## 22 Abstract

23 The Balearic region is a highly dynamic area located in the Western Mediterranean,  
24 straddling the transition between the Algerian and Provençal basins and constitutes one  
25 of the main spawning grounds for the large, migratory Atlantic bluefin (*Thunnus*  
26 *thynnus*) and other medium and small tuna species (*Thunnus alalunga*, *Auxis rochei*,  
27 *Euthynnus alleteratus* and *Katsuwonus pelamis*). In summer, despite been considered an  
28 oligotrophic region as the whole Mediterranean Sea, it harbors a relatively abundant and  
29 diverse larval fish community (LFC). In this study, we analyze the composition,  
30 abundance and the influence of abiotic and biotic factors on the horizontal structure of  
31 the LFC in the Balearic region, in early summer 2005, during the spawning season of  
32 Atlantic bluefin tuna. Hydrographically, 2005 was an unusual year with a summer  
33 situation of relatively lack of mesoscale features, weak surface currents and a general  
34 situation of high stability. A total of 128 taxa of fish larvae, belonging to 52 families,  
35 were identified. The average abundance was 1770 larvae 1000 m<sup>-3</sup>. Multivariate  
36 statistical analysis revealed LFC to have a strong horizontal structure. Cluster analysis

37 and non-metric multidimensional scaling ordination identified two larval fish  
38 assemblages. These assemblages were mainly delineated by depth and, therefore, by the  
39 spawning location of adult fish. Our results also suggest that anticyclonic eddy  
40 boundaries constitute favourable habitats for fish larvae. Also, the scenario of higher  
41 than unusual hydrographic stability found during the cruise would be responsible for the  
42 relatively lack of mesoscale features and, consequently, for the lack of influence of  
43 these features on the horizontal distribution of fish larvae and on the horizontal structure  
44 of the LFC.

## 49 **Introduction**

50 The Balearic region is a highly dynamic area located in the Western Mediterranean (Fig.  
51 1). The Balearic Archipelago straddles the transition between the Algerian and  
52 Provençal basins and plays a key role in the water mass dynamics in the Central  
53 Western Mediterranean, by conditioning water mass exchange between the two basins,  
54 through the island channels (Lopez-Jurado *et al.*, 1995; Pinot *et al.*, 2002). The input  
55 flow of Atlantic Water (AW), through the Gibraltar strait, cross the Alboran Sea and  
56 enters the Algerian basin following the North African coast, forming the Algerian  
57 Current (AC). A thermohaline front, the Almeria-Oran front (Fig. 1), is formed by the  
58 convergence of surface Atlantic waters, less saline, and Mediterranean surface waters,  
59 more saline (Tintore *et al.*, 1991). The unstable character of the AC sometimes leads to  
60 the generation of cyclonic and anticyclonic eddies (Millot, 1985, 1999). Anticyclonic  
61 eddies have a lifetime of weeks to months, move freely within the Algerian Basin and

62 some of them reach the Balearic Islands (Font *et al.*, 2004; Millot, 1987). Filaments of  
63 AW, generated when the thermohaline Almeria-Oran front becomes unstable (Tintore *et*  
64 *al.*, 1988), can also reach and even surpass the Balearic archipelago through the island  
65 channels (Fig. 1). In the Provencal basin, the Northern Current (NC) flows  
66 southwestward, along the continental slope (Fig. 1). A branch of the NC forms the  
67 Balearic Current (BC) that flows northeastward, along the northern slope of the Balearic  
68 Islands (Fig. 1). A surface front, the Balearic Front, associated with the BC, and  
69 continued in the east by the North Balearic Front (Fig. 1), separates fresher AW of the  
70 Algerian basin from colder and saltier resident AW of the Provencal basin (Salat, 1995).  
71 The surface circulation is mainly driven by density in the Algerian basin while in the  
72 Provencal basin is mainly driven by atmospheric forcing, largely wind (Hopkins, 1978).  
73 As consequence, hydrodynamic conditions in the north and south of the islands are  
74 quite different (Lopez-Jurado *et al.*, 2008).

75 The Balearic region, as the whole Mediterranean Sea, is considered an oligotrophic  
76 region during the summer stratification period (Estrada, 1996; Fernández de Puelles *et*  
77 *al.*, 2007). During summer, in the absence of riverine nutrient input (it must be pointed  
78 out that there are no permanent freshwater streams in the Balearic Islands), the  
79 biological production is mainly associated with mesoscale oceanographic features,  
80 fronts and eddies (Alcaraz *et al.*, 2007; Estrada *et al.*, 1993; Jansa *et al.*, 2004; Jansa *et*  
81 *al.*, 1998). Also, the vertical distribution of chlorophyll shows a deep chlorophyll  
82 maximum (DCM), typical of oligotrophic regions, located below the thermocline  
83 (Estrada *et al.*, 1993; Jansa *et al.*, 1998). The maximum concentration of zooplankton  
84 coincides with the DCM, where zooplankton is feeding (Alcaraz *et al.*, 2007; Saiz *et al.*,  
85 2007).

