Abstract

Aims Mild or moderate aortic regurgitation (AR) has only little effect on cardiovascular outcome in people with normal left ventricular ejection fraction (EF); therefore, it is not perceived as a major clinical problem. This study investigates whether mild or moderate AR is associated with increased short-term mortality in patients hospitalized for treatment of acute heart failure (AHF) and whether mild or moderate AR impacts differently on short-term mortality in AHF patients with reduced EF (AHFrEF), mid-range EF (AHFmrEF), or preserved EF (AHFpEF).

Methods and results This mono-centric study included 505 consecutive adult patients hospitalized for *de novo* or worsening chronic HF not related to acute ischaemia or severe valvular pathology in the echocardiogram at index hospitalization. Cox regression analysis studied the impact of AR on all-cause mortality (ACM) over the 150 days' study period. Mild or moderate AR was associated with increased ACM (HR 1.75 [95% CI: 1.1–2.7]; $P = 0.009$). The prevalence of mild or moderate AR in the study population was 42% and not significantly different between AHFpEF ($n = 227$), AHFmrEF ($n = 86$), and AHFrEF ($n = 192$) study participants (37.9% vs. 50.0% vs. 42.7%; $P = 0.144$). In AHFpEF patients, the age-adjusted hazard for ACM was increased in patients with AR compared with patients without AR (HR 2.17 [95% CI: 1.1–4.2]; $P = 0.002$). The age-adjusted hazard for ACM was increased by a trend in AHFmrEF with AR (HR 7.11, [95% CI: 0.9–57.8]; $P = 0.067$) and not different between the AHFrEF groups (HR 0.95 [95% CI: 0.5–1.8]; $P = 0.875$).

Conclusions Mild or moderate AR increased ACM only in AHFpEF patients, highlighting a distinct clinical relevance.

Keywords Acute heart failure; Aortic regurgitation; All-cause mortality

Introduction

Epidemiological studies show that the low prevalence of aortic valve insufficiency at younger age increases to a 13–29% level in the elderly.^{1–3} A similar increase has been shown for the prevalence of symptomatic heart failure (HF) in the general population, which is low at younger age but affects >40% of people at the age of 70 years and above.^{4,5} This suggests that coincidence of aortic regurgitation (AR) and HF should occur in particular in the aged.

For patients with symptomatic and asymptomatic severe AR with or without reduced left ventricular ejection fraction (LVEF), the therapeutic strategy is set out.⁶ However, the clinical importance of mild or moderate AR remains unclear in particular in HF, although about 20% of hospitalized patients with non-severe AR have also HF as shown in a more recent epidemiological hospital-based survey.⁷

We therefore studied the impact of mild or moderate AR on all-cause mortality (ACM) in patients with hospitalization for treatment of acute HF (AHF). This study population was

chosen because acute decompensation represents a fair argument for the presence of HF, which can be difficult to diagnose in particular when LVEF is in the mid-range or preserved.^{8,9} In fact, this approach has already been successfully adopted in an earlier study investigating characteristics of the HF patients with preserved LVEF.¹⁰ Another argument in favour of application of the research question to these patients is their high burden of adverse cardiovascular outcome. In theory, the latter should permit detection of interaction even in smaller-size groups with short-term follow-up.

Methods

Study population

This study combines two local prospective registries (years 2005–2009, $n = 402$; years 2015–2018, $n = 221$).^{11,12} Both registries had prospectively recruited consecutive adult AHF patients with presentation to the emergency wards followed by hospitalization at the Lausanne University Hospital. Screening excluded patients with exacerbation of obstructive pulmonary disease, acute pulmonary embolism or stress-related cardiomyopathy, acute myocardial ischaemia, or acute mechanical cause from acute coronary syndrome; patients after recent cardiac surgery; or patients with echocardiography performed short term before hospitalization.⁹ Inclusion criteria were (i) age ≥ 18 years; (ii) hospitalization for AHF treatment at the CHUV; (iii) transthoracic echocardiographic exam during index hospitalization; and (iv) written consent. Additional exclusion criteria were (i) pregnancy; (ii) comorbidity with survival time considered to be <1 year on the basis of the patient's medical history including primary pulmonary artery hypertension; (iii) severe aortic, mitral, and tricuspid regurgitation or stenosis on index echocardiography; (iv) AHF caused by acute metabolic, toxic or infectious disorders; (v) AHF with accompanying cerebrovascular insult; and (vi) prior aortic valve replacement. The study protocol was approved by the local ethics committee (CER Vaud 2019–01158).

