Abstract

The determination of total chlorophylls and total carotenoids in olive oil by using visible spectroscopy (VIS) is reported. ~~The technique proposed is rapid and non-destructive and can be used in a multi-parameter form. Moreover, it is environmentally friendly.~~ The proposed technique has been compared with the determination of these pigments by near infrared spectroscopy (NIRS) and VIS together NIRS. Several procedures for multivariate regression were tested. The reference methods used were the determination of the extinction coefficient K_{670} for total chlorophylls and K_{470} for total carotenoids. A total of 258 samples were tested. The optimization of the calibration for total chlorophylls has been set by using multiple linear regression (MLR) from the wavelengths 670-686 nm exclusively visible. Its satisfactory performance is proven from the model coefficients standard error of calibration SEC 2.63 and R^2 0.97, and the residual predictive deviation (RPD) 5.76 from the external validation. For the total carotenoids the best VIS calibration was fit by using the window of 465-475 nm and partial least squares (PLS), which provided RPD 3.68. However, the model built using the entire spectrum VIS-NIRS available (350-2500 nm) was slightly better for this last pigment, showing RPD 3.86. Hence, this study

30 33 **Introduction**

31
32
33 34 Olive oil can be consumed as a fruit juice, called virgin olive oil (VOO), which
34
35 35 characterizes it and differentiates it from other plant oils. This oil, one of the main
36
37 36 components of the Mediterranean diet, is recognized as a protector against cardiovascular
38
39 37 diseases and cancer, due to its fatty acid composition and its content in phenolic
40
41 38 compounds [1]. World production of olive oil ranges next to 3×10^6 t per year, Spain being
42
43 39 the largest producer, with an average production from the last three seasons higher to
44
45 40 1.4×10^6 t [2]. A large increase in the demand for high quality VOO during recent years can
46
47 41 be attributed not only to its particular sensory properties, but also to its potential health
48
49 42 benefits.
50

1
2
3
4
5
6
7
8
9 43 Several research results have demonstrated that plant pigments play important roles in
10 44 health [3]. The potential health benefit of a diet rich in carotenoids has been highlighted in
11 45 multiple studies where their role as antioxidants and as agents which prevent cardiovascular
12 46 diseases and degenerative eye pathologies is reported [4-5]. The provitamin A value of the
13 47 carotenoids is well known. Numerous studies have also shown the anticancer activity of β -
14 48 carotene and other carotenoids [6]. In addition, it has been reported that chlorophyll
15 49 concentrations encountered in chlorophyll-rich green vegetables can provide substantial
16 50 cancer chemoprotection, and suggested that they do so by reducing carcinogen
17 51 bioavailability [7].

18
19
20
21
22
23
24
25
26 52 On the other hand, carotenoids together with polyphenols and tocopherols provide
27 53 oxidative stability to olive oils [2]. An important role of chlorophylls and carotenoids in the
28 54 oxidative activity of processed foodstuff, due to their antioxidant nature in the dark and
29 55 pro-oxidant activity in the light, has been shown [8].

30
31
32
33
34
35 56 Moreover, the color of olive oil is an important visual attribute which has a decisive
36 57 influence on the acceptance of the product [9]. Chlorophyll and carotenoid pigments in
37 58 olive oil greatly contribute to their color, so they are commonly used for the determination
38 59 of olive oil color according to several methods [10-13]. These methods, instrumental and
39 60 visual, for olive oil color analysis and its relation with chlorophylls and carotenoids, have
40 61 been reviewed [10]. However, none of the above methods has been tuned for the rapid and
41 62 accurate determination of chlorophylls or carotenoids totals in olive oils.