86 Despite its oligotrophy, the Balearic region harbors a relatively diverse and abundant  
87 summer larval fish community (LFC) (Alemany, 1997; Alemany *et al.*, 2006; Sabates *et*  
88 *al.*, 2007). In addition, this region is recognized as one of the main spawning areas for  
89 the eastern Atlantic stock of the large migratory Atlantic bluefin (*Thunnus thynnus*),  
90 other medium and small tuna species (*Thunnus alalunga*, *Auxis rochei*, *Euthynnus*  
91 *alletteratus*, *Katsuwonus pelamis*) and other large pelagics, such as, *Xiphias gladius* or  
92 *Coryphaena hippurus* (Alemany *et al.*, 2010). The presence of larvae of these species,  
93 the reproductive strategy of most of fish species in the northwestern Mediterranean,  
94 which reproduce in spring-summer (Olivar *et al.*, 2010; Sabates *et al.*, 2007), and the  
95 mesoscale oceanographic features, enhancing biological productivity, may account for  
96 the relatively high species richness and larval fish abundances recorded in the area. On  
97 the other hand, processes such as currents, fronts and eddies influence the distribution,  
98 abundance and survival of fish larvae and, accordingly, define the abundance, structure  
99 and diversity of the LFC (Bakun, 2006; Holliday *et al.*, 2011; Lobel and Robinson,  
100 1988; Mullaney *et al.*, 2011; Rodriguez *et al.*, 2004; Sabates and Olivar, 1996).

101 The summer LFC of the Balearic region has been previously studied but at a short  
102 spatial scale. In this study, the most geographically widespread carried out on the  
103 ichthyoplankton in the region, we analyse the composition, abundance and the  
104 horizontal structure of the LFC of the Balearic region, in early summer 2005. We also  
105 analyse the influence that abiotic (depth, sea surface salinity, dynamic height and  
106 geostrophic velocity and biotic environmental factors (phytoplankton and  
107 mesozooplankton biomass) have on the horizontal structure of the LFC. We  
108 hypothesized that the horizontal distribution of fish larvae and, consequently, the  
109 horizontal structure of the LFC would reflect the mesoscale oceanographic features of  
110 the region.

111 **Material and methods**

112 Data collection

113 This study is based on data collected during the Tunibal 05 oceanographic-  
114 ichthyoplankton survey, carried out in the Balearic region (NW Mediterranean), in  
115 summer (from June 27 to July 23) 2005 (Fig. 1). A total of 190 (183 for  
116 ichthyoplankton) stations, arranged in a regular sampling grid of 10 x 10 nm, were  
117 sampled.

118 At every station, vertical profiles of conductivity, temperature and fluorescence were  
119 obtained with a Sbe 911 CTD. Profiles were to 350 m in depth (160 stations), or to 650  
120 m at selected stations (30 stations).

121 Zooplankton samples were collected with a Calvet net equipped with 55 µm mesh nets  
122 in vertical hauls, from 70 m depth to the surface. Samples were filtered immediately  
123 through 200 µ and 2 mm mesh filters to separate the three zooplankton fractions. The  
124 macrozooplankton fraction was discarded and both, the micro and mesozooplankton  
125 samples were then placed in Petri dishes and frozen at -20 °C. In the laboratory, the  
126 micro and mesozooplankton dry weight were obtained following (Lovegrove, 1966).  
127 Nonetheless, microzooplankton was not considered because for many samples their dry  
128 weight was below the detection limit of the precision balance used. Mesozooplankton  
129 dry weight biomass values were standardised to mg m<sup>-3</sup>.

130 Ichthyoplankton samples were collected with a Bongo 60 net equipped with 200 and  
131 335 µm mesh nets. Tows were oblique trying to reach 70 m depth, apart from three  
132 stations shallower than 70 m. At every station, the length of the wire was adjusted in  
133 function of the wire angle to reach 70 m depth. The volume of water filtered was  
134 measured by two flowmeters (General Oceanics) installed in the mouths of each net.

135 Ichthyoplankton samples were immediately preserved in a 4% sodium-borate buffered  
136 solution of seawater and formaldehyde. In the laboratory, all fish larvae were sorted  
137 from the 335  $\mu\text{m}$  mesh net samples, counted and identified to the lowest taxonomic  
138 level possible. Larval fish catches at each station were standardised to number  $1000\text{ m}^{-3}$ .

139

#### 140 Data analysis

141 Temperature, salinity and fluorescence records at each station were processed at their  
142 original sampling frequency and averaged at 1 m interval. Horizontal hydrographic  
143 fields were obtained with a standard optimal interpolation scheme, using an isotropic  
144 Gaussian correlation (Bretherton *et al.*, 1976; Pedder, 1993). The dynamic height at 10  
145 dbar was calculated by vertical integration of the specific volume anomaly from the  
146 level of 600 dbar, which was chosen as the level of no motion (Pinot *et al.*, 2002). At  
147 shallow stations, or when data were recorded only down to 350 m, the density anomaly  
148 at the closer 600 m station was assigned to the deepest level sampled by the CTD.  
149 Geostrophic velocities were obtained using the first-derivative of the dynamic height  
150 fields (Pinot *et al.*, 2004). Dynamic height was used as an indicator of eddies and frontal  
151 regions, because dynamic height should be higher than average in anticyclonic and  
152 frontal regions and lower than average in cyclonic eddy regions (Lindo-Atichati *et al.*,  
153 2012 and references therein). Geostrophic velocity at 10 m depth was used as an  
154 indicator of eddy boundaries and frontal regions, because geostrophic velocity should  
155 be higher in these regions (Bakun, 2006; Le Febre, 1986; Sournia, 1994).

