

PRESENT AND FUTURE HIGH-ENERGY ACCELERATORS FOR NEUTRINO EXPERIMENTS

I. Kourbanis[#], FERMILAB*, Batavia, IL 60510, U.S.A.

Abstract

There is an active neutrino program making use of the high-energy (larger than 50 GeV) accelerators both in USA at Fermilab with NuMI and at CERN in Europe with CNGS. In this paper we will review the prospects for high intensity high energy beams in those two locations during the next decade.

THE CERN NEUTRINO PROGRAM

The CNGS neutrino beam has been optimized for the $\nu_\mu \rightarrow \nu_\tau$ appearance search. The beam protons from the SPS are extracted with energies of 400 GeV hitting a graphite target 830 m from SPS. After a magnetic horn system for focusing the pions, a decay pipe of 1000 m follows. The beam-line design was accomplished on the basis of the previous experience with the WANF beam at CERN SPS [1,2].

CERN Accelerator Complex

The CERN proton accelerators that are used for CNGS are shown in Fig. 1 and are:

- Linac 2
- Proton Synchrotron Booster-PSB
- Proton Synchrotron-PS
- Super Proton Synchrotron-SPS

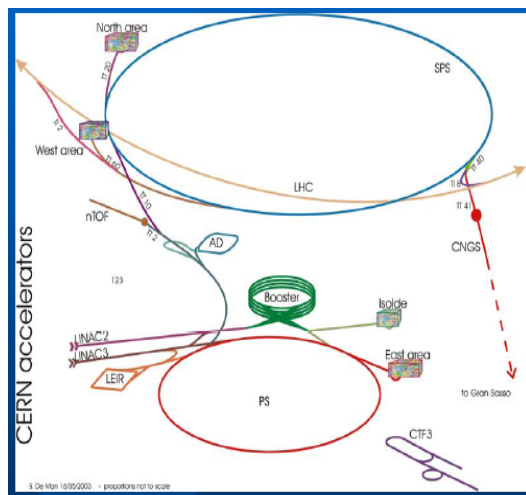

Figure 1: CERN Proton accelerators for CNGS.

The injection and extraction energies of the CERN proton accelerators along with their commissioning year are shown in Table 1 (from [3]).

Table 1: Table of the CERN accelerators used for CNGS with their inj./extr. energies and their year of commissioning

Accelerator	Inj. Kinetic Energy [GeV]	Ext. Kinetic Energy [GeV]	Commissioning year
Linac 2	0.00075	0.05	1979
PSB	0.05	1.4	1972
PS	1.4	13.1	1959
SPS	13.1	399.1	1976

As can be seen from table 1, most of the CERN proton accelerators are already more than 30 years old and are the same accelerators that are going to be used as LHC injectors. The nominal LHC beam has a much higher (x10) bunch intensity than the nominal CNGS beam but lower total beam intensity.

Accelerator Upgrades

In order to prepare for the high intensity LHC beam the CERN accelerator chain has been upgraded [4]. Some of the upgrades/modifications included:

- In the Booster acceleration at harmonic $h=1$ replaced the $h=5$ used in the past in order to help the coupled bunch instabilities.
- In the PS the injection energy was increased from 1 GeV to 1.4 GeV to reduce space charge tune spread.
- In the SPS the longitudinal impedance was greatly reduced by shielding 800 vacuum ports along with kickers and septa. This eliminated the microwave instability greatly reducing the longitudinal emittance blow-up during acceleration.
- The equipment used for leptons were removed from all machines. This included a 114 MHz RF system in the PS and three RF systems in the SPS.

High Intensity SPS operation for CNGS

In 2004, during a 3 week beam test a maximum intensity of $5.3E13$ protons was obtained at 400 GeV in a CNGS cycle. The main limitation for further intensity increase was the beam loss [4].