42
43
44
45
46
47
48
49 63 Studies on the pigment composition in products derived from olives are relatively few [3].
50 64 The first high performance liquid chromatographic studies on the pigment fractions of

1
2
3
4
5
6
7
8
9 65 mono-varietal VOOs from some Spanish olive varieties were done by Mínguez et al. [14-
10 15] and Gandul et al. [16-17]. Also the separation of olive oil chlorophyll and carotenoid
11
12 67 pigments by thin layer chromatography and spectrophotometric identification has been
13
14 68 described [18].
15

16
17 69 Mínguez et al. [19] describes a simple way for the determination of overall level of
18
19 70 carotenoids and chlorophylls in olive oils which improved analysis speed, which is a factor
20
21 71 worth pointing out. However, it still requires the use of solvents and a considerable amount
22
23 72 of time for data processing. Taking into account the specific extinction coefficients of these
24
25 73 pigments, and the usual level of concentration in olive oils, it is usually necessary a
26
27 74 previous dilution of samples in order to achieve a measurable absorbance value. However,
28
29 75 another way of getting these measurable absorbance values could be the use of a shorter
30
31 76 pathlength during absorbance measurements.
32

33 77 In the context of raising competition in the olive sector, technological innovation must play
34
35 78 an important role by providing the necessary improvements in the sector to live up to the
36
37 79 circumstances. On the other hand, the environmental protection concern should be taken
38
39 80 into account. Among the different actors involved in the production and marketing of olive
40
41 81 oil, the industry plays a key role. In the olive mill, instant olive oil characterization is
42
43 82 required to separate the different products in different deposits, according to their
44
45 83 characteristics, thus maintaining its quality, identity and traceability. These intensive
46
47 84 controls of olive oil quality would be possible only with analytical systems able to provide
48
49 85 immediately and continuously all necessary information. Using the techniques available up
50
51 86 to date, this is not possible yet satisfactorily. The non-destructive techniques are an
52

1
2
3
4
5
6
7
8
9 87 alternative which is expected to provide new solutions, requiring its development and
10 88 validation.

11
12
13 89 With these purposes, Sikorska et al. [20] reported the capability of the fluorescence
14 90 techniques to monitor chlorophyll content in oil products. Otherwise, the interaction
15 91 between pigments and near-infrared radiation (750–2500 nm) could provide useful
16 92 correlations for determining olive oil chlorophylls and carotenoids. In fact, near infrared
17 93 spectroscopy (NIRS) has been reported multiple times for plant pigment determination [21-
18 94 27], as well the suitability of NIRS to determine the main olive oil quality parameters, such
19 95 as acidity, peroxides, K270 and K232, has been shown repeatedly [28-32]. Monitoring
20 96 carotenoid and chlorophyll in virgin olive oil has been reported by visible-near infrared
21 97 transmittance spectroscopy (VIS-NIRS) [26], although in this study the separate analysis of
22 98 the wavelengths that contribute to the predictive models of chlorophylls and carotenoids is
23 99 very scarcely reported. Nevertheless, the use of the VIS spectrum only could be better than
24 100 their use together with the NIR region for predictive model for these pigments. The
25 101 literature on the use of visible spectroscopy for the determination of quality parameters of
26 102 olive oil is very little, very recently being reported the potential of UV-Visible spectroscopy
27 103 as fingerprint technique in combination with chemometrics for classification of Spanish
28 104 extra virgin olive oils [33]. Thus, there are much interest on clarify the respective
29 105 contributions of visible and NIR regions in predictive models for these olive oil's
30 106 compounds, as the simplicity of the technique may have a significant impact in reducing
31 107 the cost of the instrument used.

1
2
3
4
5
6
7
8
9 108 In the other hand, regarding multivariate methods, when the factors are few in number, are
10 109 not significantly redundant and have a well-understood relationship to the responses, then
11 multiple linear regression (MLR) can be a good way to turn data into information.
12 110
13 111 However, if any of these three conditions breaks down, MLR can be inefficient or
14 inappropriate. Partial Least Squares (PLS) is a method for constructing predictive models
15 112 when the factors are many and highly collinear [34]. Principal Component Regression
16 113 PCR) is also a popular method intended to overcome the problem of multicollinearity
17 114 which arises with spectral data [35]. The difference between PLS and PCR is usually quite
18 115 small, but PLS [36] will usually give results comparable to PCR-results using fewer
19 116 components [37].