156 In early summer, the surface warming in the Mediterranean Sea is strong. Thus, sea  
157 surface temperature (SST) does not depend on the geographical position but on  
158 sampling date. As consequence, temperature was not useful for characterizing surface

159 water masses. Sea surface salinity (SSS), salinity at 10 m depth, was considered the best  
160 parameter for this purpose.

161 The relation between environmental variables, SSS, dynamic height, geostrophic  
162 velocity, depth-integrated (5-200 m) fluorescence, as an estimate of phytoplankton  
163 biomass, mesozooplankton biomass and larval fish concentration was tested using  
164 Pearson's correlation coefficient in SPSS v. 19.0.

165 Taxon diversity was calculated for each station using the Shannon-Wiener diversity  
166 index ( $H'$ ) in PRIMER v. 6.1.6 (Plymouth Routines In Multivariate Ecological  
167 Research).

168 Following Clarke and Ainsworth (1993) and Field *et al.* (1982), non-parametric  
169 multivariate techniques in PRIMER were used to study the horizontal structure of the  
170 LFC. Cluster analysis in conjunction with non-metric multidimensional (MDS)  
171 ordination was used to identify larval fish and taxa assemblages. Only "non rare taxa,  
172 those found in >5% of the stations and/or had a relative abundance of >0.04%, were  
173 included in the analysis. Cluster analysis and MDS were performed on a Bray-Curtis  
174 similarity matrix (Bray and Curtis, 1957), generated from the  $\log_e(x+1)$  transformed  
175 data of larval fish abundances. Data were transformed to down-weight the influence of  
176 more abundant taxa (Clarke and Ainsworth, 1993; Field *et al.*, 1982). Hierarchical  
177 agglomerative clustering with group-average linking, carried out on the similarity  
178 matrix, was used to delineate assemblages with distinct community structure. Arbitrary  
179 cut-off levels were chosen on dendrograms to produce ecologically interpretable  
180 clusters (Field *et al.*, 1982; Auth and Brodeur, 2006). The adequacy of the classification  
181 analysis was checked by superimposing the results of the clustering on MDS plots  
182 generated from the same similarity matrices (Auth and Brodeur, 2006; Clarke and  
183 Ainsworth, 1993; Clarke and Warwick, 2001). A 2-dimensional ordination approach

184 was adopted because the stress level ( $\leq 0.16$ ) was acceptably low (Clarke and  
185 Ainsworth, 1993; Clarke and Warwick, 2001).

186 The relationship between biological and environmental variables and “non rare” taxa  
187 was assessed with Canonical Correspondence Analysis (CCA) in CANOCO 4.5 (ter  
188 Braak and Smilauer, 2002). CCA is a multivariate method to elucidate the relationships  
189 between assemblages of species and their environment (ter Braak and Verdonschot,  
190 1995). Rare species, as above, were not included in the analysis. Larval abundances  
191 were  $\log_e(x+1)$  transformed before analysis. The explanatory variables were station  
192 depth, SSS, dynamic height, geostrophic velocity, depth-integrated fluorescence and  
193 zooplankton biomass. SST was not included in the analysis because of its temporal  
194 variability, daily increase, as indicated above. Canonical axes were tested for  
195 significance with a Monte Carlo permutation test (9999 permutations) in CANOCO (ter  
196 Braak and Smilauer, 2002).

197

## 198 **Results**

### 199 Hydrography and plankton

200 In summer, in the absence of the winter atmospheric forcing, the density gradient  
201 dominates and allows AW inputs to enter the Balearic region. Thus, the southernmost  
202 part of our study area was occupied by fresh AW (salinity  $< 37.5$ ) (Fig. 2a). Weak inputs  
203 of this water crossed the Ibiza channel and, surrounding the northern Ibiza Island,  
204 returned into the Algerian basin through the Mallorca channel. The northeastern corner  
205 was occupied by resident AW (salinity  $> 38$ ), isolated patches of resident AW were also  
206 found in the north of the area, and the rest of the region was occupied by mixed AW  
207 (salinity  $37.5 - 38$ ) (Fig. 2a). Consequently, the boundary between fresh and resident

208 AW was found south of the archipelago. The main hydrographic mesoscale features  
209 observed during the study were two anticyclonic eddies. A strong, fresh AW  
210 anticyclonic eddy was located south of the Mallorca Channel, centered at 38.5° N (Fig.  
211 2b). Another weak, mixed AW anticyclonic eddy was found at the east of Mallorca and  
212 the south of Menorca Island (Fig. 2b). Surface currents, including the BC flow, were  
213 also relatively weak (Fig. 2b).

