na has been received back in new component: {Na Nb}Ka
Outgoing test for A because fresh term Na was sent out earlier in < {A Na}Kb >
Sender may be attempting to initiate an outgoing test by transmitting Nb in encrypted form.

<Parties> : <Message> >> A -> B : {Nb}Kb
Encrypted term(s) < Nb > with key Kb is readable by recipient only.
The encrypted/fresh nonce Nb has been received back in new component: {Nb}Kb
Outgoing test for B because fresh term Nb was sent out earlier in < {Na Nb}Ka > >
```

Figure 4.6 – Needham-Schroeder Protocol (w/ Server)

This test results in output similar to earlier tests with Needham-Schroeder. The only real difference is the interaction with the server that occurs between each party.

### 4.2.6 Kerberos Protocol

The Kerberos protocol results are very similar to Neuman-Stubblebine. In Chapter 2, an in-depth description of how this protocol works is given. The layout used here, which contains more specific information in each message, is taken directly from [29]. Regarding the analysis, there are no surprises in the output. The only subjective action was not to tag all keys and timestamps as fresh, even though they are. The reason is that, based on the Neuman-Stubblebine output, nothing further would be gained from this except a more lengthy output.

**C -> A : U G L1 *N1**
**A -> C : U {U C G *Kcg Tst Tex}Kag {G *Kcg Tst Tex N1}Ku**
**C -> G : S L2 *N2 {U C G *Kcg Tst Tex}Kag {C *T1}Kcg**
**G -> C : U {U C S *Kcs Tst1 Tex1}Kcg {S *Kcs Tst1 Tex1 N2}Kcg**
**C -> S : {U C S Kcs Tst1 Tex1}Kcg {C *T2}Kcs**
**S -> C : {T2}Kcs**

**<Parties> : <Message> >> C -> A : U G L1 *N1**
**Sender may be attempting to initiate an incoming test by transmitting N1 in the clear.**

**<Parties> : <Message> >> A -> C : U {U C G *Kcg Tst Tex}Kag {G *Kcg Tst Tex N1}Ku**
**Encrypted term(s) < U C G *Kcg Tst Tex > with key Kag is readable by sender only.**
**Sender may be attempting to initiate an outgoing test by transmitting Kcg in encrypted form.**
**Encrypted term(s) < G *Kcg Tst Tex N1 > with key Ku is readable by neither sender nor receiver.**
**Warning: Sender is transmitting nonce Kcg in two separate components, invalidating its use as an outgoing test.**
**Sender may be attempting to initiate an outgoing test by transmitting an invalid Kcg in encrypted form.**

**<Parties> : <Message> >> C -> G : S L2 *N2 {U C G *Kcg Tst Tex}Kag {C *T1}Kcg**
**Sender may be attempting to initiate an incoming test by transmitting N2 in the clear.**
**Encrypted term(s) < U C G *Kcg Tst Tex > with key Kag is readable by recipient only.**
**Unsolicited test for G because of nonce Kcg within test component < {U C G Kcg Tst Tex}Kag >**
**Encrypt term(s) < C *T1 > with key Kcg is readable by both sender/receiver.**
**Sender may be attempting to initiate an outgoing test by transmitting T1 in encrypted form.**
**Unsolicited test for G because of nonce T1 within test component < {C T1}Kcg >**

**<Parties> : <Message> >> G -> C : U {U C S *Kcs Tst1 Tex1}Kcg {S *Kcs Tst1 Tex1 N2}Kcg**
**Encrypt term(s) < U C S *Kcs Tst1 Tex1 > with key Kcg is readable by both sender/receiver.**
**Pseudo-unsolicited test for C because Kcs is a newly received fresh nonce, but C has sent items to G previously.**
**Sender may be attempting to initiate an outgoing test by transmitting Kcs in encrypted form.**
**Encrypt term(s) < S *Kcs Tst1 Tex1 N2 > with key Kcg is readable by both sender/receiver.**
**Warning: C is seeing Kcs again...but it's tagged with * (fresh) identifier!**
**Warning: Sender is transmitting nonce Kcs in two separate components, invalidating its use as an outgoing test.**
**Sender may be attempting to initiate an outgoing test by transmitting an invalid Kcs in encrypted form.**
**The unencrypted/fresh nonce N2 has been received back in new component: {S Kcs Tst1 Tex1 N2}Kcg**
**Incoming test for C because fresh term N2 was sent out earlier in < N2 >**

**<Parties> : <Message> >> C -> S : {U C S Kcs Tst1 Tex1}Kcg {C *T2}Kcs**
**Encrypted term(s) < U C S Kcs Tst1 Tex1 > with key Kcg is readable by sender only.**
**Encrypt term(s) < C *T2 > with key Kcs is readable by both sender/receiver.**
**Sender may be attempting to initiate an outgoing test by transmitting T2 in encrypted form.**
**Unsolicited test for S because of nonce T2 within test component < {C T2}Kcs >**

**<Parties> : <Message> >> S -> C : {T2}Kcs**
**Encrypt term(s) < T2 > with key Kcs is readable by both sender/receiver.**
**The encrypted/fresh nonce T2 has been received back in new component: {T2}Kcs**
**Outgoing/Incoming test for C because fresh term T2 was sent out earlier in < {C T2}Kcs >**

Figure 4.7 – Kerberos Protocol

### 4.2.7 Analyzing Otway-Rees

In this section, the Otway-Rees protocol is analyzed using the SPA. Figure 4.8 shows the output generated from the SPA.