20 118 ~~For this purpose~~To answer the above questions, here is reported a study on method for
21 119 determination of chlorophylls total and carotenoids total in olive oil by using VIS
22 120 multivariate models. †The contribution of the spectral regions ultraviolet (UV, 350-400
23 121 nm), VIS (400-779 nm) and NIR (780-2500 nm) to predictive models of total chlorophylls
24 122 and total carotenoids of olive oil have been studied. from the spectral regions ultraviolet
25 123 (UV, 350-400 nm), VIS (400-779 nm) and NIR (780-2500 nm) is reported. Chlorophylls
26 124 total and carotenoids total in olive oil have been determined by using VIS multivariate
27 125 models, which performance were better than that obtained from single wavelengths. A short
28 126 optical pathlength of 5 mm was used for the purpose of getting measurable absorbance
29 127 values without olive oil dilution. The procedures Single Linear Regression (SLR), Multiple
30 128 Linear Regression (MLR), Principal Component Regression (PCR) and Partial Least
31 129 Squares (PLS) were tested. The technique proposed is truly rapid and non-destructive, it
32 130 does not require the use of solvents or reagents, it is environmentally friendly and can be

1
2
3
4
5
6
7
8
9 131 | ~~used in a multi-parameter form. On the other hand, it is potentially less prone to~~
10 132 | ~~experimental errors, because there is neither sample weighing nor volume adjustment.~~

11
12
13 133 | **Materials and methods**

14
15
16 134 | Virgin olive oils

17
18 135 | The development of predictive models was carried out based on spectra acquisition and
19
20 136 | reference analysis of VOO extracted in the Instituto de la Grasa (CSIC), from samples
21
22 137 | provided by a research project, taken in different olive groves of the provinces of Seville
23
24 138 | and Huelva. All the samples were extracted by a lab mill MC2 (Ingeniería y Sistemas, S.L.,
25
26 139 | Spain). The VOO samples amounted to 258, and were composed of the varieties Picual,
27
28 140 | Arbequina and Manzanilla in equal quantities. The first two are quantitatively important
29
30 141 | cultivars in the production of olive oil in Spain. Manzanilla cv. is for table olives, but each
31
32 142 | campaign a small part of its production is used for olive oil extraction, with specific quality
33
34 143 | characteristics highly valued. The reason of including different olive cultivars in the study
35
36 144 | is to assure diversity in sample pigments composition. Olive oil samples were stored at 4°C
37
38 145 | until spectra acquisition.

39
40 146 | Instrumentation

41
42 147 | Spectral acquisition was carried out using an UV/VIS/NIR Labspec Pro (Analytical
43
44 148 | Spectral Devices Inc., Boulder). Labspec Pro is equipped with three detectors. The detector
45
46 149 | for the ultraviolet and visible range (350-1000nm) is a fixed reflective holographic diode
47
48 150 | array. The wavelength range 1000-1800 nm is covered by a holographic fast scanner
49
50 151 | InGaAs detector cooled at -25°C. The same device before mentioned coupled with a high

1
2
3
4
5
6
7
8
9 152 order blocking filter operates over an 1800-2500 nm interval. The instrument is equipped
10 153 with internal shutters and automatic offset correction, the scanning speed being 100 ms.
11
12 154 The spectrometer can be used with a spectrophotometric cuvette accessory for
13
14 155 transmittance measurement, joined by fiber optic connectors to the light source
15
16 156 spectrometer by one side of the accessory and to a detector on the opposite side.

17 18 19 157 Spectral acquisition

20
21 158 The performance of the models built including the NIR spectrum together with the visible
22
23 159 is to be assessed. Hence, the temperature of the sample should be considered since it plays
24
25 160 an important role on the NIR radiation it reflects and absorb [348], and it constitutes a
26
27 161 decisive factor in NIR spectroscopy. Therefore, the samples were taken from 4 °C storage
28
29 162 and placed in a laboratory at approximately 25 °C for 18 h before processing. Prior to the
30
31 163 recording of spectra, 125 mL containers of the samples were placed in a thermostated water
32
33 164 bath fixed at 33 °C for 30 min, verifying temperature stability. The spectra acquisition was
34
35 165 performed nondestructively in transmittance mode with each virgin olive oil sample,
36
37 166 without further sample preparation, for two replicates of each sample. For the purpose of
38
39 167 avoiding the use of cleaning solvents, the quartz cuvette was cleaned after each spectrum
40
41 168 acquisition using oil excess from the next sample.