214 The water column showed a strong thermal stratification. The mixed layer, defined as  
215 the layer where temperature and salinity were homogeneous due to solar heating and  
216 turbulence induced by weak easterlies, was 15 m of average thickness and with  
217 temperatures between 20 and 26 °C. It was followed by a strong thermal gradient to  
218 around 60 m depth. From this depth to 150 m, the temperature decreased gradually to  
219 reach ~13 °C, the deep-water temperature (Fig. 3). As mentioned above, SST depended  
220 on sampling date. Thus, the lowest SST was recorded at the beginning of the cruise and  
221 the highest SST was measured at the end of the cruise. In fact there was a significant  
222 correlation between SST and sampling dates ( $r = 0.62$  for temperature at 5 m depth and  
223  $r = 0.34$  for temperature at 10 m depth,  $p < 0.01$  in both cases).

224 The vertical distribution of fluorescence showed a deep fluorescence maximum (DFM)  
225 located at an average depth of about 75 m, below the thermocline (Fig. 3). The  
226 horizontal distributions of depth-integrated fluorescence and mesozooplankton biomass  
227 showed irregular patterns (Fig. 4). The most noticeable feature of these distributions  
228 was that the highest values for both these biological variables were recorded in the  
229 oceanic region. In fact, the correlation of depth-integrated fluorescence and  
230 mesozooplankton biomass with depth was significant ( $r = 0.30$ ,  $p < 0.01$  and  $r = 0.16$ ,  $p$   
231  $< 0.05$ , respectively). Also, it must be pointed out that the correlation between them was  
232 not significant.

233 The larval fish community

234 A total of 54545 fish larvae were caught in this study, including 128 taxa belonging to  
235 52 families (Table I). Myctophidae, with 17, and Gobiidae, with 12, were the families  
236 with the largest number of taxa. The abundance of fish larvae ranged from 90 to 5991 L  
237  $1000\text{ m}^{-3}$ , with a mean of  $1770\text{ L }1000\text{ m}^{-3}$ . Larvae of the families Myctophidae, which  
238 accounted for 50% of total catch, and Gonostomatidae, 33% of total catch, were the  
239 most abundant. *Hygophum* spp was the most abundant and one of the most common  
240 taxa, accounting for 25.1% of the total larval fish abundance and being caught at 95.1%  
241 of the stations. The second most abundant species was *Cyclothone braueri* (24.6%),  
242 which also was the most common taxa, appearing at almost all stations (98.9%). Other  
243 abundant and common taxa were *Ceratoscopelus maderensis*, 14.3% of the larval fish  
244 abundance and appearing at 97.8% of the stations, *Cyclothone pygmaea*, 7.6% of the  
245 larval fish abundance and captured at 91.8% of the stations and *Lampanyctus crocodilus*  
246 that accounted for 4.2% of the larval fish abundance and was captured at 89.1% of the  
247 stations. Only for three neritic species their relative abundances were above 1% of total  
248 larval catch. These species were *Auxis rochei*, which accounted for 2.3% of larval fish  
249 abundance and was caught at 44.8% of the stations, *Sardinella aurita*, 1.6% of the larval  
250 abundance and caught in 25.7% of the stations and *Engraulis encrasicolus*, 1.4% of the  
251 larval fish abundance and present in 33.9% of the stations. The horizontal distribution of  
252 fish larvae, with low concentrations around the islands and the highest recorded away  
253 from these (Fig. 5), showed similar pattern to that of depth-integrated fluorescence and  
254 mesozooplankton biomass (Fig. 4). Individual species also showed irregular patterns of  
255 horizontal distribution (Fig. 5). As expected, larvae of oceanic species showed higher  
256 concentrations in the oceanic region and larvae of neritic species showed higher  
257 concentration in the neritic region (Fig. 5). Nevertheless, larvae of oceanic species were

258 caught in the neritic region, as were larvae of neritic species caught in the oceanic  
259 region (Fig. 5). Larval fish abundance was correlated with geostrophic velocity ( $r =$   
260  $0.16$ ,  $p < 0.05$ ) and with the species diversity index ( $r = -0.28$ ,  $p < 0.01$ ).

261 The number of taxa per station ranged from 7 to 35, with the maximum values recorded  
262 around the islands (Fig. 6a). Larval diversity was relatively high, ranging from 0.92 to  
263 2.98. Its horizontal distribution followed a similar pattern to the number of taxa, with  
264 the highest values also recorded around the islands (Fig. 6b). Larval diversity was  
265 correlated with SSS ( $r = 0.34$ ,  $p < 0.01$ ) and with larval abundance, as indicated above.