Typical beam intensities in the different machines are shown in Table 2. The beam intensity in the SPS along with the energy ramp is shown in Fig. 2. It takes two PS injections 1.2 sec apart to fill the SPS for CNGS. Unlike the LHC beam, this beam crosses transition energy, not only in the PS but also in the SPS.

Table 2: Beam transmission through CERN accelerator chain for the high intensity SPS run CNGS (From [4]).

Accelerator	Injected Intensity (E13)	Accelerated Intensity (E13)	Extracted Intensity (E13)	Acc. Eff. (%)
Booster	4.3	3.84	3.65	84.9
PS	3.57	3.42	3.15	88.2
SPS	3.0x2	5.7 after tr.	-----	
SPS	2.9x2	5.5 after tr.	5.3	91.3

With the present injectors, it was demonstrated that a maximum intensity of 3×10^{13} protons can be injected into the SPS every 1.2 sec. Taking into account beam losses, this could lead to a total intensity of 5.7×10^{13} protons at 400 GeV in the SPS. This corresponds to a beam power of 608 KW (assuming a 6 sec SPS cycle).

The present rf system in the SPS limits the beam intensity that can be accelerated to about 6×10^{13} protons/cycle. The CNGS target limits the SPS intensity to $2 \times 3.5 \times 10^{13}$ pot per 6 sec cycle (“ultimate intensity”).

Figure 2: Beam transmission in the SPS at the end of the high intensity run. The sharp loss during acceleration is happening during transition crossing.

Addressing the beam loss limitations

As it can be seen in Table 2 the overall efficiency for the record SPS intensities taking into account and the loss during transfers is about 62%. In order to be able to run at his high intensities the beam loss especially at the high energies must be minimized. The 3 most important losses along with proposed solutions are outlined below.

- Losses at extraction in the PS. Plan to reduce these losses by changing the present multi-turn extraction (transverse slicing of the PS beam in the horizontal plane by a thin electrostatic septum) with a novel scheme using resonant islands [6].
- Low energy losses in the SPS. Those losses happen at injection, at the injection front porch and during transition crossing. These losses will be reduced by opening the physical vertical aperture of the SPS, and

modifying the rf beam control to reduce transient beam loading during transition crossing.

- SPS extraction losses. The cause of these losses is beam in the extraction kicker gap. The beam in the gap is originated at injection due to the poor capture of the injected batches and the recapture of particles at the start of ramp. A new beam control for the separate capture of each batch and cleaning of the beam gap at low energy with the transverse damper is expected to greatly improve those losses.

Total number of protons with the present Injectors

The total number of protons to the CNGS target depends not only on the peak beam intensity but also on the beam availability and the beam sharing with other users. For 200 days (1.7×10^7 sec) of operation with 80% machine efficiency and with 45% of the SPS time available for CNGS, we obtain 5.9×10^{19} pot per year for an intensity of 5.7×10^{13} protons at 400 GeV. If no other user of the SPS is scheduled (except LHC) the SPS time available for SPS can be as high as 85% and the number of protons per year can be as high as 1.11×10^{20} . It should be noted here that the CNGS neutrino components were designed to tolerate up to 1.38×10^{20} pot for 5 years [5].

Proton flux for CNGS with new injectors

In order to maximize the LHC performance, most of the CERN injectors are to be replaced with new higher performance accelerators [5,7].

In the first stage, a new linac, Linac4 is built, injecting protons at 160 MeV thus halving the space charge effects in PSB.

In the second stage, the PS is replaced by PS2, a new 50 GeV synchrotron. The PS2 will be double the size of the PS and will be able to accelerate up to 1.1×10^{14} protons per pulse (3.6 sec). Because of the size of PS2 its injection energy has to be higher than 3.5 GeV so as an intermediate solution the PS will be used as an injector till a 3.5-4 GeV superconducting linac the SPL is built. This will limit PS2 performance because of space charge limitations in the PS and because of cycling and filling constraints between the two machines.