42
43 169 The whole spectrum comprised in the interval 350-2500 nm was acquired, each spectral
44
45 170 variable corresponding to a 1 nm interval. The spectrometer was configured for continuous
46
47 171 acquisition of 50 spectra, recorded their average as representative spectrum of the sample.
48
49 172 Scans were performed in a Hellma quartz spectrophotometric cuvette with 5 mm path
50
51 173 length. Indico Pro software (Analytical Spectral Devices Inc., Boulder) was used for this

1
2
3
4
5
6
7
8
9 174 purpose. The acquisition process required for each sample was less than a minute, all steps
10 175 included.

11
12
13 176 Reference analysis

14
15
16 177 Chlorophyll total and carotenoids total analyses in olive oils samples were determined
17 178 through the method described by Mínguez et al. [19]. Briefly, the chlorophyll and the
18 179 carotenoid fractions were evaluated from the absorption spectrum at 670 nm and 470 nm
19 180 respectively, from the pigment extract in cyclohexane (Merck for spectroscopy, Darmstadt,
20 181 Germany), using the same solvent as blank reference. The absorption maximum at 670 nm
21 182 in the spectrum of the total extract is due exclusively to the presence of the chlorophyll
22 183 fraction. As pheophytin "a" is the major component of this fraction, the group of
23 184 chlorophyll derivatives can be evaluated as if all were pheophytin "a", after calculating the
24 185 coefficient of specific extinction in cyclohexane. The value in ethyl ether is $\mathcal{E}_o = 613$ nm
25 186 [19].

26
27
28
29
30
31
32
33
34
35
36 187 The spectrum of the carotenoid fraction takes the form of the dominant pigment, lutein.
37 188 Thus, it is possible to evaluate the yellow pigments in the total spectrum as if they are all
38 189 lutein [19]. The maximum at 470 nm is chosen after obtaining the corresponding coefficient
39 190 of extinction because it is a zone without interference from the pheophytin "a". This value
40 191 is reported $\mathcal{E}_o = 2000$ [19].

41
42
43
44
45
46
47
48 192 For the procedure, 7.5 g oil were weighed exactly, dissolved in cyclohexane and taken to a
49 193 final volume of 25 mL. Once the absorption spectrum was obtained, the chlorophyll total

1
2
3
4
5
6
7
8 194 and carotenoids total fractions were deduced at 670 nm and 470 nm respectively, and
9
10 195 expressed as mg.Kg⁻¹. All the samples were measured with two replicates.

11
12
13 196 Chemometry and calibration procedure

14
15
16 197 Prior to calibrations the transmittance data were transformed to absorbance and mean
17
18 198 normalized. Savitzsky-Golay derivatives first and second were tested to see if they improve
19
20 199 the performance of the models. The UV, VIS and NIR spectral regions were tested to prove
21
22 200 the advantages these can provide, either using exclusively the NIR spectrum (1100-2500
23
24 201 nm), or by using the visible spectrum (400-1099 nm) together with UV (350-399 nm) and
25
26 202 NIR.

27
28 203 Partial Least Squares (PLS) was used for the selection of the specific spectral variables
29
30 204 which should be included in the models. The procedure of selection consisted on
31
32 205 performing several consecutive cycles of elimination of variables whose contribution to the
33
34 206 model is null. It was made by selecting those variables whose spectral correlation
35
36 207 coefficients with the parameter analyzed were closer to zero. This elimination was carried
37
38 208 out by using the 'Mark with rectangle' option on the regression coefficients graph of The
39
40 209 Unscrambler. Variable selection ended in the last cycle which improved the statistical
41
42 210 model R² and R²_{cv}. Model fitness was assessed by its standard error of calibration (SEC)
43
44 211 and proximity between R² and R²_{cv}, independently from the model validation procedure
45
46 212 below described