266 Cluster analysis identified two LFAs at a similarity level of 41% (Fig. 7a). MDS  
267 ordination produced the same results (Fig. 7b). Assemblages were named after the  
268 location of the stations they occupied. The neritic assemblage occupied almost  
269 exclusively stations located inside the 200 m isobath, while the oceanic assemblage  
270 occupied the stations located outside the 200 m isobath (Fig. 7c). This two group  
271 classification was reinforced by the formation by cluster analysis and MDS ordination  
272 of two taxa assemblages: a neritic and an oceanic one (Fig. 8). The neritic assemblage  
273 was formed by larvae of those taxa that as adults inhabit the neritic region and also  
274 reproduce there. The oceanic assemblage was formed by larvae of fish species that as  
275 adults live and reproduce in the oceanic region. The allocation of larval fish taxa into  
276 one of these two groups was quite accurate, only a taxon *Arnoglossus thori*, a flatfish  
277 inhabiting shelf bottoms, clustered with oceanic taxa.

278

#### 279 Relationship between larval fish taxa and environment

280 The Monte Carlo permutation test showed that only the first two canonical axes were  
281 significant ( $p < 0.05$ ). These two axes explained 88.0% of the variance of the species–

282 environment relationship. The species-environment correlation coefficients for the first  
283 two CCA axes were 0.70 and 0.56, respectively. In the CCA biplot, environmental  
284 variables are represented by arrows, with origin at the centre of the biplot and pointing  
285 in the direction of its increase. The length of environmental arrows and their orientation  
286 on the biplot determine their relative importance to each axis (ter Braak and  
287 Verdonschot, 1995; ter Braak, 1986). Then, according to Figure 9, depth was the most  
288 important variable in explaining taxa distribution. This variable, depth-integrated  
289 fluorescence, mesozooplankton biomass, dynamic height and geostrophic velocity were  
290 negatively correlated with axis 1; only SSS was positively correlated with this axis (Fig.  
291 9). The geographical representation of scores of each station confirms that axis 1 is a  
292 depth axis (Fig. 10a). Accordingly, oceanic taxa appeared on the negative side of this  
293 axis (Fig. 9). In general, these taxa clustered near the centre of the CCA biplot (Fig. 9).  
294 Only two neritic taxa, *Arnoglossus thori* and *Mullus barbatus*, were located on the left  
295 side of axis 1, although very close to the right side region of the CCA biplot (Fig. 9).  
296 Most taxa that appeared at the very right side of the axis 1 are demersal fish species  
297 (e.g. *Gobius niger*, *Spicara smaris*, *Pagrus pagrus* or Ophidiidae) with relative littoral  
298 distribution. Larvae of neritic epipelagic taxa (e.g. *Auxis rochei*, *Trachurus*  
299 *mediterraneus* or *Engraulis encrasicolus*) were located on the right side of Axis I but  
300 near of centre of the CCA biplot. Only the oceanic specie *Thunnus thynnus* was located  
301 on the right side of the CCA biplot, although near its centre, as most of the oceanic taxa  
302 (Fig. 9). Axis 2 was positively correlated with depth and dynamic height (Fig. 9). The  
303 geographical representation of scores of each station shows that axis 2, unlike axis 1,  
304 could not be identified with any of the environmental variables (Fig. 10). *A. thori*,  
305 *Myctophum punctatum*, *Lobianchia dofleini* and *Mullus barbatus* were the species that  
306 showed the highest correlation with axis 2 (Fig. 9).

307 The groups of larval fish taxa formed by cluster analysis and MDS ordination (Fig. 8)  
308 also appeared in the CCA with little difference (Fig. 9). This indicates strong support of  
309 taxa grouping and their relationship with the considered environmental variables (Leps  
310 and Smilauer, 2003).

311

## 312 **Discussion**

### 313 Hydrography

314 Hydrographically, 2005 was an unusual year because there were consecutive episodes  
315 of severe winter leading to violent convective events, with the development of a  
316 thermohaline anomaly in deep waters (Lopez-Jurado *et al.*, 2005). Even so, no winter  
317 intermediate water (WIW) was formed, since all the surface water masses affected by  
318 the cold and intense winter winds became deep Mediterranean waters (Lopez-Jurado *et*  
319 *al.*, 2005). In addition, the winter atmospheric forcing, which dominates in the  
320 Provencal basin (Hopkins, 1978), favoured that colder and saltier surface waters moved  
321 south of the Balearic archipelago (Lopez-Jurado *et al.*, 2005). When this forcing  
322 decayed, the recent AW progressed northward generating oceanic fronts along 39° N  
323 parallel. During summer, as surface currents were relatively weak, there was no intense  
324 inflow of oceanic surface waters towards coastal areas, or currents transporting shelf  
325 waters offshore. Also, the Balearic Current Balearic Current (BC) only received weak  
326 fresh AW inputs through the Ibiza Channel, because the anticyclonic eddy located south  
327 of Mallorca blocked its passage through the Mallorca channel. According to Alemany *et*  
328 *al.* (2010), the hydrodynamic scenario observed during this survey was more stable than  
329 those found in similar summer surveys carried out in previous years in the region. This

330 stability would be responsible for the relatively lack of mesoscale hydrographic features  
331 found in the area at the time of the study.