**A -> B : *M A B {*Na1 *M A B}Kas**
**B -> S : M A B {Na1 M A B}Kas {*Nb1 M A B}Kbs**
**S -> B : M {Na1 *Kab}Kas {Nb1 *Kab}Kbs**
**B -> A : M {Na1 Kab}Kas**

**<Parties> : <Message> >> A -> B : *M A B {*Na1 *M A B}Kas**
**Sender may be attempting to initiate an incoming test by transmitting M in the clear.**
**Encrypted term(s) < *Na1 *M A B > with key Kas is readable by sender only.**
**Sender may be attempting to initiate an outgoing test by transmitting Na1 in encrypted form.**
**Sender may be attempting to initiate an outgoing test by transmitting M in encrypted form.**
**Sender is sending the same nonce M out both encrypted and plain.**
**It may only be used to complete an incoming test.**

**<Parties> : <Message> >> B -> S : M A B {Na1 M A B}Kas {*Nb1 M A B}Kbs**
**Encrypted term(s) < Na1 M A B > with key Kas is readable by recipient only.**
**Unsolicited test for S because of nonce Na1 within test component < {Na1 M A B}Kas >**
**Unsolicited test for S because of nonce M within test component < {Na1 M A B}Kas >**
**Encrypt term(s) < *Nb1 M A B > with key Kbs is readable by both sender/receiver.**
**Sender may be attempting to initiate an outgoing test by transmitting Nb1 in encrypted form.**
**Unsolicited test for S because of nonce Nb1 within test component < {Nb1 M A B}Kbs >**

**<Parties> : <Message> >> S -> B : M {Na1 *Kab}Kas {Nb1 *Kab}Kbs**
**Encrypted term(s) < Na1 *Kab > with key Kas is readable by sender only.**
**Sender may be attempting to initiate an outgoing test by transmitting Kab in encrypted form.**
**Encrypt term(s) < Nb1 *Kab > with key Kbs is readable by both sender/receiver.**
**The encrypted/fresh nonce Nb1 has been received back in new component: {Nb1 Kab}Kbs**
**Outgoing/Incoming test for B because fresh term Nb1 was sent out earlier in < {Nb1 M A B}Kbs >**
**Pseudo-unsolicited test for B because Kab is a newly received fresh nonce, but B has sent items to S previously.**
**Warning: Sender is transmitting nonce Kab in two separate components, invalidating its use as an outgoing test.**
**Sender may be attempting to initiate an outgoing test by transmitting an invalid Kab in encrypted form.**

**<Parties> : <Message> >> B -> A : M {Na1 Kab}Kas**
**Encrypted term(s) < Na1 Kab > with key Kas is readable by recipient only.**
**The encrypted/fresh nonce Na1 has been received back in new component: {Na1 Kab}Kas**
**Outgoing/Incoming test for A because fresh term Na1 was sent out earlier in < {Na1 M A B}Kas >**
**Unsolicited test for A because of nonce Kab within test component < {Na1 Kab}Kas >**

Figure 4.8 – Output of Otway-Rees protocol run

In the Otway-Rees run there is nothing new being seen by the analyzer that has not already been demonstrated. The only important thing to get from this is that the SPA is capable of accurately finding authentication tests and examples of basic mischievous/erroneous activity.

