## Abstract

The aim of present work is to study the effect of VC and/or Cr<sub>2</sub>C<sub>3</sub> in densification, microstructural development and mechanical behavior of nanocrystalline WC-12wt.%Co powders when they are sintered by spark plasma sintering (SPS) and hot isostatic pressing (HIP). The results were compared to those corresponding to conventional sintering in vacuum. The density, microstructure, X-ray diffraction, hardness and fracture toughness of the sintered materials were evaluated. Materials prepared by SPS exhibits full densification at lower temperature (1100 °C) and a shorter stay time (5 min), allowing the grain growth control. However, the effect of the inhibitors during SPS process is considerably lower than in conventional sintering. Materials prepared by HIP at 1100 °C and 30 min present full densification and a better control of microstructure in the presence of VC. The added amount of VC allows obtaining homogeneous microstructures with an average grain size of 120 nm. The hardness and fracture toughness values obtained were about 2100 HV<sub>30</sub> and close to 10 MPa m<sup>1/2</sup>, respectively.

**Keywords:** WC–Co cemented carbides; nanocrystalline powders; grain growth inhibitors; SPS; HIP.

## Introduction

WC-Co hardmetals are widely used as cutting tools and dies due to their high wear resistance and toughness [1-3]. Manufacturing WC-Co cemented carbides with fine grain size even nanometer scale is a good method to improve its properties. As an example, hardness and strength of WC-Co hardmetals can be improved by decreasing the WC grain size to the nanometer scale. However, the production of bulk

1 nanocrystalline (grain sizes <100 nm) cemented tungsten carbide remains a  
2 technological challenge because of their fast grain growth during sintering.  
3

4  
5 The consolidation of nanostructured WC-Co powder has been studied using a variety of  
6 techniques including the standard liquid phase sintering (LPS) [4-9], hot isostatic  
7 pressing (HIP) [10], unconventional processes such as microwave sintering [11,12] and  
8 spark plasma sintering (SPS) [13-18], high frequency induction-heated sintering  
9 (HFIHS) [19-21], rapid omni compaction (ROC) [22], pulse plasma sintering (PPS) [23]  
10 and ultrahigh pressure rapid hot consolidation (UPRC) [24]. Due to the high  
11 temperature during sintering, grain growth occurs very quickly and it explains that the  
12 finest average grain sizes of sintered WC-Co reported in the literature up to date, using  
13 nanograined powders, is around 200-300 nm. Considerable efforts have been dedicated  
14 to study the densification and grain growth control during sintering of the nanosized  
15 WC-Co powders in order to achieve the goal of obtaining fully dense nanostructured  
16 WC-Co materials.  
17

18 One of the keys for controlling the grain growth of WC-Co composites is a suitable  
19 selection of additives as grain growth inhibitors. Vanadium carbide (VC) and chromium  
20 carbide ( $\text{Cr}_3\text{C}_2$ ) are the most effective grain growth inhibitors for this system thanks to  
21 their high solubility and mobility in cobalt phase at low temperatures [25-27].  
22

23 Moreover, the grain growth can be inhibited by using special sintering technologies  
24 allowing very high heating rates, increasing the densification rate, even at lower  
25 sintering temperature and shorter holding times, such as microwave sintering [28], rapid  
26 hot pressing sintering [12,29], spark plasma sintering (SPS) [30], and so on. In this  
27 sense, spark plasma sintering, that is also known as pulse electric current sintering  
28

1 (PECS), is a newly developed sintering method, which enables a powder compact to be  
2 sintered by passing high pulsed electric current through the compact. It has been  
3  
4 successfully used for composites, functionally graded materials and nanocrystalline  
5  
6 materials. It is therefore highly interesting to investigate the effect of grain growth  
7  
8 inhibitors on the WC grain growth and its mechanical properties when they are  
9  
10 combined with the use of PECS sintering technique [31].  
11  
12  
13  
14

15 In this paper, nanocrystalline WC-Co powders with different additions of VC/Cr<sub>3</sub>C<sub>2</sub>  
16  
17 inhibitors were fully densified by SPS and HIP sintering methods at 1100 °C. The effect  
18  
19 of the amount of inhibitor in the density, microstructure, hardness and fracture  
20  
21 toughness were investigated and compared with conventional sintering in vacuum at  
22  
23 1400 °C.  
24  
25  
26  
27

## 28 **Experimental procedure**

29  
30 The mixture used in this work was nanocrystalline WC-12Co powders with WC particle  
31  
32 size of 30-80 nm, manufactured by Inframat Advanced Materials. The appropriate  
33  
34 amounts of vanadium carbide (VC) and chromium carbide (Cr<sub>2</sub>C<sub>3</sub>) were added to the  
35  
36 raw powders, which were used as grain growth inhibitors. Free Carbon was added to all  
37  
38 compositions in order to adjust final C content in the sintered samples. Designation and  
39  
40 compositions of the final powder mixtures are shown in Table 1.  
41  
42  
43  
44  
45  
46