Acquisition of anthropometric, biological, and clinical data

Anthropometric, biological, clinical admission data and medical history were collected from the individual patients' electronic health report at the Lausanne University Hospital (T. A., G. T., and N. S.). Data accuracy was tested by revisiting 30% of randomly selected patients' data revealing 99.7% correctness (T. A. and N. S.). Standard transthoracic echocardiographic images and parameters were acquired by board-certified cardiologists. Echocardiographic analysis was

performed offline using EchoPac software, version 4.0.4 (GE Medical Systems) (G. T., N. B., J. R., and P. M.). LVEF was assessed using the Simpson method; the severity of valvular regurgitations was graded using a multiparametric assessment as recommended by the European Association of Cardiovascular Imaging.^{13,14}

Types of heart failure

Participants were classified to suffer from chronic HF (CHF) when presenting clinical signs of CHF before index admission as documented in the patients' history. Patients were classified to have AHF with preserved EF (AHFpEF) when LVEF was $\geq 50\%$, AHF with mid-range EF (AHFmrEF) when LVEF was $\geq 40\text{--}49\%$, and AHF with reduced EF (AHFrEF) when LVEF was $<40\%$ in analogy to the European Society of Cardiology guidelines for the diagnosis and treatment of AHF and CHF.⁸

Study outcome: all-cause mortality over the study period of 150 days after hospital admission for treatment of decompensated heart failure

ACM was seized over a 150 days' period starting on the day of hospital admission; 99.8% of study patients had a length of hospital stay < 30 days.

Statistical analysis

Analyses were performed with Stata® 13.1 (StataCorp, College Station, TX, USA). As normal distribution could not be ensured for most of the variables, all continuous variables are shown as medians with inter-quartile ranges. Categorical variables were shown as per cent (absolute number).

Associations with AR were tested using the Mann–Whitney *U*-test for continuous variables and the χ^2 test for categorical variables. The Kruskal–Wallis test with the Mann–Whitney *U*-test and the χ^2 as a post-hoc test were performed to compare interval variables with categorical variables between the three different types of HF.

Cox regression analysis was used to identify parameters that were associated with ACM over the study period. The hazard ratio (HR) accompanied by its 95% CI was used as a measure of strength for Cox regression analysis results.

Variables that showed at least very weak evidence ($P < 0.2$) for an association with type of HF (Tables S1 and S2), mild or moderate AR, and ACM were included in the multivariable Cox regression analysis to study the impact of mild or moderate AR on ACM according to the type of HF. Thus, an interaction term between type of HF and AR was forced in the multivariable model. To get to the final model, covariates with a non-significant *P*-value

($P > 0.05$) were removed in a stepwise backward approach. The test of proportional hazards assumption was used for the final model to test the prerequisite to use a Cox regression model.

Results

Screening and inclusion into the study population

Screening excluded myocardial ischaemia ($n = 129$) and echocardiography at short term before index hospitalization ($n = 118$). Thirty patients were excluded after initial inclusion because of severe valvular pathology at index echocardiography; 34 patients were excluded because of severe non-cardiac pathology suspected to impact on short-term mortality. Five hundred five study participants were retained for the final analysis (cohort 2005–2009 and 2015–2018, $n = 311$ and $n = 194$, respectively).

Demographic, clinical, medical, and biological characteristics of acute heart failure patients without or with mild or moderate aortic regurgitation

The prevalence of mild or moderate AR was 42% (211/505) in this study population; 43% (216/505) were female; 52% (261/505) had a history of previous myocardial infarction.

AR patients were older (80.5 [74.2–85.7] vs. 77.8 [68.7–84.3] years; $P = 0.002$), the body mass index (BMI) was lower (25.8 [23.5–31.1] vs. 26.9 [24–31.6]; $P = 0.014$), and diabetes and smoking were less prevalent (62 [29.4%] vs. 133 [45.2%], $P < 0.001$; 103 [48.8%] vs. 173 [59%], $P = 0.023$). All other cardiovascular risk factors were not significantly different between groups (Table 1). Patients with AR were less frequently implanted with an internal cardiac defibrillator (8 [3.8%] vs. 25 [8.5%], $P = 0.035$), treated with statins (77 [36.7%] vs. 134 [45.7%], $P = 0.042$), oral antidiabetics (26 [12.4%] vs. 59 [20.1%], $P = 0.023$), or insulin (27 [12.9%] vs. 64 [21.8%], $P = 0.01$) (Table 1). The serum glucose level was lower at admission in patients without AR (6.8 [5.9–8.4] vs.

