

# Selective Segment Initialization: Exploiting NVRAM to Reduce Device Startup Latency

Myungsik Kim, Jinchul Shin, and Youjip Won

**Abstract**—We propose Selective Segment Initialization (SSI) to exploit NVRAM to reduce the device startup latency. SSI locates a kernel binary image in byte-addressable NVRAM and boots the system using this image, eliminating the need to load it from storage. SSI also eliminates the process of decompressing and relocating the OS kernel image in embedded linux system. The key technical ingredients of SSI are precisely identifying the kernel segments where contents are updated in the course of booting and selectively reloading only these sections each time the system reboots. The fresh copy of the sections can be maintained in NVRAM, NAND flash, NOR flash, etc. SSI reduced the size of the kernel binary image loaded from storage into memory by 90% and reduced the overall device startup time by 54%. This approach can be used not only for cold boot (with NVRAM) but also for warm boot, in which the contents of DRAM persist across the system restart.

**Index Terms**—Selective Segment Initialization, Nonvolatile Random Access Memory (NVRAM), Fast boot, Embedded Linux.

## I. INTRODUCTION

REDUCING boot-up time is of critical concern for modern embedded devices. This work exploits byte-addressable NVRAM to reduce the startup latency of modern embedded devices, e.g., smartphones and smart TVs. The recent advancement of NVRAM opens up new avenues for improving the performance [1] and reliability [2] of computing devices. Adopting byte-addressable NVRAM, e.g., FRAM, STT-MRAM, and Phase-Change RAM, makes it possible to provide finer access granularity in existing block devices [3] and to provide persistence in existing memory subsystems [4]. This study focuses on reducing the startup latency using NVRAM, a newly emerging memory device. The key technical ingredient in this approach is the handling of the kernel's writable sections. In legacy computing paradigm, some sections are implicitly initialized by the loader, e.g., the data section (.data), and some sections are explicitly initialized by the program itself, e.g., global variables with initial values (.bss). Since most sections of a kernel image are read-only, locating the kernel image in the byte-addressable NVRAM would eliminate the process of loading and relocating the kernel binary image.

This work is sponsored by IT R&D program MKE/KEIT (No.10041608, Embedded system Software for New-memory based Smart Device).

Manuscript received October 11, 2013.

When the kernel image resides in NVRAM, the state of each segment will persist and when segments maintain their data in a persistent manner, the kernel reboots with its variables retaining their previous values, the system can enter an undefined state, eventually causing deadlock or some other malfunction. This study identifies the segments that have been “implicitly” initialized in the legacy startup phase and develops a technique called “Selective Segment Initialization (SSI)” to explicitly initialize only those segments. In SSI method, a clean copy of the morphable sections is maintained separately. When booting, the SSI overwrites the morphable segments with their clean copies, bypassing the OS kernel loading process. This approach eliminates the process of loading and decompressing the kernel image while maintaining the contents of the NVRAM during startup.

## II. RELATED WORK

There are a number of approaches for reducing the startup latency of computing devices [5]. Snapshot retains a dump image of memory in the device's storage and loads this image during startup to initialize the device [6]. The problem comes from snapshotting size that the more large size of memory dumps to storage, the more time is needed for snapshot.

Execute-In-Place (XIP) is a technique that eliminates the time required to load a binary image from storage by locating it in byte-readable non-volatile memory (e.g., NOR flash) and executing it directly from that location. XIP boot executes the program directly from where it is stored, reducing boot-up latency. However, while this approach reduces startup time, the overall performance of the OS decreases due to the lower speed of NOR compared to DRAM. In addition, NOR flash cannot supply sufficient size compared to NAND in same cost. Kexec is a rebooting technique whereby the operating system directly reloads the kernel image, bypassing the hardware initialization process [7]. It is widely used in kernel upgrade.

Recently, a number of techniques have been proposed for reducing the startup time of embedded devices. Jo et al. applied snapshot booting to Smart TVs [8]. They proposed to execute two sets of tasks in booting concurrently so that tasks with different resource consumption characteristics are executed in parallel [9]. Baik et al. categorized snapshot images for Smart TVs into two groups: the essential-snapshot-image, which is required to initialize the device, and the add-on-image, which can be loaded on demand [10]. SSI complements the existing efforts. None of the existing works distinguishes the read/write characteristics of individual kernel segments nor treats them differently for NVRAM.