## 4.3 Non-Regular Protocol Test Cases

This section examines several test cases meant to test the reliability of the SPA against cases that, although not representative of any real protocol, may undoubtedly surface in a similar form. These test cases are essentially designed to test the analyzers ability to recognize common mischievous activities as defined in the Dolev-Yao threat model.

### 4.3.1 Repeating Message

This section examines how the SPA can verify a case in which a principal retransmits an identical message back to the sender. In Figure 4.9, principal *A* transmits a test component containing a fresh nonce. From a receiver's point of view, this constitutes an unsolicited test. However, the intended recipient simply retransmits the message back to the sender. Because the component received back is not altered, *A* cannot deduce that an intended party performed any action on the component; therefore, this does not constitute an outgoing test.

**A -> B : {*Na}Kab**
**B -> A : {Na}Kab**

**<Parties> : <Message> >> A -> B : {*Na}Kab**
**Encrypt term(s) < *Na > with key Kab is readable by both sender/receiver.**
**Sender may be attempting to initiate an outgoing test by transmitting Na in encrypted form.**

**Unsolicited test for B because of nonce Na within test component < {Na}Kab >**

**<Parties> : <Message> >> B -> A : {Na}Kab**
**Encrypt term(s) < Na > with key Kab is readable by both sender/receiver.**
**The encrypted nonce Na has been received back, but in a duplicated transmission!**
**The component {Na}Kab was sent out identically by this sender.**

Figure 4.9 - Repeating Message

### 4.3.2 Sub Term Relationship of Encrypted Test Component

This section covers a test that demonstrates the analyzers ability to verify usage of test components as a whole in an improper manner. Recall from Chapter 2 that the definition of a test component stipulates that a test component cannot exist as a proper subterm of any other term on any other regular node. In this example, *B* attempts to use *A*'s encrypted message as his own 'fresh' term when communicating with *C*. The analyzer, which looks ahead, realizes this and flags the original component as invalid! Because of this, *A* is no longer able to complete is outgoing test. Since we are using asymmetric cryptography, no unsolicited tests occur either. The only test that might have occurred in this run would be an outgoing if *C* gets his fresh nonce back at a later time.

**A -> B : {*Na}Kb**
**B -> C : {{Na}Kb}Kc**
**C -> B : {{Na}Kb *Nc}Kb**
**B -> A : {Na Nc}Ka**

**<Parties> : <Message> >> A -> B : {*Na}Kb**
**Encrypted term(s) < *Na > with key Kb is readable by recipient only.**
**{Na}Kb is an invalid test component because it's either a proper**
**subterm of another component or is a duplicate transmission!**
**Receiver is receiving an invalid test component {Na}Kb otherwise, it would be an unsolicited test with fresh term Na**

**<Parties> : <Message> >> B -> C : {{Na}Kb}Kc**
**Encrypted term(s) < {Na}Kb > with key Kc is readable by recipient only.**
**Encrypted term(s) < Na > with key Kb is readable by sender only.**

**<Parties> : <Message> >> C -> B : {{Na}Kb *Nc}Kb**
**Encrypted term(s) < {Na}Kb *Nc > with key Kb is readable by recipient only.**

**Encrypted term(s) < Na > with key Kb is readable by recipient only.**
**Sender may be attempting to initiate an outgoing test by transmitting Nc in encrypted form.**

**<Parties> : <Message> >> B -> A : {Na Nc}Ka**
**Encrypted term(s) < Na Nc > with key Ka is readable by recipient only.**

Figure 4.10 - Sub-Term Re-Encryption

### 4.3.3 Unreadable Encryption on Messages

The final improper protocol test involves testing the SPA's ability to check for proper encryption. In Figure 4.11, the SPA is running the Needham-Schroeder protocol but on line two of the input file, the encryption ensures *A* cannot read the message. Therefore, the SPA should not show any example of an outgoing test. Correctly so, the SPA does not. In fact, notice the SPA's ability to demonstrate duplicate transmission of messages.