With the new injector PS2, the length of the SPS cycle for CNGS can be reduced to 4.8 sec. A total of 1.0×10^{14} protons can be accelerated to 400 GeV in the SPS for a total beam power of 1.3 MW. The total number of protons per year can reach 2.4×10^{20} pot assuming 85% SPS availability. A new rf system will be needed in the SPS to accelerate this beam intensity. It should also be noted that the CNGS facility will also need a re-design and a major rebuild.

The protons on the CNGS target for the different scenarios are shown in Table 3 [5]. For all the scenarios 200 days of operation with 80% machine availability is assumed.

Table 3: Protons on target per year (E19) to CNGS for different scenarios.

	SPS cycle length	6 sec		4.8 sec	
	Injection momentum	14 GeV		26 GeV	
	Beam sharing	0.45	0.85	0.45	0.85
	Max SPS Intensity @ 400 GeV (E13)				
Present injectors + machines' improvements	4.8-"Nominal CNGS"	5	9.4		
	5.7-"Max. SPS"	5.9	11.1		
Future injectors +SPS RF Upgrade	7-"Ultimate CNGS"			9	17.1
Future injectors +new SPS RF system + CNGS new equipment design	10-"Max. PS2"			12.9	24.5

THE FERMILAB NEUTRINO PROGRAM

The NuMI neutrino beam has been optimized for neutrino oscillations. The beam protons from Main Injector are extracted at 120 GeV hitting a graphite target 375 m away. The pions coming out of the target are focused with a system of two magnetic horns and decay in a 675 m long pipe. The pion focusing of NuMI can be optimized for 3 different neutrino energies by adjusting the locations of the second horn and target with respect to the first horn [8].

Fermilab Accelerator complex

The Fermilab proton accelerators that are currently used for NuMI are shown in Fig. 3 and are:

- Linac
- Booster accelerator
- Main Injector

There are also shown the two antiproton production and storage rings the Debuncher and the Accumulator along with the newest antiproton storage ring the Recycler. Those rings are to be re-configured at the end of the collider program in order to be used in the neutrino program.

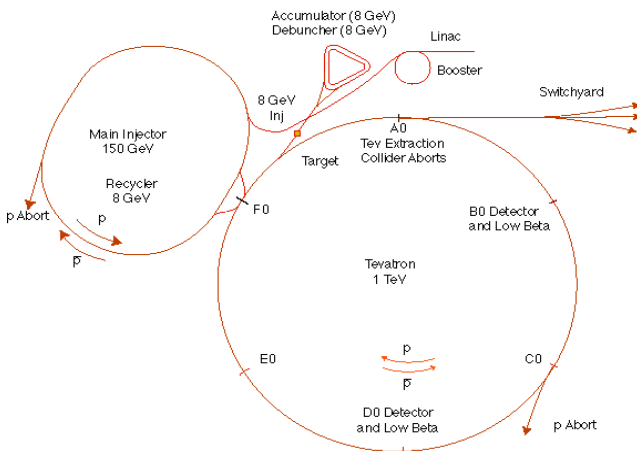

Figure 3: Fermilab Proton accelerators.

The Injection and extraction energies of the Fermilab accelerators along with their commissioning year are shown in Table 6. Except the Main Injector the Fermilab injectors are as old as the CERN accelerators. The high energy part of the linac was upgraded in 1993 raising the extraction energy to 400 MeV from 200 MeV. The Booster has been also upgraded with a collimation system and a new injection system.

Table 4: Table of the Fermilab accelerators used for NuMI with their injection/extraction energies and their year of commissioning.

Accelerator	Injection Kinetic Energy [GeV]	Extraction Kinetic Energy [GeV]	Commissioning year
Linac	0.025	0.4	1970
Booster	0.4	8	1971
Main Injector	8	119	1999
Recycler	8	8	2004
Debuncher/ Accumulator	8	8	1986

Current NuMI operation

The NuMI neutrino beam was commissioned in 2005. Since then more than 3.4×10^{20} protons have been delivered to the NuMI target.