### III. BACKGROUND

#### A. Starting Up a Device : Hardware Initialization

The system boot-up process in embedded systems consists of switching the power on, loading the boot loader, loading the OS kernel from storage, and transferring control to the kernel. Fig. 1 illustrates booting process of mobile SoC, where boot loader and kernel are stored in NAND flash. First, the micro boot loader (U-Boot\_BL1) at NAND flash is loaded into ms (Fig. 1(a)). The built-in 32 KB internal ROM code (BL0), downloads the code from the initial 16 KB of NAND into the internal RAM when selected NAND boot mode. The micro boot loader is required because the internal RAM is too small (96 KB) to accommodate the entire boot loader. The micro boot loader then fetches the main body of the U-Boot code into DRAM (Fig. 1(b)). Afterwards, the main boot loader initializes the hardware to loads the kernel into DRAM (Fig. 1(c)).

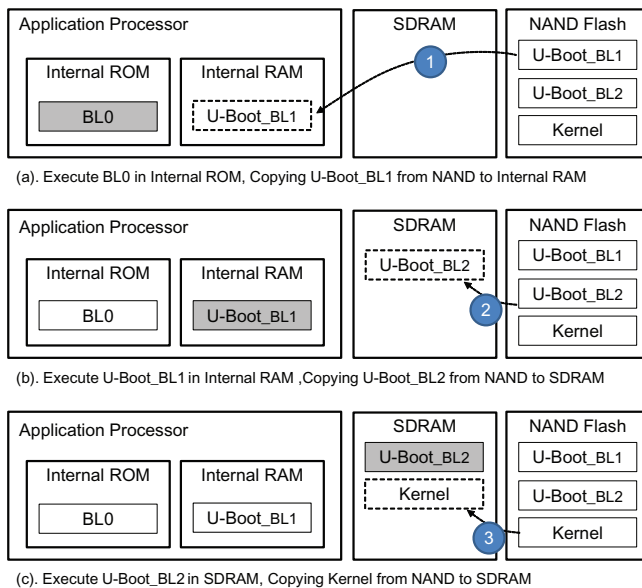

Fig. 1. Image Copying Phase of Boot-up Process in Mobile SoC

#### B. Loading the Kernel Image

When the boot loader finishes initializing the hardware, it loads the OS kernel image into memory. For an embedded system, a binary image of the Linux kernel is normally stored in compressed form, named zImage. Fig. 2 shows the structure of a compressed kernel which consists of three components: piggy.gz, misc.o and head.o. piggy.gz is the compressed binary image of the OS kernel, misc.o is the decompression module that is used to decompress piggy.gz, and head.o contains initialization instructions at boot-up time. To boot the kernel, the compressed image is first loaded into main memory by the boot loader. Control is then passed to head.o, which initializes the CPU. misc.o decompresses the kernel binary image, piggy.gz. The decompressed kernel image is then relocated to the appropriate memory address. At this point, control passes to the relocated kernel, which then initializes kernel objects, loads device drivers for various devices, initializes peripherals, and starts the user service.

Fig. 2. Making Compressed Kernel Binary from Executable Kernel Image

### IV. SELECTIVE SEGMENT INITIALIZATION

#### A. Motivation

Over time, it is generally accepted that NOR flash is used for code fetching memory in lightweight embedded systems. NOR-XIP is a suitable solution for microcontrollers because it requires a small amount of RAM with a simple memory model [11]. But NOR flash has a performance drawback, which is slow access time compared to DRAM. Therefore, a modern embedded Linux system exploits Store and Download (SnD) method with NAND (or eMMC) and DRAM instead of NOR-XIP. SnD models use a compressed image to minimize a footprint of a program in a storage system, so it needs steps for image loading and decompression when booting. SnD is able to provide faster instruction fetching speeds because the program codes reside in DRAM, called “shadowing”. Byte-addressable NVRAM, which can harbor data in a persistent manner with access latency comparable to that of DRAM, but NVRAM is also an emerging technology that may be difficult to be replaced by DRAM in short periods of time. Therefore, this study explores a compromise on booting schemes even if they change DRAM to NVRAM, still having the benefit of the SnD model. A new scheme follows suit with the conventional SnD method without significantly changing the memory organization to maximize usability. In this case, we can use the benefits of SnD methods such as memory space saving using compressed images and data integrity checking by decompression. The objective of this work is to relocate the kernel image to byte-addressable NVRAM and to reuse the relocated kernel image. Thus, we eliminate the overhead of loading, decompressing, and relocating the OS kernel.

#### B. Problem Assessment

While maintaining the kernel binary image in NVRAM and eliminating a significant fraction of the entire booting procedure such as loading, it raises new issues that require elaborate treatment. In legacy booting procedures, some kernel sections are implicitly initialized when the OS is loaded from storage. If the kernel is maintained persistently in NVRAM and removes loading steps at warm-boot procedures, these sections are initialized only when the OS is loaded from the storage to NVRAM. In subsequent warm-booting, the OS kernel starts to execute from the previously stored state of these sections. This may lead the system to enter an undefined state.