47
48 213 The methods Principal Component Regression (PCR), Multiple Linear Regression (MLR)
49
50 214 and Single Linear Regression (SLR) were tested. ~~Single linear regression (SLR), multi~~

19 242 **Results and discussion**

20 21 22 243 Olive oil visible spectrum

23
24 244 The assignment of the major visible absorption bands of olive oil has been described by
25 245 Moyano et al. [9]. Olive oil visible spectra characteristic of the Picual, Manzanilla and
26 246 Arbequina are shown in Figure 1. An initial peak appeared close to 420 nm. This area
27 247 corresponds to the absorption by olive oil of wavelength dark blue colored light, which
28 248 could be due mainly to carotenoids, as well as to pheophytin a, pheophorbide a and
29 249 pyropheophytin a. A second peak near 460 nm was found, corresponding to the absorption
30 250 of the blue light, characteristic of carotenoids. Finally, a third peak was observed
31 251 approximately at 670 nm, coinciding with the chlorophyll absorption.

1
2
3
4
5
6
7
8
9 257 the calibrations, as can be seen. The chlorophyll total and carotenoids total contents average
10 258 from the calibration set analyzed were 17.23 ± 15.83 and 11.08 ± 7.46 mg.Kg⁻¹, respectively.

11
12
13 259 Spectral Variable Analysis and Chemometry

14
15
16 260 The tests carried out using Savitzky-Golay derivatives first and second didn't improve the
17 261 fit of the models, whereas the absorbance data mean normalized provided the best
18 262 outcomes. The visible window of 670-686 nm gave the best performance for predicting
19 263 chlorophyll total, as result from the tests with different wavelength intervals, as is detailed
20 264 below. On the contrary, the entire spectrum available (350-2500 nm) brought the best
21 265 yields for carotenoids total. As is shown in Table 2, the PLS models built exclusively from
22 266 NIR region provided R² 0.56 and 0.62 for the predictive models of chlorophylls and
23 267 carotenoids respectively, values which are too low for intend to use these models for
24 268 analysis.

32
33 269 Chlorophylls

34
35
36 270 The tests to determinate the wavelengths with an optimal contribution to the total
37 271 chlorophylls predictive calibration procedure of multivariate analysis indicated the most
38 272 appropriate suitable for total chlorophylls was MLR (Ch₁) using the VIS window 670-686
39 273 nm. The best procedure of multivariate analysis using this window was MLR (Ch₁), as
40 274 proven from its statistics R² 0.97 and SEC 2.63, shown in Table 2. PLS (Ch₂) and PCR
41 275 (Ch₃) using the same wavelengths showed lower performance, and very similar between
42 276 both according their statistics, with R² 0.96 for both and SEC 3.20 and 3.22 (Table 2).
43 277 Interestingly, both PLS and PCR, did provide R2 slightly lower only than MLR, but their
44 278 SEC were 21.7% and 22.7% higher, hence they were worst. The calibration developed

1
2
3
4
5
6
7
8
9 279 using VIS and NIR regions, by using the procedure previously described for selection of
10 280 spectral variables (Ch₄), did not improve statistical indicators of calibration neither the
11 281 predictive performance compared to Ch₁, as it was proved by the data shown in Table 2,
12 282 with SEC 3.13. Particularly noteworthy is the predictive model obtained by SLR (Ch₅) with
13 283 the only variable corresponding to a spectral wavelength of 670 nm, the same used in the
14 284 K₆₇₀ reference, showed low efficacy with SEC 5.71. This fact emphasizes that using one
15 285 only wavelength is not a better approach for determining chlorophylls by visible
16 286 spectroscopy than using the multivariate method with the window 670-686 nm. Likewise,
17 287 the models built using MLR with the window restricted to 670-672 nm spectral variables
18 288 were no better (data not shown). On the other hand, the calibration built exclusively using
19 289 NIR (Ch₆) gave the worst performance among the methods assessed, as evidenced by their
20 290 SEC 10.47 and R² 0.56 values (Table 2). These data reveal that chlorophyll content of the
21 291 olive oil does not appear to be significant in the NIR spectrum. The good fit among
22 292 prediction and measurement from the data used for the chlorophyll total calibration Ch₁
23 293 using the VIS window 670-686 nm is shown in Figure 2.