**A -> B : {*Na}Kb**
**B -> A : {Na *Nb}Kb**
**A -> B : {Na Nb}Kb**

**<Parties> : <Message> >> A -> B : {*Na}Kb**
**Encrypted term(s) < *Na > with key Kb is readable by recipient only.**
**Sender may be attempting to initiate an outgoing test by transmitting Na in encrypted form.**

**<Parties> : <Message> >> B -> A : {Na *Nb}Kb**
**Encrypted term(s) < Na *Nb > with key Kb is readable by sender only.**
**Sender may be attempting to initiate an outgoing test by transmitting Nb in encrypted form.**

**<Parties> : <Message> >> A -> B : {Na Nb}Kb**
**Encrypted term(s) < Na Nb > with key Kb is readable by recipient only.**
**The encrypted nonce Nb has been received back, but in a duplicated transmission!**
**The component {Na Nb}Kb was sent out identically by this sender.**

Figure 4.11 – Needham-Schroeder with improper encryption

## 4.4 Summary

This chapter described the results of running several normal protocols and several incorrect protocols on the SPA. The output of each test is described in detail in order for the reader to have a greater appreciation of what the tool is doing. It is evident that the

tool provides a reliable means of determining if and where any authentication tests occur in the occurrence of a particular protocol. The SPA also demonstrates its ability to ascertain improper behavior, as demonstrated in the 'improper' protocols. Although the SPA is not designed to show weaknesses in a protocol, the absence of authentication tests should raise flags regarding a protocol and thus increase skepticism regarding its security. The next chapter gives final analysis of the results of running the SPA on communication protocols.

# V. Conclusions and Recommendations

## 5.1 Chapter Overview

This chapter provides conclusions as to the success of the research and provides a roadmap for future work in the field of protocol analysis. It provides insight into what the Secure Protocol Analyzer accomplishes and how another modeling language may or may not provide better analysis of protocols in the future.

## 5.1 Conclusions of Research

The SPA successfully shows that protocol analysis with a tool developed in Java is highly valuable in the performance of protocol analysis. In particular, the SPA is able to determine when and where outgoing, incoming and unsolicited tests occur within a protocol run. Using string comparisons vice type comparisons requires specific values be given and does limit the application to analysis based on completed static runs. However, putting together numerous protocols in generic text files proves much easier than individual protocol development as noted in other protocol analyzers [27, 11]. It also allows for much quicker analysis of the protocol because it does not have to dynamically create a search tree, instead it only examines the post-run state of the protocol as entered in the input text file. In conclusion, the SPA allows the taking of any protocol as input in a standard text file and generates accurate output that shows occurrences of authentication tests, and it does so very quickly.

## 5.3 Significance of Research

This research is significant because it creates a simple-to-use tool that effectively shows the presence of authentication tests. Although there are numerous other methods for analyzing protocols, this method proves easy to use, accurate in its results and, more importantly, it enables any protocol to be entered in with minimal effort by the user. Another important result of this work is that output from the SPA can be tailored to one's unique work. This opens the possibility that output from the SPA could be used as input for other theorem checking tools or protocol analysis tools that may look for different aspects regarding a particular protocol. Finally, this fast automation of analysis is important because the longer a protocol is left in use without in-depth analysis being performed on it, the more the chance of mischievous persons finding a potential weakness during its use and exploiting it.

## 5.4 Recommendations for Future Research

Although the tool is fairly complete in its present form, added functionality will certainly improve the effectiveness of the tool. For example, adding functionality that would include provisions for penetrator capabilities. This would entail adding in a means to examine static runs and evaluate what information a penetrator is able to derive based on the Dolev-Yao threat model. From this information, the tool might be able to start developing its own messages in an effort to show the user that it is possible to implant false messages leading to potential havoc on the principals. Another function worth adding is that of showing all the keys used during the protocol exchange. From this, the analyzer can show the keys actually used for encryption, whether they are safe or not,

then show the set assumed to be safe as defined by Guttman. Also, as stated in [5], since the authentication tests work even if n and n' are on different strands, add to the analyzer the ability to find the tests within different strands.

Another course of action is development in another modeling language altogether. Using an analyzer developed through a model checker would allow dynamic creation of search trees where numerous different states can be analyzed showing not only where and when authentication tests occur but also how to better develop the protocol to ensure the authentication tests do occur and that certain states are never reached.