ACEI, angiotensin-converting enzyme inhibitor; AR, aortic regurgitation of mild or moderate severity; ARB, angiotensin receptor blocker; ARNI, angiotensin II receptor blocker neprilysin inhibitor; BMI, body mass index; COPD, chronic obstructive pulmonary disease; DBP, diastolic blood pressure; Hx of Afib/flutter, history of persistent/paroxysmal/permanent atrial fibrillation or flutter; Hx of HF, history of heart failure; Hx of MI, history of myocardial infarction; ICD, implantable cardioverter defibrillator; LADI, left atrium diameter index; LVEDDI, left ventricular end-diastolic diameter index; LVEF, left ventricular ejection fraction; LVMI, left ventricular mass index; MRA, mineralocorticoid receptor antagonist; SBP, systolic blood pressure.

7.4 [6.0–10.1] mmol/L, $P = 0.041$). Electrolytes, renal function, and haematological parameters were not significantly different between patients with or without AR (*Table 2*).

Echocardiographic characteristics of acute heart failure patients without or with mild or moderate aortic regurgitation

Patients with AR had a larger indexed LV end-diastolic diameter (LVEDD) (30 [27–34] vs. 28.2 [25–32] mm/m², $P = 0.004$); LV mass index was higher (120 [93–144] vs. 109 [86–132] g/m², $P = 0.004$). The prevalence of mild or moderate mitral regurgitation (MR) (91.4% [$n = 192$] vs. 76.5% [$n = 225$], $P < 0.001$) and tricuspid regurgitation (85.2% [$n = 178$] vs. 73.8% [$n = 217$], $P = 0.002$) was higher in patients with AR. Mild or moderate aortic stenosis with or without AR was not significantly different between both groups (14.7% [$n = 31$] vs. 15.0% [$n = 44$], $P = 0.932$) (*Table 3*).

Parameters associated with all-cause mortality in univariable Cox regression analysis

Parameters that were associated ACM over the study period ($P < 0.05$) were dyslipidaemia (HR 0.44 [0.29–0.67], $P < 0.001$), BMI per kg/m² (HR 0.92 [0.89–0.96], $P < 0.001$), systolic blood pressure at admission per mmHg (HR 0.99 [0.98–0.99], $P = 0.004$), age per year (HR 1.04 [1.01–1.06], $P = 0.002$), mild or moderate AR (HR 1.75 [1.15–2.66], $P = 0.009$), HFmrEF (HR 0.38 [0.18–0.82], $P = 0.013$ compared with HFrEF), pacemaker (HR 1.26 [1.08–3.2], $P = 0.025$), red cell distribution width per % (HR 1.08 [1.01–1.15], $P = 0.029$), mineralocorticoid receptor antagonist treatment (HR 1.71 [1.04–2.81], $P = 0.035$), LVMi per g/m² (HR 1.01 [1.00–1.01], $P = 0.037$), statin treatment (HR 0.62 [0.40–0.98], $P = 0.039$), and LVEDDi per mm/m² (HR 1.04 [1.00–1.08], $P = 0.040$) (*Table 4*).

AR, aortic regurgitation; RDW, red cell distribution width.

Kaplan–Meier estimates of survival in accordance to the type of heart failure

Figure S1 demonstrates that Kaplan–Meier estimates of survival differ significantly between the different types of HF with the best survival for patients with HFmrEF and lower survival for HFpEF and HFrEF patients ($P = 0.024$). *Figure S2* shows similar results when multivariable analysis and Cox Hazard proportional analysis were applied to picture survival.