24
25

27
28
29
30
31
32
33
34
35
36
37
38 294 The assessment of the models was mainly carried out by using them to determine the
39 295 chlorophyll total content of a set of 54 samples, which was initially reserved for this
40 296 purpose. The RPD of each multivariate procedure from the same validation set, proves the
41 297 results referred above. The dispersion plot of this prediction is demonstrated in Figure 2
42 298 (Vch₁). As it's evidenced by the RPD value 5.76, shown in Table 2, the predictive model
43 299 performance was very satisfactory. This ratio, the most widely used for determining the
44 300 acceptability of a model, must reach the threshold of 3 for this purpose [36], which was
45 301 fairly exceeded.

1
2
3
4
5
6
7
8
9 302 VIS/NIR transmittance spectroscopy has been reported successful for on-line monitoring
10 303 carotenoid and chlorophyll pigments in virgin olive oil [26], where the separate analysis of
11 304 the wavelengths contributing to the predictive models of chlorophylls and carotenoids was
12 305 very scarce. The PLS model carried out in the present work including NIR together VIS
13 306 regions (Ch₄), similarly to the work is reported above [26], provides RPD 4.05 which
14 307 shows is valid for practical use and agrees with the study referred. However, its
15 308 performance was clearly lower to the model built using wavelengths VIS only.

21
22
23 309 Figure 2

24
25 310 The spectral windows more suitable for build the models were slightly different among the
26 311 different multivariate analysis methods (data not shown), that highlights the interaction
27 312 between the variables and the model method. Hence, it reveals that most appropriate
28 313 spectral variables to predict a certain parameter may depend on the nature of the predictive
29 314 model.

30
31
32
33
34
35 315 Carotenoids

36
37
38 316 The tests to determinate the wavelengths with an optimal contribution to the total
39 317 carotenoids predictive calibration revealed the most suitable was the VIS window 465-475
40 318 nm. The PLS (Ca₁) and PCR (Ca₂) models using these visible wavelengths of 465-475 nm
41 319 window developed using PLS (Ca₁) and PCR (Ca₂) showed statistics SEC 2.28 and 2.30
42 320 and R² 0.91 and 0.90, which are very similar, and RPD 3.68 from the external validations
43 321 both (Table 2). These results demonstrate that using this window of the visible spectrum is
44 322 suitable to determine total carotenoids. The calibration developed using MLR with the
45 323 same wavelengths 465-475 nm (Ca₃) showed statistics similar to those from PLS and PCR,

1
2
3
4
5
6
7
8
9 324 although the SEP 2.11 and RPD 3.31 from the external validation were worst. This gospel
10 325 agrees with the possibility of deleting factors, thus reducing dimensionality, what
11 326 constitutes the major advantage of PCR regarding MLR. The possible advantage of PLS
12 327 over PCR is that it incorporates more information in the model-building phase [35], and
13 328 reflected actually on the R^2 and SEC of the predictive models of total carotenoids built by
14 329 PLS, slightly better than that of PCR.

Formatted: Superscript

20 330 Nevertheless, the best performance for predicting the total carotenoids of the olive oils was
21 331 brought by the PLS model built from the entire spectrum available of 350-2500 nm (Ca_4),
22 332 being proven for the calibration SEC 1.74 and R^2 0.95 and RPD 3.86 from the external
23 333 validation exercises, shown in Table 2. As in the case of predicting total chlorophyll, this
24 334 result agrees with the previously referred study [26], which reported as successful the on-
25 335 line monitoring of the total carotenoids of virgin olive oil using VIS/NIRS.