In the current NuMI operation a total of 7 Booster batches are injected in Main Injector in a mixed mode cycle. First two batches are injected, slipped stacked and recaptured. Then 5 more Booster batches are injected and the whole beam is accelerated to 120 GeV. At 120 GeV the slipped stacked beam gets extracted first to the pbar target and then the 5 remaining Booster batches get extracted to the NuMI target. The total Main Injector intensity is around 3.3×10^{13} protons per cycle out of which 2.45×10^{13} go to the NuMI target. It should be noted that in this stage the repetition rate of the mixed mode cycle is not determined by the Main Injector cycle time (2.0 sec) but by the antiproton stacking requirements that limit the min. rep rate to 2.2 sec or larger.

For the proton projections to the NuMI target a total of 308 days (2.7×10^7 sec) of running a year is assumed with 61% overall efficiency (85% complex uptime, 90% average to peak correction and 80% NuMI uptime) to get 1.7×10^{20} protons per year.

Upgrades for higher neutrino power

All the Fermilab upgrades for higher neutrino power take advantage of the Main Injector capabilities:

- Large transverse acceptance ($40 \pi - \text{mm} - \text{mrad}$) and momentum aperture (1.7%).
- Fast cycle time (1.5 sec)
- RF system that can be upgraded to accelerate more beam power.

Three stages of upgrades are envisioned that are known as the “Proton Plan”, the “NOvA Project” and the “SNUMI”.

“Proton Plan”

In this first stage of upgrades expected to become operational in 2008, the Main Injector intensity to NuMI is increased by implementing slip stacking for the NuMI batches (multi-batch slip stacking). Ten Booster batches are slipped stacked in Main Injector into five double intensity ones and recaptured. After recapture an additional batch is injected and the whole beam is accelerated to 120 GeV. The Main Injector cycle time is increased to 2.2 sec because of the extra injections. The whole process is expected to be 95% efficient and assuming an intensity of 4.3×10^{12} protons per Booster batch, the total Main Injector intensity at 120 GeV is 4.5×10^{13} with 3.7×10^{13} protons delivered to NuMI target.

The beam power to NuMI will be increased to 320 KW and the total number of protons per year to the NuMI target to 2.8×10^{20} .

The multi-batch has been successfully demonstrated in Main Injector [9] where a record intensity of 4.6×10^{13} protons has been accelerated (Fig. 4). At this stage the managing of losses is the big challenge. A two stage collimation system has been specifically designed to localize the losses from un-captured beam during acceleration [10]. The distribution of losses around Main Injector with and without the collimators is shown in Fig. 5. The Main Injector bunch by bunch transverse dampers will be re-configured to work during slip stacking. These dampers will be also used to anti-damp any beam that would end up in the antiproton extraction kicker gap.

Figure 4: Beam intensity in Main Injector with multi-batch slip stacking.

Figure 5: Power loss distribution across Main Injector without (top) and with collimators (bottom).

The “NOvA Project”

In this stage planned to happen after the end of the collider run, the Recycler Ring is re-configured from an antiproton storage ring to a proton ring where the multi-batch slip stacking is taking place. Since all the beam will be extracted to NuMI up to twelve Booster batches can be slipped stacked in the Recycler. After slip stacking is complete the beam is transferred in the Main Injector where is accelerated to 120 GeV. The Main Injector cycle time is now reduced to 1.5 sec since most of the 8 GeV dwell time is eliminated. By installing two extra rf cavities (from spares) and upgrading the defocusing quad supply we can increase the maximum acceleration rate in the Main Injector ramp from 204 to 240 GeV/sec and reduce the cycle time to 1.33 sec. The beam intensity in the Main Injector is increased by only 9% to 4.9×10^{13} protons while the beam power and the protons per year to the NuMI target are increased by about a factor of 2 to 700 KW and 6.1×10^{20} respectively.