Interaction of mild or moderate aortic regurgitation and type of heart failure on all-cause mortality over the study period using multivariable Cox regression analysis

ACM was higher in the group of AHF patients with AR (HR 1.75, [95% CI: 1.1–2.7], $P = 0.009$) despite the overall more favourable cardiovascular risk profile of this group. The final model of multivariable Cox regression analysis with mild or moderate AR as dependent variable included all variables of the univariable Cox regression that showed at least very weak evidence ($P < 0.2$) for an association with first, mild, or moderate AR, second, 150 days' ACM, and, third, type of HF (*Table 4*). There was no evidence for a violation of the proportional hazard assumption ($P = 0.369$). *Figure 1* illustrates the interaction of mild or moderate AR and the type of HF on ACM. The hazard of HFpEF patients without AR was used as reference. Within the HFpEF group, the presence of AR increased the HR significantly when compared with the absence of AR (HR: 2.17 [95% CI: 1.13–4.15], $P = 0.02$). Compared with the reference, we observed a more than twofold increased hazard in HFrEF without AR (HR: 2.55 [95% CI: 1.33–4.87], $P = 0.005$) and in HFrEF with AR (HR: 2.43 [95% CI 1.26–4.69], $P = 0.008$). The HR of HFmrEF patients without AR was not different to respective HFpEF patients (HR: 0.2 [95% CI: 0.03–1.52], $P = 0.874$), and presence of AR in HFmrEF patients showed a trend towards increased ACM in the HFmrEF group (HR: 7.11 [95% CI: 0.87–57.79], $P = 0.067$) (*Figure 1*).

Table 3 Echocardiographic characteristics of acute heart failure in patients with or without moderate aortic regurgitation

Tables S2 and S3 demonstrate demographics and clinical parameters in HFpEF patients with or without mild to moderate AR. HFpEF patients with mild to moderate AR had a higher prevalence of female gender (57 [66.3%] vs. 70 patients [49.6%, *P* = 0.014], while smoking (32 [37.2%] vs. 77 [55%] patients, *P* = 0.009) and diabetes mellitus (21 [24.4%] vs. 53 [37.6%] patients, *P* = 0.04) were less prevalent. Furthermore, diabetes was less often treated with insulin (9 [10.5%] vs. 31 [22%, *P* = 0.027]). Biological parameters were not significantly different between groups.

had mild or moderate AR.⁷ Although not providing definite proof of a pathophysiological role of mild to moderate AR, the increase of the prevalence of AR in parallel with the clinical severity of HF was nonetheless intriguing and the reason for the present study. In fact, 42% of study participants in this study had mild or moderate AR, which not only exceeds considerably the respective prevalence reported elsewhere^{2,3,7,17} but may suggest likewise that the prevalence of mild or moderate AR increases in parallel with the severity of HF.

Characteristics of the study population

The present study population included only 505 AHF patients; we, therefore, discuss first whether the basic characteristics of the study population such as portion of three HF types, gender, age, and mortality permit broader application of the study results.

A prominent characteristic of the present cohort is the 61% prevalence of participants with mid-range or preserved LVEF. In fact, the prevalence of AHF patients with LVEF ≥ 40% was lower in many previous AHF registries, in particular when these studies had recruited participants during the first years of the millennium.¹⁸ However, the more recent prospective, multicentre Kyoto Congestive Heart Failure (KCHF) registry, which had recruited AHF patients in the years 2014–2016, reported a similar proportion of AHF patients with LVEF ≥ 40% (61%).¹⁹ In addition, a similar proportion of AHF patients with LVEF ≥ 40% (62%) was reported from the Get With The Guidelines registry, which had recruited AHF patients in the years 2005–2010.²⁰ Of note, the number of AHF patients with LVEF ≥ 40% had progressively increased between 2005 and 2010 from 48% to 53% in the latter registry²¹; in addition, a similar trend had been reported for AHF admissions in the Olmsted county where the percentage of patients with preserved LVEF increased from 38% to 54% in the years 1986 to 2002.²²

With respect to gender distribution, the present study population is comparable with that of other AHF registries,¹⁸ and the 56% of female patients in the HFpEF group correspond to the female proportion reported in many HFpEF

Discussion

This study adds to the current knowledge in AHF that AR of mild or moderate severity is a determinant of short-term ACM in AHF patients with preserved LVEF. AR is highly prevalent in patients with preserved LVEF hospitalized for treatment of AHF, suggesting that efforts to reduce the clinical impact of AR have the potential to improve outcome in these patients.