47 The mixtures were milled for 2 h in a Fritsch Pulverisette 7 planetary ball mill using  
48  
49 isopropyl alcohol as the liquid medium and under protective Argon atmosphere. The  
50  
51 ball-to-powder weight ratio was 10:1 and the rotation speed was 700 rpm. 2.5 wt.% of  
52  
53 polyethylene glycol (PEG 1500) was used as organic binder in the mixtures  
54  
55  
56  
57  
58

64  
65

1 consolidated by HIP and vacuum. After wet milling, powder mixes were dried at 110 °C  
2 during 2 h under Argon atmosphere.  
3

4  
5 SPS sintering: The powder samples were placed into a graphite die with an inner  
6 diameter of 20 mm and cold uniaxially pressed at 30 MPa. Then, they were introduced  
7 in a spark plasma sintering apparatus HP D 25/1 (FCT System) under low vacuum (10-1  
8 mbar) and sintered at 1100 °C for 5 min under an applied pressure of 80 MPa and a  
9 heating rate of 100 °C min<sup>-1</sup>.

14  
15  
16  
17

18  
19 HIP and vacuum sintering: Green compacts were prepared by uniaxial pressing at 200  
20 MPa into a matrix with an inner diameter of 5 mm and were consolidated by two routes:  
21 vacuum sintering at 1400 °C for 30 minutes (heating rate of 10 °C min<sup>-1</sup>), in a high  
22 vacuum Carbolite furnace (VS: 10<sup>-4</sup> mbar), and glass-encapsulated HIPing (GEHIP) at  
23 1100 °C for 30 minutes and 120 MPa pressure (heating rate of 30 °C min<sup>-1</sup>) using a HIP  
24 2000 EPSI N.V system. In the two sintering routes, a previous step where the organic  
25 binder is burned out in a vacuum furnace at 450 °C for 60 minutes (heating rate of 3 °C  
26 min<sup>-1</sup>) was included.

39 Powders morphology and microstructures of the sintered materials have been  
40 characterized by field emission scanning electron microscopy (FESEM). The  
41 consolidated materials densities were measured following the Archimedes' method with  
42 ethanol immersion, according to ISO 3369 standard. The porosity has been analyzed by  
43 quantitative metallographic of polished surfaces according to ISO 4505 standard, where  
44 A00, A02, A04, A06 codes correspond to 0.02, 0.06, 0.2, 0.6 vol.% porosity,  
45 respectively (for pore sizes below 10 microns). Similar codes are assigned to B type  
46 porosity (pores in the range of 10-25 microns). The WC grain size was measured using  
47  
48

1 two methods: lineal intercept method, following standard ASTM E112 and image  
2 analysis Image-Pro Plus software that also allowed obtaining grain size distributions.  
3

4  
5 Vickers hardness measurements have been carried out applying a load of 30 kg,  
6 according to standard ASTM E92-72. Indentation fracture toughness  $K_{IC}$  has been  
7  
8 estimated by applying the Palmqvist model to cracks generated by indentation, using the  
9  
10 Shetty equation [32]. For the study of crystalline phases X-ray diffraction (XRD)  
11  
12 technique was used (Bruker Theta model D8 advance apparatus, fitted with a Cu  
13  
14 filament). Scanning range ( $2\theta$ ) was varied from  $20^\circ$  to  $90^\circ$  and ICDD PDF-2 (2004)  
15  
16 database was used for phase identification. The XRD analysis was carried out on the  
17  
18 section perpendicular to uniaxial pressed direction.

## 26 **Results and discussion**

27  
28 Figure 1 shows FESEM images of the general morphology of nanocrystalline WC-12Co  
29  
30 commercial powders. In these photographs, it can be seen that although the powders are  
31  
32 forming agglomerates with an average size around 500 nm (Figure 1a), the WC average  
33  
34 grain size in the WC-12Co mixture is around 30-80 nm (Figure 1b).  
35  
36  
37  
38

39  
40 Once the powders are put into the mould it is important to have information about the  
41  
42 shrinkage of the sample. In the case of SPS sintering, this information can be obtained  
43  
44 from the expansion or contraction of the system during the cycle. The evolution of  
45  
46 displacement (piston travel) in function of time, pressure and temperature during SPS  
47  
48 cycle for the three compositions studied is shown in Figure 2. None of the curves shows  
49  
50 an expansion in the compact, so in contrast with Cha et al. [30] has reported, there is no  
51  
52 evidence of the formation of liquid phase during the sintering.  
53  
54  
55  
56  
57  
58  
59