Fig. 3 illustrates this situation, in which `lock` is a global variable used to protect the critical section. It resides in `.data`

and is initialized to 0 at compile time. When the kernel is loaded into memory for the first time and `lock` equals 0, the program exits a while loop controlled by this logical value. As the kernel executes, it eventually sets the value of `lock` to 1. If the kernel is restarted when the `lock` variable in NVRAM retains the value of 1, the boot process will not be able to exit the while loop.

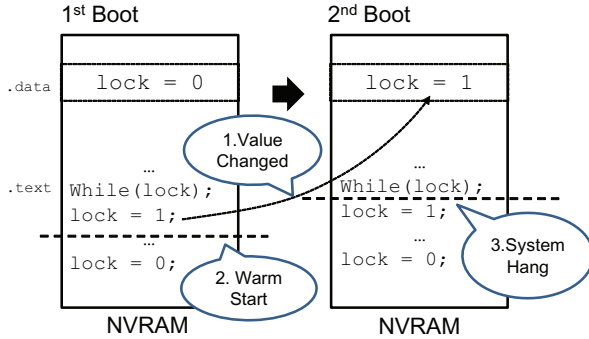

Fig. 3. An Example of Boot Failure in NVRAM

### C. Identifying Reusable Kernel Segments

One of the key ingredients of SSI is to determine the reusability of individual sections. We analyze the ELF image of a Linux kernel. Based on the analysis, we determine which portion of memory address in NVRAM needs to be reset and which portion of memory addressed in NVRAM can be re-used. `objdump` was used to analyze the section organization of the kernel image. Table I shows the result that all sections are read-only except `.init`, `.data`, and `.bss`. `.init.rodata` contains the constant variables used for the OS kernel initialization. A separate section (`.bss`) contains global and static variables and a code segment that explicitly initializes these variables. SSI uses the section map to partition the kernel image and to determine the location (DRAM vs. NVRAM) of the individual sections.

TABLE I  
SECTION ANALYSIS OF THE KERNEL IMAGE

Section	Attributes	Address (Hex)	Size (KB)
<code>.text.head</code>	CONTENTS, ALLOC, LOAD, <b>READONLY</b> , CODE	c0008000	1.0
<code>.init</code>	CONTENTS, ALLOC, LOAD, CODE	c00083e0	167.0
<code>.text</code>	CONTENTS, ALLOC, LOAD, <b>READONLY</b> , CODE	c0032000	5008.2

<code>.bss</code>	ALLOC	c0557140	248.2

### D. Selective Segment Initialization

The legacy computing paradigm separates the notion of “memory” and “storage” and explicitly defines the tasks to be done in the “loading” phase, e.g. initialization of a certain section. Compiler generates the binary so that a certain section of the image is initialized each time it is loaded from storage to memory. However, when “load” phase does not exist,

modification is needed in all or some of compiler, linker, loader and operating system for ELF based binary file to be still legitimate. Important constraint is to minimize the chances in the existing software development tools, e.g. compiler, loader, linker and OS to use NVRAM to harbor OS kernel. In this work, we identify the sections in ELF which cannot be re-used and to explicitly initialize these sections each time the OS kernel starts. We call this technique Selective Segment Initialization (SSI). A clean copy of each morphable section can be stored in byte addressable NVRAM, or in block device, e.g. NAND based storage. In booting with SSI, we identify the sections with read/write (RW) permission; maintain the clean copy of RW sections in separate location, and load (or initialize) only the RW sections. When the clean copy of RO sections remain in NVRAM, boot loader loads only RW sections and therefore significantly reduces the time to load, decompress and relocate the whole kernel segments. This work can be used not only in NVRAM enabled systems but also in legacy DRAM systems where DRAM contents remain at warm boot session.

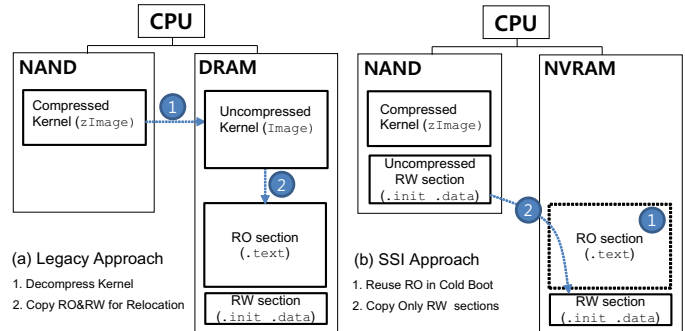

Fig. 4. The Difference of Startup Procedure between Legacy and SSI Boot

Fig. 4 shows the difference of startup procedure between legacy and SSI approach. In SSI restart, a fresh version of `.data` and `.init` sections are explicitly initialized each time when the OS kernel restarts. According to our experiment, the compressed image of the OS kernel is 3,420 KB, whereas the combined size of the `.init` and `.data` sections corresponds to only 357 KB. Thus, SSI can reduce the amount of data to be loaded from NAND storage to 1/10.