Prevalence of aortic regurgitation and chronic heart failure in the general population and in heart failure populations

Mild to moderate AR is in general not regarded as a major clinical problem in patients with normal LVEF^{15,16} despite its high prevalence in the age groups > 70 years.^{2,3} HF is also highly prevalent in the elder age groups,⁴ making coincidental occurrence of HF with AR likely. In fact, mild or moderate AR was observed in 8.3% of ambulatory patients with HF symptoms in a community study involving 79.043 echocardiographic studies.¹⁷ Further evidence supporting a role of AR in HF derives from a retrospective population-level epidemiological study in Scotland, which showed that 25% of hospitalized patients with a diagnosis of AR had HF. The fact that only 3.3% of all these hospitalized AR cases had aortic valve replacement surgery suggests that the majority of the HF cases

studies.²³ Mean age was high in the present study population but not different to reports from the KCHF or the Get With The Guidelines registry^{19–21} although higher when compared with AHF registries in the past.¹⁸ However, patients with

LVEF < 40% were younger than patients with LVEF ≥ 40%, similar to other reports.²⁰ Of note, 30 and 90 days' mortality of the present study population correspond to results reported from Canadian Enhanced Feedback for Effective Cardiac Treatment (EFFECT) and OPTIMIZE-HF registry, respectively.²⁴ Last but not the least, the survival was best in HFmrEF patients but lower in HFpEF and HFrEF patients, corresponding to results reported from the Get With The Guidelines registry.²⁰ Altogether, this remarkable similarity of the characteristics of the present study population with other more contemporary AHF study cohorts suggests broad applicability of the results of the present study.

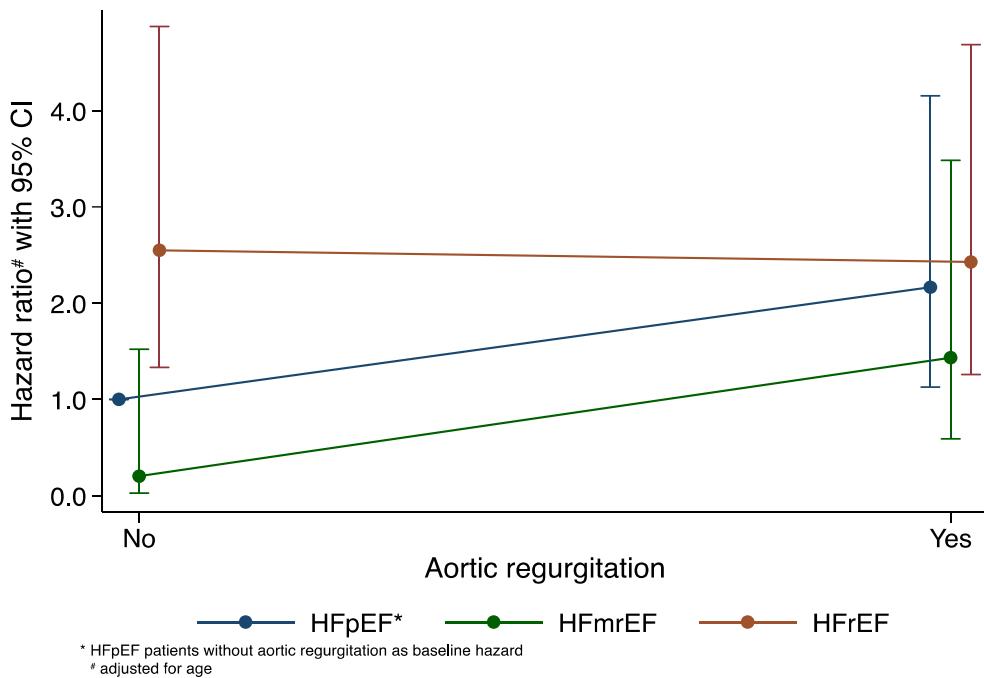

The role of aortic regurgitation for all-cause mortality in acute heart failure patients

AR was in our study population associated with an increased risk for ACM despite the short period of follow-up. This association was observed against the background of a more favourable cardiovascular risk profile of the AHF patients with AR who were less often smokers or diabetics. However, we did not observe the negative correlation between AR and diabetes that had been reported from the Strong Heart study.²⁵