332 During the stratified summer situation and in the absence of riverine nutrient input, the  
333 only nutrient source in the region has to be related with the mesoscale oceanographic  
334 processes in the region. The horizontal distribution of depth-integrated fluorescence and  
335 mesozooplankton biomass, with relatively low concentrations around the islands and the  
336 highest values recorded in the oceanic region (Fig. 4), supports that biological  
337 production in the region during the study was not related with inputs of nutrients from  
338 the islands. It has been reported that Chl a maxima during summer in the Balearic  
339 region, are associated with hydrographic features, such as fronts and eddies (Estrada *et*  
340 *al.*, 1993; Jansa *et al.*, 2004; Jansa *et al.*, 1998), which constitute important fertilization  
341 sources (Alcaraz *et al.*, 2007; Bakun, 2012). Concretely, during 2001-2003 summers,  
342 Jansa *et al.* (2004) found those maxima, of up to  $8 \mu\text{g l}^{-1}$ , in subsurface strata, in the  
343 border of anticyclonic eddies. In this study, the lack of significant correlation of the  
344 horizontal distributions of depth-integrated fluorescence with dynamic height and  
345 geostrophic velocities did no support the relationship between Chl a and mesoscale  
346 hydrographic features. Though, the significant correlation between depth-integrated  
347 fluorescence and SSS indicates that biological production was higher in resident AW  
348 waters, richer in nutrients than in the fresh, nutrient depleted AW (Estrada, 1996). This  
349 relationship of depth-integrated fluorescence with resident AW may mask the  
350 relationship of phytoplankton with mesoscale hydrographic features. The most  
351 noticeable were the above mentioned two eddies, one of them of fresh and the other of  
352 mixed AW (Fig. 2).

353 The vertical distribution of fluorescence, with a deep fluorescence maximum (DFM), is  
354 typical of the Mediterranean Sea during the stratification period (Estrada, 1996). In open

355 waters off the Balearic Islands, Jansa *et al.* (2004) found significant concentrations of  
356 chlorophyll at the DCM level in summer. It has also been reported that during the  
357 stratification period, the main zooplankton peak coincides with the DCM (Alcaraz *et al.*,  
358 2007). Copepods nauplii and copepodites, the main food items for fish larvae, also  
359 concentrate at this depth (Olivar *et al.*, 2010; Sabates *et al.*, 2009). So, our sampling to  
360 70 m depth, may have not included zooplankton maximum leading to an  
361 underestimation of the true values of the mesozooplankton biomass. This also may  
362 account for the lack of relationship between the horizontal distribution of depth-  
363 integrated fluorescence and mesozooplankton biomass.

364

#### 365 The larval fish community

366 The number of larval fish taxa captured is higher than those found in previous  
367 ichthyoplankton studies carried out in our study area, in summer, (Alemany *et al.*, 2006;  
368 Torres *et al.*, 2011), off the nearby Catalan coast (Olivar *et al.*, 2010; Sabates, 1990) or  
369 in other regions of the Mediterranean Sea, such as the Aegean Sea (Somarakis *et al.*,  
370 2002; Somarakis *et al.*, 2011), Gulf of Gabes (Zarrad *et al.*, 2013) or the Alboran Sea  
371 (Rodriguez, 1990). Species richness was only slightly lower or comparable to that  
372 reported for subtropical areas (e.g. Keane and Neira, 2008; Moyano and Hernandez-  
373 Leon, 2011; Muhling *et al.*, 2008). The higher species richness found in this study in  
374 relation with other previously carried out in the region, in summer, may be due to the  
375 fact that our study covered a larger area than Alemany *et al.* (2006) and a larger area  
376 and sampling deeper than Torres *et al.* (2011). In addition, larvae of large migratory  
377 tuna and other pelagic species that reproduce around the Balearic archipelago, the large  
378 area covered in this study, including the island shelves and the oceanic region, and the

379 great number of stations sampled could explain the higher specific richness found in this  
380 study in relation with other Mediterranean regions.

381 The patterns of horizontal distribution shown by species richness and diversity, with the  
382 highest values recorded around the islands, may be related with the narrowness of the  
383 island shelves that leads to an overlap of larvae of neritic and oceanic species in the  
384 proximity of the islands. Also, eddies found in the area could approach oceanic larvae to  
385 the islands, as reported for other marine regions (Franco *et al.*, 2006; Lobel and  
386 Robinson, 1986; Olivar *et al.*, 2010). For its part, the negative correlation between  
387 larval abundance and species diversity indicates that the increase in larval abundance is  
388 related with the proliferation of a single or a few taxa rather than with the increase in  
389 abundances of all taxa that made up the larval fish community.