## V. IMPLEMENTATION & EXPERIMENT

### A. Implementation of Dual Mode Booting

At startup, the boot loader decides whether to “Cold Boot” or “SSI Boot”. Cold boot occurs if it is explicitly chosen or if a kernel image does not exist in NVRAM. The start address and the size information are verified by examining the location of the symbols in each section. SSI boot uses the uncompressed `.data` and `.init` sections and links them with the existing kernel sections in memory. SSI can also be used in soft-reset of commodity smartphones. For this approach, a hot-key for soft-reset and dedicated device driver for SSI Boot were developed in an existing smartphone platform. Pseudocode 1 shows the implementation of SSI boot function. For cold boot, the entire kernel image is loaded from storage into memory and is

initialized. When SSI boot, the copying and decompressing of kernel image phases can be eliminated by maintaining a kernel image in NVRAM. When a reboot is triggered during the booting process or when the kernel reboots due to a system crash, the boot loader is set to perform a cold boot.

### Pseudocode 1 Dual Mode Booting for SSI Boot

```

1: Start U-Boot
2: if Reset Status == Power Reset then                                ▷ Cold Boot mode
3:   Copy compressed kernel image (zImage)
4:   Decompress kernel image
5: else                                                                ▷ SSI Boot mode, Reset Status == Soft Reset
6:   Copy uncompressed RW section (.init,.data)
7: end if
8: Start kernel_start()

```

Evaluation was conducted in a smartphone development board with mobile SoC. S5PC100 mobile SoC which has ARM Cortex-A8 core at 667MHz, 128 MB of NAND flash, and 512 MB of DDR2-SDRAM are included. We implemented SSI Boot scheme into the U-Boot firmware at early boot stage on Linux kernel 2.6.29. For SSI enabled booting, the modified U-Boot loads the clean copies of `.init` and `.data` sections from NAND flash memory and overwrites the respective sections with the clean version to NVRAM. The read-only sections and the `.bss` section, which have explicit initialization mechanisms, are reused. We use software reset and SDRAM to emulate NVRAM. When the software reset is pressed, the SSI enabled boot loader executes the kernel image in NVRAM(emulated with SDRAM) after it initializes the `.data` and `.init` sections. The software reset was implemented by the GPIO device driver. If the reset button is pressed, the button driver will generate the software reset by writing `0xc100` at `SWRESET` register. When the software reset is triggered, the Program Counter jumps to the system reset vector and U-Boot firmware starts. U-Boot was modified to identify the type of booting. If the reset is a power-on-reset, U-Boot will load the full kernel image. Otherwise, U-Boot will load only the `.data` and `.init` sections. The time spent at each boot stage was measured by the internal PWM timer no. 3 in mobile SoC. The PWM timer was initialized with 1 ms resolution at the beginning of the U-Boot. It measured the time without running U-Boot or kernel debug service.

### B. Results

The size of the compressed kernel image (zImage) was 3164 KB. The total size of morphable segments (`.data` and `.init`) corresponded to 339 KB. With SSI, the amount of data loaded from storage decreases by 89% from 3164 KB to 339 KB. Table II and Fig. 5 shows the system boot times for cold boot and SSI boot. The time was measured from power-on to the end of the boot script. As a result, boot time decreased by 54%. The time for U-Boot was the same for cold boot and SSI boot. The time for loading the kernel image was 1,459 ms and 175 ms for cold boot and SSI boot, respectively. SSI reduced the kernel copying time to by reusing read-only sections that previously resided in NVRAM. In addition, SSI boot does not needed the kernel decompression time.

TABLE II  
TIME MEASUREMENT OF KERNEL BOOT

Step	Cold Boot	SSI Boot
Boot loader (U-boot)	402 ms	402 ms
Kernel Copy	1459 ms	175 ms
Kernel Decompression	491 ms	0 ms
Kernel Init	1540 ms	1540 ms
Total Time	3892 ms	2117 ms
Time Reduction in %	N/A	54%

Fig. 5. Comparison of Startup Time in Cold Boot and SSI Boot

## VI. CONCLUSION

A new startup mechanism, called Selective Segment Initialization (SSI), was proposed to exploit byte-addressable NVRAM to improve the device start-up latency. In SSI, reusable kernel sections are maintained in NVRAM and morphable kernel sections are selectively initialized in an explicit manner. This approach enables the legacy system to exploit the non-volatility of byte-addressable NVRAM without significantly modifying the existing software stack. We implemented SSI in an existing smartphone platform and achieved 54% reduction in overall startup latency of linux kernel.