A couple of new injection lines need to be build, one from the Booster to the Recycler and one from Recycler to Main Injector. Five new kicker systems will also need to be build for Recycler that also include a gap clearing kicker. This kicker will be used to cleanly abort any beam that has leaked during slip stacking in the injection gap. A new 53MHz system will be required for slip stacking in Recycler.

The “SNUMI” plan

The number of Booster batches that is stacked in Recycler cannot be increased any more by using slip stacking because of the larger momentum aperture required and the beam losses. It has been proposed to use momentum stacking in the antiproton Accumulator in

order to further increase the intensity in Main Injector and to NuMI [11].

The steps in this multi-stage Proton Accumulator scheme are outlined below:

- Momentum stack in the Accumulator. For this step a Booster batch is injected at the high momentum orbit of the Accumulator every 67 msec. The new batch is decelerated towards the core orbit and gets merged with existing beam. After momentum stacking of 3 Booster batches the beam is captured and extracted to the Recycler.
- Box Car Stack in the Recycler. The Recycler gets loaded with a new Accumulator batch every 200 msec. A total of six Accumulator batches are placed sequentially around the Recycler.
- Load the Main Injector in a single turn.

The main advantages of the momentum stacking include:

- No transient beam loading effects
- Speed of the process
- Small longitudinal emittance dilution
- No need of transfer coggng in the Booster

For this stage two new beam lines will be needed, one to connect the Booster to Accumulator and another one to connect the Accumulator to the Recycler. Two 7.5 MHz rf systems will be needed, one in the Accumulator for recapturing the beam, and one in the Recycler for accepting the Accumulator beam. Before transferring the Recycler beam to the Main Injector the beam will be recaptured in 53 MHz using the rf system that was installed for slip stacking.

Assuming 4.7×10^{12} protons per Booster batch, the Main Injector intensity reaches 8.3×10^{13} protons and the beam power to NuMI the 1.2 MW. In order to accelerate this higher beam power a second power tube needs to be installed in each of the Main Injector cavities. The installation of a γ_i system in Main Injector is also planned. The protons per year to NuMI can reach 10×10^{20} . The SNuMI plan is currently at a conceptual stage and it is not yet officially supported.

The present and future scenarios for NuMI are summarized in Table 5. The upgrades of the NuMI facility required for all the above stages are outlined in [12].

Figure 4: Tracking simulation of the energy profile vs. time for momentum stacking three Booster batches.

Table 5: Present and future operating scenarios for NuMI.

	Present Conditions Multi-batch slip-stacking in MI	Proton Plan Multi-batch slip-stacking in MI	NOvA Multi-batch slip-stacking in Recycler	SNuMI Momentum Stacking in the Accumulator, boxcar stacking in Recycler
Booster intensity (protons/batch)	$4.3-4.5 \times 10^{12}$	4.3×10^{12}	4.3×10^{12}	4.7×10^{12}
No. Booster batches	7	11	12	18
MI cycle time (s)	2.4	2.2	1.333	1.333
MI intensity (ppp)	3.3×10^{13}	4.5×10^{13}	4.9×10^{13}	8.3×10^{13}
To anti-proton source (ppp)	8.8×10^{12}	8.2×10^{12}	0	0
To NuMI (ppp)	2.45×10^{13}	3.7×10^{13}	4.9×10^{13}	8.3×10^{13}
NuMI beam power (kW)	192	320	700	1200
PoT/yr to NuMI	2×10^{20}	3×10^{20}	6×10^{20}	10×10^{20}

CONCLUSIONS

There is an active program of upgrades to the high energy accelerators both at CERN and at Fermilab that will raise the beam power available to neutrino experiments to 1.2-1.3MW. The CERN upgrades depend on new injectors while the Fermilab ones depend on the Main Injector and reconfiguration of existing antiproton storage rings.