390 Larval fish abundances were also higher than reported for the region by Alemany *et al.*  
391 (2006). But, the study of Alemany *et al.* (2006) was restricted to two small areas off the  
392 Mallorca Island, covering the coastal-slope region. So, the fact that larval abundances  
393 were higher in the oceanic region would account for the relatively higher larval  
394 abundance recorded in this study. Another characteristic of the LFC was that larval  
395 abundances were also higher than those found in other more productive marine regions,  
396 such as the Taiwan strait (Hsieh *et al.*, 2012) or the California Current region (Auth and  
397 Brodeur, 2006). This finding is counterintuitive because the Mediterranean Sea in  
398 summer, as mentioned above, is considered oligotrophic. Nevertheless, during this  
399 season, in the Western Mediterranean, the DCM and the relatively high zooplankton  
400 biomass associated to it (Alcaraz, 1985) offers an important food source for fish larvae  
401 (Sabates *et al.*, 2007). Moreover, there may be deep zooplankton hotspots, located in the  
402 border of anticyclonic eddies and associated to the phytoplankton hotspots found in  
403 other studies (e.g. Jansa *et al.*, 2004). These zooplankton hot spots may also constitute

404 feeding regions for fish larvae. Furthermore, currents that flow through the islands and  
405 eddies may trap and transport neritic larvae off the island shelves (Leis, 1982; Lobel and  
406 Robinson, 1986; Olivar *et al.*, 2010). In this sense, simulations suggest that during  
407 summer a relatively small proportion (~30%) of neritic larvae in the Balearic Islands  
408 could be advected offshore (Basterretxea *et al.*, 2012). All these factors may account for  
409 the relatively high larval fish abundance found in this study and also for the fact that the  
410 higher abundances were recorded in the oceanic region.

411 In addition, the vertical distribution of larval food would also be favourable for the  
412 LFC found in the region. In stratified waters, fish larvae show a stratified vertical  
413 distribution. With some exceptions, larvae of neritic species are distributed in the mixed  
414 layer and the upper region of the thermocline, while larvae of oceanic species show a  
415 deeper distribution, generally below the thermocline (Ahlstrom, 1959). Larvae of neritic  
416 taxa caught in this study, apart from e.g. Gobiidae and Callionymidae, show a shallow  
417 vertical distribution in the region (Olivar *et al.*, 2010; Olivar and Sabates, 1997; Torres  
418 *et al.*, 2011), but also some of them perform daily vertical migrations. This is the case of  
419 larger *S. aurita* and *E. encrasicolus* larvae, the second and third most abundant neritic  
420 species caught in this study, that move downward during the daytime, to the DCM in  
421 the case of *E. encrasicolus* (Olivar *et al.*, 2001; Sabates *et al.*, 2008). As for larvae of  
422 mesopelagic taxa, which widely dominated the LFC, show a deeper distribution, even  
423 below the thermocline (Olivar *et al.*, 2010; Olivar and Sabates, 1997; Rodriguez *et al.*,  
424 2006; Sabates, 2004). Only two Gonostomatidae species *Cyclothone braueri* and *C.*  
425 *pygmaea* and the Myctophyidae *Ceratoscopelus maderensis* reach the surface mixed  
426 layer (Olivar *et al.*, 2010; Rodriguez *et al.*, 2006; Torres *et al.*, 2011). That is to say, the  
427 vertical distribution of larval food would be favourable for most oceanic-mesopelagic  
428 larvae and also for larvae of neritic species, which are able to perform diel vertical

429 migration. Also, the larvae of tuna and most neritic species, with shallow vertical  
430 distribution, would be favoured because they would not have to share the scarce trophic  
431 resources of the surface layers. The lack of correlation between larval fish abundance  
432 and mesozooplankton biomass may be explained either by the consumption of  
433 zooplankton by fish larvae or the fact that, as indicated above, our sampling may have  
434 not included the zooplankton maximum.

435 Neritic larvae advected offshore do not necessarily have to get lost for the adult neritic  
436 fish populations of the islands. They may return to the island shelves, either passively  
437 transported by eddies (Franco *et al.*, 2006; Lobel and Robinson, 1986) or actively  
438 swimming (Leis, 2007; Leis and Carson-Ewart, 1997; Stobutzki and Bellwood, 1997).  
439 In this case, eddies would also function as a nursery area for these larvae (Govoni *et al.*,  
440 2010; Lobel and Robinson, 1986; Logerwell and Smith, 2001; Sabates *et al.*, 2013). It  
441 has to be indicated that neritic larvae caught in the oceanic region were advanced larvae  
442 (even juveniles), in apparently very good condition (author's personal observation).  
443 Moreover, some of these larvae, e.g. *Mullus* and Bothidae species, have a long pelagic  
444 stage (Macpherson and Raventos, 2006; Russell, 1976). These two aspects would  
445 increase the chance of survival for those larvae.

446 Multivariate analysis indicates that depth and, consequently, the spawning location of  
447 adult fishes were the main factors in shaping the horizontal structure of the LFC. This is  
448 consistent with that reported in previous LFC studies in our study area (Alemany *et al.*,  
449 2006), other regions in the Mediterranean Sea (Sabates, 1990; Somarakis *et al.*, 2011)  
450 and elsewhere in the world (Auth, 2008; Muhling and Beckley, 2007; Rodriguez *et al.*,  
451 2009). The influence of depth on larval fish distribution is clear in the case of larvae of  
452 neritic species, which most of them clustered on the very right side of the CCA biplot,  
453 but not for oceanic taxa. The clustering of most of these taxa near the centre of the

454 CCA biplot suggests that their distribution was little influenced by any of the  
455 environmental variables considered in this study (ter Braak, 1986). However, in the case  
456 of depth this may be an artefact caused by the narrowness of the island shelf. In fact,  
457 88% of the ichthyoplankton stations were deeper than 200 m and 95% were deeper than  
458 100 m. This would explain the high percentage of occurrences and the wide horizontal  
459 distribution shown by many oceanic taxa. For its part, the significant correlation found  
460 between larval abundances and geostrophic velocity suggests some accumulation of fish  
461 larvae in anticyclonic eddy borders. This agrees with Lindo-Atichati *et al.* (2012) who,  
462 in the Gulf of Mexico, found higher densities of *T. thynnus* and *Auxis* spp in the  
463 boundaries of anticyclonic eddy regions.