The other main recommendation for future research is to produce a similar analyzer using the Maude language specifically. As stated earlier, dynamic evaluation of protocols allows users to see first-hand the actual operation of a protocol run, versus the after effect of the run as entered in static format. As explained in Chapter 2, Maude's rewriting ability would enable it to generate dynamic states very easily. With this dynamic evaluation, using a Dolev-Yao threat model, also built into the modeling language, the user can ascertain all the possible states that a protocol can be in and all the possible information that can be derived. This includes states that the protocol should not necessarily be in. Limitations would have to be placed on this method to ensure that state space explosion and other problems do not occur as described in greater detail in Chapter 2.

Although there are numerous other protocol analyzers [11, 12, 24], none seem to exhibit the all-knowing power to ascertain whether protocols are susceptible to attack. However, built upon the foundation of a solid, powerful and easy to use tool the research

and tool generated here gives analysts a clear roadmap into the future of protocol analysis.

This is where the main() function is.  This is the driver of the
program!  Here is where the following occurs:
individual instances of principal are created from the 'from' and 'to'
of the message, they are placed in a vector
and passed around.  Also, each message is broken into components and
analyzed if it's a duplicate or subterm (subterm
verification also is checked in encryption class).  Depending on check,
the comp is placed in wither test_comp vector
or bad_comp vector.   After this steps are done, it then starts the
process by analyzing 1 message at a time, depending
on what the instance is, it call getreadabletext.  Since a message may
contain sub-parts, getreadabletext is also called
recursively in other classes such as encryption and text.

This is a key class.  Here is where an addnonce, that is called from
text class, ends up.  This has
numerous flags and variables passed in.  This class does the test for
tests.  Whenever the string value
is set to sender, values sent in apply to that particular instance of
sender, created in protocolanalyzer class.
Likewise for receiver.  Not much else to say on this class except that
tests work basically like this:  Whenever I
am in sender mode, whatever nonce is passed in is placed in a vector
(sent_nonces if encr/sent_unencrypted is sent unencr)
As long as the comp isn't disqualified, that is.  These flags are
checked mostly in all the if's of the receiver.
Then whenever I am receiver, I check through my sent_nonce and
sent_unencerypted vectors and see if the nonce passed
in is there, if so it completes whatever test is applicable.

package protocolB;
/**
* Stephen Mancini and Robert Graham
* AFIT/ENG
* 23 Feb 2004

The purpose of this class is as follows:
Whenever an instance of an encrypted term is called, it happens here.
This class will ascertain if
a particular message is readable by sender, receiver, both or neither.
This happens through recursive calls
of getreadabletext() which is abstract and located several classes.
The arguments are the same, however, based
```

```
on who can read it, the from and to strings are set to relevant
setting.  For instance, if a sender can read it
the from string is set to that value.
Bottom line, based on key values, sender and receiver are set and
getreadabletext function is called...

The public reporting burden for this collection of information is estimated to average 1 hour per response, including the time for reviewing instructions, searching existing data sources, gathering and maintaining the data needed, and completing and reviewing the collection of information. Send comments regarding this burden estimate or any other aspect of the collection of information, including suggestions for reducing this burden to Department of Defense, Washington Headquarters Services, Directorate for Information Operations and Reports (0704-0188), 1215 Jefferson Davis Highway, Suite 1204, Arlington, VA 22202-4302. Respondents should be aware that notwithstanding any other provision of law, no person shall be subject to an penalty for failing to comply with a collection of information if it does not display a currently valid OMB control number.

**13. SUPPLEMENTARY NOTES**

**14. ABSTRACT** When Roger Needham and Michael Schroeder first introduced a seemingly secure protocol [24], it took over 18 years to discover that even with the most secure encryption, the conversations using this protocol were still subject to penetration. To date, there is still no one protocol that is accepted for universal use. Because of this, analysis of the protocol outside the encryption is becoming more important. Recent work by Joshua Guttman and others [9] have identified several properties that good protocols often exhibit. Termed "Authentication Tests", these properties have been very useful in examining protocols. The purpose of this research is to automate these tests and thus help expedite the analysis of both existing and future protocols.

The success of this research is shown through rapid analysis of numerous protocols for the existence of authentication tests. The result of this is that an analyst is now able to ascertain in near real-time whether or not a proposed protocol is of a sound design or whether an existing protocol may contain previously unknown weaknesses. The other achievement of this research is the generality of the input process involved. Although there exist other protocol analyzers, their use is limited primarily due to their complexity of use. With the tool generated here, an analyst needs only to enter their protocol into a standard text file; and almost immediately, the analyzer determines the existence of the authentication tests.