1 The addition of inhibitors does not significantly affect the contraction experimented  
2 during the SPS cycles. Only the mixture with VC added exhibited a delay in the  
3 displacement curve in comparison with the composition without additives. However,  
4 the maximum difference does not exceed 3%. It can be noted that more than 50% of the  
5 displacement happens during the pressure step until the maximum pressure is applied  
6 (80 MPa). It is in the second part of the heating step, from 650 to 1100 °C, where it can  
7 be distinguished the differences in their behaviour. From this results, a more difficult  
8 densification for the sample with VC as assistive can be expected.  
9

10  
11 The relative density, porosity and WC average grain size of the mixtures fabricated by  
12 SPS, HIP and vacuum are shown in Table 2. Materials consolidated by SPS and HIP  
13 present a higher relative density compared with that obtained by vacuum, even if the  
14 final sintering temperature is considerable lower. This revealed the effectiveness of both  
15 pressure assisted sintering techniques, SPS and HIP, in the solid state densification. This  
16 good densification results obtained for all the compositions tested in this work confirm  
17 that the selected consolidation temperature was correct for allowing the plastic flow of  
18 cobalt under pressure. This binder plastic deformation, leading to rearrangement of WC  
19 nanograins and diffusion phenomena, are the fundamental mechanisms considered for  
20 densification in the absence of liquid phase [10].  
21  
22

23  
24 Materials without inhibitors (N) consolidated by SPS and HIP are fully densified, while  
25 all the samples with additives show a low residual porosity, more pronounced in the  
26 materials with VC (NV). This result is agreed with the behaviour observed during SPS  
27 sintering. The incomplete densification in the solid state by inhibitors effect is  
28 associated with the limitation of the diffusion phenomena and migration of Co [5].  
29  
30 However, density values obtained by the SPS technique are much higher than those  
31  
32  
33  
34

61  
62  
63  
64  
65

1 observed in the literature [15, 33, 34]. This is probably due to smaller particle size and  
2 increased pressure used during sintering process. If the particle size is smaller, the  
3  
4 increase in surface area allows the diffusion phenomena in a higher degree and the final  
5  
6 density is closer to the theoretical value.  
7  
8  
9

10 XRD results show no evidence of  $\eta$  phase ( $\text{Co}_3\text{W}_3\text{C}$  or  $\text{Co}_6\text{W}_6\text{C}$ ) formation in any of the  
11  
12 compositions sintered by the three consolidation techniques. The absence of secondary  
13  
14 phases confirms the efficacy of the addition of free carbon on the carbon content control  
15  
16 of the material sintered in solid phase, even by rapid sintering processes. Figure 3 shows  
17  
18 the XRD pattern of the NV composition after consolidation. It can be noted the peak  
19  
20 height of WC (0001) plane in the material sintered by SPS is higher than in the samples  
21  
22 obtained by other two processes. This indicates a certain degree of orientation of WC  
23  
24 grains in the materials sintered by SPS, with a preference orientation of (0001) crystal  
25  
26 planes perpendicular to uniaxial pressed direction.  
27  
28  
29  
30  
31  
32

33 The microstructure of materials consolidated by SPS and HIP can be observed in Figure  
34  
35 4. In both processes, a microstructural inhomogeneity can be appreciated, which is  
36  
37 typical for the solid phase sintering, with Co segregations and lack of wettability. This  
38  
39 fact improves the interactions between carbides, promoting coalescence phenomena that  
40  
41 are responsible for the grain growth [35,36].  
42  
43  
44  
45

46 In the absence of inhibitors, the SPS technique has allowed obtaining materials with the  
47  
48 finest microstructure. This is due to the combination of low sintering temperature,  
49  
50 similar to HIP process and a very short processing time. These are the optimal  
51  
52 conditions for limiting grain growth if we consider that no additives are being used,  
53  
54 because high temperature for liquid formation is avoided and long time that promotes  
55  
56  
57  
58  
59

1 grain growth are suppressed. Nevertheless, in these conditions, densification would be  
2 also hindered. The near full density SPS samples obtained reveal that under the suitable  
3 experimental conditions densification without grain growth can be reached. The  
4 inhibitors addition, especially VC, has been clearly demonstrated as an effective method  
5 for controlling the grain growth during WC sintering. In this work this strategy has been  
6 employed for SPS and HIP sintering techniques in order to combine the additives effect  
7 with low sintering temperature. The efficiency of both inhibitors is more significant in  
8 the HIP process. The combination of VC addition (NV) and consolidation by HIP has  
9 allowed obtaining near-nanocrystalline cemented carbides, with an average grain size of  
10 122 nm WC. This microstructure is one of the finest reported in literature [35].  
11  
12  
13  
14  
15  
16  
17  
18  
19  
20  
21  
22  
23  
24