464 The apparently low influence that mesoscale oceanographic features had on the  
465 horizontal structure of the LFC in this highly dynamic region contrasts with the large  
466 influence that mesoscale features have on the horizontal structure of the LFC in similar  
467 regions, e.g. off the nearby Catalan coast (Olivar *et al.*, 2010; Sabates, 1990; Sabates *et*  
468 *al.*, 2007) and other places around the world (Franco *et al.*, 2006; Holliday *et al.*, 2011;  
469 Keane and Neira, 2008; Rodriguez *et al.*, 2004). The scenario of relatively high  
470 hydrographic stability found during the cruise should explain the low influence of  
471 mesoscale oceanographic features on the horizontal structure of the LFC. Also, the  
472 presence of only two LFAs, a coastal and an offshore, reported for other regions with a  
473 narrow continental shelf (Auth and Brodeur, 2006; Richardson and Percy, 1977;  
474 Rodriguez *et al.*, 2009), indicates that, despite the narrowness of the shelf, most neritic  
475 larvae remain in the neritic region and most oceanic larvae in the oceanic region. This  
476 would agree with the above mentioned Basterretxea *et al.* (2012) simulation results that  
477 suggest most neritic larvae during summer, in the Balearic Islands, remain in the neritic  
478 region.

479 In summary, the Balearic region during early summer harbours a relatively abundant  
480 and diverse LFC dominated by larvae of oceanic mesopelagic species. Larval fish  
481 assemblages were mainly delineated by depth and consequently by the spawning  
482 location of adult fish. Thus, our hypothesis that the structure of the LFC should reflect  
483 the mesoscale oceanographic features of the region was not confirmed. The unusual,  
484 from the meteorological and hydrographical point of view, 2005 year and the scenario  
485 of higher-than usual hydrographic stability would be responsible for the relatively lack  
486 of mesoscale features and, consequently, for the lack of influence of these features on  
487 the horizontal distribution and structure of the LFC.

Table I. Alphabetical list of larval fish families collected in the Balearic Sea, in July 2005, taxa code (Code), their relative abundance (RA, %) and their percentage of occurrence (%O)

Family and species	Code	RA	%O
Apogonidae			
<i>Apogon (Apogon) imberbis</i>		0.031	3.3
Argentiniidae			
<i>Glossanodon leioglossus</i>		0.002	0.5
Blenniidae			
<i>Parablennius pilicornis</i>		0.002	0.5
Unidentified sp		0.020	
Bramidae			
<i>Brama brama</i>		0.004	1.1
Bothidae			
<i>Arnoglossus imperialis</i>		0.002	0.5
<i>Arnoglossus laterna</i>		0.009	1.6
<i>Arnoglossus rueppelli</i>		0.007	1.6
<i>Arnoglossus thori</i>	At	0.062	9.8
<i>Bothus podas</i>		0.019	4.9
<i>Arnoglossus</i> spp	Aspp	0.084	7.1
Callionymidae			
<i>Callionymus</i> spp	Cspp	0.048	9.3
Caproidae			
<i>Capros aper</i>		0.011	3.3
Carangidae			
<i>Trachinotus ovatus</i>		0.002	0.5
<i>Trachurus mediterraneus</i>	Tm	0.434	20.2
<i>Trachurus</i> spp	Tspp	0.871	13.7
<i>Seriola dumerili</i>		0.035	4.9
Carapidae			
<i>Carapus acus</i>		0.002	0.5
Cepolidae			
<i>Cepola rubescens</i>	Cr	0.299	15.8
Chlorophthalmidae			
<i>Chlorophthalmus agassizii</i>		0.002	0.5
Clupeidae			
<i>Sardinella aurita</i>	Sa	1.638	25.7
Centracanthidae			
<i>Spicara flexuosa</i>		0.002	0.5
<i>Spicara smaris</i>	Ss	0.420	8.7
<i>Spicara</i> spp		0.009	0.5
Centriscidae			
<i>Macroramphosus scolopax</i>		0.002	0.5
Congridae			
<i>Ariosoma balearicum</i>		0.002	0.5
Coryphaenidae			
<i>Coryphaena hippurus</i>		0.004	1.1
Dactylopteridae			
<i>Dactylopterus volitans</i>		0.007	1.6
Engraulidae			
<i>Engraulis encrasicolus</i>	Ee	1.365	33.9