AR furthermore remained independently related with ACM in AHF patients with preserved LVEF, raising the question of why AR is of prognostic relevance in AHF with preserved LVEF but not in AHF with either mid-range or reduced LVEF. HFpEF is characterized by disorder of muscular and hemodynamic processes affecting propagation of blood flow during early diastole of the left ventricle. In the study participants with preserved LVEF and AR, we observed a numerically higher left ventricular mass index and a numerically increased frequency of mild or moderate tricuspid regurgitation. This combination is compatible with an increased left ventricular end-diastolic pressure (LVEDP), suggesting that the small regurgitant volume of mild or moderate aortic valve insufficiency resulted in a disproportionate increase of the LVEDP in the small and stiff left ventricles of these patients. This effect may be even worsen left ventricular dysfunction volume when patients already suffer from increased volume charge resulting from mild or moderate MR. This pathophysiological concept can furthermore explain why the small regurgitant volume is of prognostic relevance in HFpEF patients but not in HFmrEF or HFrEF patients. In fact, their LV end-diastolic volume usually is larger, which should dampen the rise of the LVEDP with a small aortic regurgitant volume.

However, it is also important to note that even a small aortic regurgitant volume will result in a coronary steal with a subsequently reduced intracoronary blood flow. The coronary steal maybe of little relevance at rest but may nonetheless induce subendocardial hypoxia with exertion when the LVEDP increases disproportionately and the coronary

Figure 1 Illustration of the interaction of mild or moderate AR and type of heart failure on 150 days' ACM using multivariable Cox regression. The hazards in the different groups are compared with those of HFpEF without AR as baseline hazard. ACM, all-cause mortality; AR, aortic regurgitation; HFpEF, heart failure with preserved ejection fraction.

steal reduces the filling of the pre-existing pathological microcirculation of the HFpEF heart at the same time.²⁶

AR may furthermore disturb the diastolic vortex, which is a swirling structure responsible for entering a significant fraction of LV filling volume at no energetic or pressure cost. In the normal heart, the vortex is responsible for entering about 13% the filling volume, while this portion is reduced to 5% in hypertrophic cardiomyopathy.²⁷ Impaired generation of this swirling structure has also been shown in HFpEF,²⁸ and perturbation of the vortex function has been associated with increased cardiovascular mortality and rehospitalization.²⁹ Biomechanical models of the left ventricle have visualized that the regurgitant jet of mild or moderate AR impedes vortex formation as a function of its severity,³⁰ suggesting that already a small regurgitant volume should worsen the pre-existing pathologic vortex formation in patients with preserved LVEF. Support of this hypothesis derives from the observation that mild AR after transcatheter aortic valve replacement increased mortality in patients with a baseline LVEF of $50 \pm 13\%$ as reported from a series of patients operated at the Cleveland Clinic.³¹ Certainly, these patients do not represent the classical stable HF patient with preserved LVEF patient but nevertheless provide evidence that new mild or moderate AR significantly impacts on mortality within a time period of not even 3 years.

Therapeutic implications

Improvement of AHF patients with preserved LVEF and AR was associated with a decrease of systolic and diastolic blood pressure and reduction of heart rate in addition. More recently, independent association has been found between diastolic blood pressure or resting heart rate with mortality in chronic moderate to severe AR.³² This investigation showed that diastolic blood pressure < 70 mmHg and resting heart rate > 60 b.p.m. increased ACM. Corresponding studies are missing in AHF patients with mild to moderate AR but should be useful for guidance of therapeutic management of these patients. Careful monitoring of these parameters in the ambulatory setting may therefore prevent decompensation, in particular in AHFpEF patients with AR. Whether implantation of a hemodynamic monitoring device in the pulmonary circulation is an option if traditional surveillance fails warrants investigation.

Limitations

The relatively small study population and the mono-centric study design represent a methodological limitation with respect to the applicability of the study results. Nevertheless, study participants were recruited from consecutive patients

presenting to the emergency department, and key characteristics of the study participants are comparable with those of other AHF cohorts. Furthermore, the post-hoc study design did not allow for retrospective distinction of the cause of mortality in particular in those study participants followed up by the 2005–2009 cohort. However, the short-term follow-up and the careful exclusion of AHF patients with adverse prognosis related to co-morbidity suggests that case fatality was likely due to cardiovascular cause. In the acknowledgement of these limitations, the study results of this study remain therefore hypothesis generating.

Conclusions

The results of this study suggest that AR of mild or moderate severity is of prognostic relevance in patients with preserved LVEF and hospitalization for treatment of AHF. This observation merits attention because coincidence of AR and HF is frequent in the elderly. Therefore, better understanding of the interaction between AR and LV dysfunction in HFrEF patients is necessary and will help to reduce the negative impact of mild or moderate AR in these patients.