25 The lesser effect of inhibitors in the SPS process is due to the limitation of diffusion  
26 phenomena as a result of the shorter processing times, which makes it difficult the  
27 adequate distribution and location of the additives. The mechanisms of growth  
28 inhibition are the subject of many research studies [10,15-18]. The effect of VC and  
29  $\text{Cr}_2\text{C}_3$  on the WC grain growth inhibition has been explained in the presence of the  
30 liquid phase by limiting of the solution-reprecipitation mechanisms. This is due to the V  
31 and/or Cr dissolution in the cobalt which reducing the solubility of WC in the liquid  
32 phase. The inhibitory action of these additives in the solid state is not fully clear.  
33 Studies realized suggest the formation of a V or Cr rich thin interfacial layer which  
34 suppresses the WC dissolution. This film on the surface of WC grains contributes to the  
35 resistance to the diffusion of W [35]. As it has been previously explained, the short  
36 processing times for SPS sintering allowed the suppression of grain growth by limiting  
37 the diffusion phenomena. When the additives are used, they need a diffusion step or a  
38 reaction time in order to operate. As in the SPS sintering this time is too short, the  
39

1 additives efficiency is lower in comparison with the other sintering techniques. It is  
2 important to note that when the results of SPS sintering are observed isolated, it can be  
3 seen the effect of the additives. Then, the combination of SPS sintering and inhibitors  
4 use improves the grain growth control. In any case, more studies are needed to  
5 understand the roles of these carbides on grain growth inhibition during solid state  
6 sintering.

15 Diameter equivalent distribution of the WC grains of NV composition consolidated by  
16 SPS and HIP by are plotted in Figure 5. For this composition, the grains percentage with  
17 nanometric size was about 30% for the material obtained by SPS while it was more than  
18 55% for sintered by HIP. In both cases 99% of the grains present a size that is less than  
19 400 nm. From these results it can be concluded that there are two kinetic effects for  
20 controlling the WC grain growth. On one side the self diffusion phenomena that leads to  
21 grain growth and in the other side, the inhibitor particles diffusion that allows the WC  
22 grain growth control by different mechanism proposed in the literature. It is important  
23 to highlight his result because it opens the possibility of getting the smallest particle size  
24 in dense WC by an accurate design of the sintering cycle.

41 Finally, the hardness and fracture toughness values of the three compositions  
42 consolidated by SPS, HIP and vacuum sintering are compared in Figure 6. Materials  
43 without inhibitors (N) sintered by SPS and HIP reach hardness values >20% higher than  
44 the corresponding sintered in vacuum. This result is directly related with the full  
45 densification and smaller grain size obtained by these techniques. The higher hardness  
46 values of the sample without inhibitor (N composition) sintered by SPS and HIP, make  
47 that the increase obtained with the inhibitors addition (NCr and NV compositions) are  
48 less significant than in the samples consolidated by liquid phase conventional sintering.

However, hardness values about 2100 HV<sub>30</sub> has been achieved for NV composition sintered by HIP, which represents an increase of 15% compared to the mixture without inhibitor, N composition. This improvement in hardness is accompanied by a loss of fracture toughness, due probably to loss of strain capacity of the binder as a result of decreasing mean free path and/or the dissolution of VC. In any case, the fracture toughness values obtained for the hardest materials are close to 10 MPa m<sup>1/2</sup>. It is well understood that the hardness of cemented carbides materials is inversely proportional to its grain size and that the fracture toughness is inversely proportional to the hardness, although the relationship between the hardness and fracture toughness may not be linear when the grain sizes are extremely fine. Therefore, a finer grain size usually results in lower fracture toughness. However, for nanostructured metallic alloys and ceramics, it has been noted that the mechanisms of strengthening are different because of the large volume fractions of grain boundaries. The deformation mechanisms depend on grain boundary sliding and diffusion-controlled processes [37]. Thus, the effect of interfaces on the deformation mechanisms and/or change in the crack propagation path could contribute to better fracture toughness.

WC-12Co-VC/Cr<sub>2</sub>C<sub>3</sub> cemented carbides near fully dense were obtained by SPS and HIP in solid phase at 1100 °C. The addition of inhibitors, especially VC, has been demonstrated to be an efficient method for controlling the grain growth in the solid state, even by rapid sintering processes. However, in SPS technique, a lesser effect of both inhibitors has been observed due to extremely short processing time, thus limiting the appropriate distribution and location of the additives. The good microstructural

1 control achieved by VC addition and HIP sintering at low temperature has allowed  
2 manufacturing near-nanostructured materials with average WC grain size of 120 nm. As  
3  
4 result, materials with an attractive combination of properties were obtained: hardness  
5  
6 values about 2100 HV<sub>30</sub> and fracture toughness values close to 10 MPa m<sup>1/2</sup>.