32 336 Again we must emphasize that models constructed by SLR (Ca_5) from the single spectral
33 337 variable 470 nm used in the reference method showed no better performance than using the
34 338 wavelengths 465-475 nm, that is demonstrated by the SEP 2.63 and RPD 2.66 from the
35 339 external validation and by the calibration R^2 0.81 and SEC 3.27, included in Table 2. As
36 340 well, the PLS model developed from exclusively NIR region for predicting total
37 341 carotenoids provided the worst outcome, with R^2 0.62, value which is too low for intend to
38 342 practical use. The good fit among predictions and measurements from the calibration for
39 343 total carotenoids from the exclusively visible window of 465-475 nm is shown in Figure 3
40 344 (Ca_1) and the same from the external validation (Vca_1). The PLS model VIS/NIRS from

14
15
16 348 **Conclusions**

17
18 349 Multivariate models set in this work from the wavelength intervals 670-686 nm for total
19 350 chlorophylls and 465-475 nm for total carotenoids clearly improved those built by SLR
20 351 from the single wavelengths used in the reference methods. None of the wavelengths from
21 352 the spectrum NIR or UV regions assessed in this study provided any improvement in the
22 353 performance of the multivariate model for total chlorophylls.

23
24 354 The spectral variables used in the models were very few, allowing the use of VIS standard
25 355 spectrophotometers, therefore relatively inexpensive. The technique proposed is truly rapid
26 356 and non-destructive, and easy to use also. Moreover, it is potentially less prone to
27 357 experimental errors, because there is neither sample weighing nor volume adjustment.
28 358 Another major advantage is the possibility of a multi-parametric determination of
29 359 chlorophylls and carotenoids from a single measurement. Last but not least, it should be
30 360 noted that the technique proposed is environmentally friendly, avoiding a considerable
31 361 consumption of solvents or reagents, which aids in avoiding environmental costs. In
32 362 summary, the proposed technique can be advantageous for the determination of total
33 363 chlorophylls and carotenoids.

509 Figure 4. Predictive model VIS/NIRS for total carotenoids (Ca₄) and external validation
510 (Vca₄).

For Peer Review

	Total chlorophylls		Total carotenoids	
	<i>Calibration</i>	<i>Validation</i>	<i>Calibration</i>	<i>Validation</i>
N ^a	205	53	205	50
Range	1.39-88.13	1.47-74.35	2.05-38.53	2.62-36.16
\bar{X} ^b	17.23	15.58	11.08	10.39
σ ^c	15.83	13.99	7.46	6.99

Table 1. Statistics of chlorophylls and carotenoids from the calibration and validation sets. ^aN, size; ^b \bar{X} , mean (mg Kg⁻¹); ^c σ , standard deviation (mg Kg⁻¹).

For Peer Review

Model	Total chlorophylls				Total carotenoids				
	Calibration		Validation		Model	Calibration		Validation	
	R ²	SEC	SEP	RPD		R ²	SEC	SEP	RPD
Ch ₁ -MLR	0.97	2.63	2.43	5.76	Ca ₁ -PLS	0.91	2.28	1.90	3.68
Ch ₂ -PLS	0.96	3.20	2.73	5.12	Ca ₂ -PCR	0.90	2.30	1.90	3.68
Ch ₃ -PCR	0.96	3.22	2.72	5.14	Ca ₃ -MLR	0.91	2.19	2.11	3.31
Ch ₄ -PLS ^a	0.96	3.13	3.51	4.05	Ca ₄ -PLS ⁽¹⁾	0.95	1.74	1.81	3.86
Ch ₅ -SLR	0.87	5.71	4.27	3.28	Ca ₅ -SLR	0.81	3.27	2.63	2.66
Ch ₆ -PLS ^b	0.56	10.47			Ca ₆ -PLS ⁽²⁾	0.62	4.58		

Table 2. Statistics of the models built by Multiple Linear Regression (MLR), Principal Component Regression (PCR), Partial Least Squares (PLS), Simple Linear Regression (SLR), PLS from UV, VIS and NIR regions (PLS^a) and PLS from exclusively NIR region (PLS^b). R², model squared coefficient of calibration; SEC, standard error of calibration; SEP, standard error of performance; RPD, residual predictive deviation.
