26 **Short title:** Natural or synthetic variations in human bocavirus 1 capsids

27 **ABSTRACT**

28 Human bocavirus 1 (HBoV1) is a parvovirus that gathers increasing attention due to its
29 pleiotropic role as a pathogen and emerging vector for human gene therapy. Curiously, albeit a
30 large variety of HBoV1 capsid variants has been isolated from human samples, only one has
31 been studied as a gene transfer vector to date. Here, we analyzed a cohort of HBoV1-positive
32 samples and managed to PCR-amplify and sequence 29 distinct HBoV1 capsid variants. These
33 differed from the originally reported HBoV1 reference strain in 32 nucleotides or four amino
34 acids, including a frequent change of threonine to serine at position 590. Interestingly, this
35 T590S mutation was associated with lower viral loads in infected patients. Analysis of the time
36 course of infection in two patients for up to 15 weeks revealed a gradual accumulation of
37 T590S, concurrent with drops in viral loads. Surprisingly, in a recombinant vector context,
38 T590S was beneficial and significantly increased titers as compared to T590 variants but had no
39 major impact on their transduction ability or immunoreactivity. Additional targeted mutations in
40 the HBoV1 capsid identified several residues that are critical for transduction, capsid assembly
41 or DNA packaging. Our new findings on the phylogeny, infectivity and immunoreactivity of
42 HBoV1 capsid variants improve our understanding of bocaviral biology and suggest strategies
43 to enhance HBoV1 gene transfer vectors.

44

45 **IMPORTANCE**

46 The family of *Parvoviridae* comprises a wide variety of members that exhibit a unique biology
47 and that are concurrently highly interesting as a scaffold for the development of human gene
48 therapy vectors. A most notable example is human bocavirus 1 (HBoV1), which we and others
49 have recently harnessed to cross-package and deliver recombinant genomes derived from
50 another parvovirus, the adeno-associated virus (AAV). Here, we expanded the repertoire of
51 known HBoV1 variants by cloning 29 distinct HBoV1 capsid sequences from primary human
52 samples and by analyzing their properties as AAV/HBoV1 gene transfer vectors. This led to our

53 discovery of a mutational hot spot at HBoV1 capsid position 590 that has accumulated in two
54 patients during natural infection and that lowers viral loads but increases vector yields. Thereby,
55 our study expands our current understanding of HBoV1 biology in infected human subjects and
56 concomitantly provides avenues to improve AAV/HBoV1 gene transfer vectors.

77

78 INTRODUCTION

79 Parvoviruses are small, non-enveloped viruses that package a single-stranded (ss)DNA
80 genome of ~5-6 kb. This genome contains two main open reading frames (ORF) that comprise
81 the non-structural (*ns*) and the capsid genes (*cap* or *vp*). Bocaviruses (BoV), which belong to
82 the autonomous parvoviruses, harbor an additional unique ORF that encodes the
83 nucleophosphoprotein 1 (NP1). Intriguingly, a series of recent reports implies that ssDNA
84 viruses including parvoviruses may evolve more rapidly than anticipated, evidenced by
85 measurements of high nucleotide substitution rates (10^{-3} to 10^{-6} substitutions/site/year) that are
86 comparable to the rate of RNA virus counterparts (1, 2). For example, high rates of 1×10^{-4}
87 substitutions/site/year were inferred for some autonomous parvoviruses such as the carnivore
88 parvoviruses (3, 4), human parvovirus B19 (5) and porcine parvovirus (6). Moreover, several
89 studies have estimated a similar rate of both, structural and non-structural parvovirus gene
90 evolution. For example, in human bocavirus 1 (HBoV1), the *np1* ORF shows the highest rate of
91 mutations among the *ns* genes that correlates with significant changes in viral titer (7). This
92 could be a result of the multiple roles of NP1 in viral replication (8) and capsid protein
93 expression (9), in addition to its immunomodulatory function (10). Changes in the C-terminal
94 part of the *ns1* ORF were shown to directly influence the role of NP1 in viral genome replication
95 (8), which underlines the importance of a tightly regulated co-evolution of the non-structural
96 genes. Viral titers are also influenced by mutations in the structural *vp* gene, especially in the
97 VP1u region that is vital for the infectivity of the virus (7, 11).

98 The parvoviral capsid is an important determinant of virus tropism, host range and reaction to
99 the immune system. It was shown that even small amino acid (aa) changes in the *vp* ORF can
100 largely alter virus-cell interactions including cell-type preference. For instance, adeno-
101 associated virus type 1 (AAV1) and AAV6 share 99% aa identity but exhibit a distinct polarity
102 bias in primary airway epithelia (pHAE) (12) as well as different abilities to transduce human and

103 mouse hematopoietic stem cells (13). Even aa changes in the VP proteins within one AAV
104 serotype can drastically alter viral features, as exemplified by the two sub-types of AAV3,
105 AAV3a and AAV3b, which differ by only 6 aa but display distinct affinities to heparin (14, 15).
106 Another example is the pair of rodent parvoviruses MVMP and MVMI (minute virus of mice) that
107 share 97% sequence identity but differ in their *in vitro* (16) and *in vivo* cell tropisms (17).
108 Similarly, the CPV2 and CPV-2a strains (canine parvovirus) differ only in four amino acids,
109 which, however, lead to the extended feline tropism of CPV-2a (18).

110 This rich repertoire of parvoviruses with distinct properties has drawn enormous interest to their
111 potential use as gene transfer vectors in cancer and gene therapy. In the recombinant genomes
112 of these vectors, either all viral sequences or parts thereof are replaced by transgenes of
113 interest. To package the recombinant genomes, the missing viral elements have to be supplied
114 *in trans* during vector production (19-22). In particular, AAV has emerged as a promising viral
115 vector following its extensive study for over five decades. A major reason for its popularity is the
116 feasibility to pseudotype recombinant AAV2 genomes with AAV capsids from other natural
117 serotypes or synthetic variants, which allows for transgene delivery to different target organs
118 (23). Another recent example of interesting parvoviral vectors are chimeric rAAV/BoV vectors in
119 which a rAAV genome is pseudotyped with the capsid proteins from primate BoV (22, 24). One
120 of these BoV variants, HBoV1, has a unique tropism for the airways and has been utilized as
121 gene delivery vehicle *in vitro* and *in vivo* (25). Curiously, despite the wealth of HBoV1 *vp*
122 sequences that were isolated in many areas of the world, only one particular HBoV1 variant
123 (GenBank: GQ925675) has so far been used as viral vector.

124 Accordingly, we aimed to study whether and how naturally occurring variations in the HBoV1 *vp*
125 sequence affect properties of the virus. To this end, we constructed a battery of new
126 pseudotyped viral vectors from HBoV1 variants that were *de novo* isolated from patient samples
127 or described in previous studies. Next, we packaged a *Gaussia* luciferase (Gluc)-encoding rAAV

128 genome into each of the various HBoV1 capsids. This allowed us to characterize the effects of
129 naturally occurring single-point mutations ("singletons") on viral DNA packaging, transduction
130 and immunological reactivity with anti-HBoV1 antibodies. The results of our work reveal
131 interesting, previously underappreciated aspects of HBoV1 biology and have important
132 implications for the choice and use of rAAV/HBoV1 vectors in future gene therapy applications.

133

134 **RESULTS**

135 *Analysis of capsid DNA and protein sequence diversity in naturally occurring HBoV1 variants*

136 To analyze the natural sequence diversity of HBoV1 capsid genes and proteins, we collected a
137 total of 64 samples from patients at the University Hospitals in Heidelberg and Cologne (both
138 Germany) who had previously been tested positive for HBoV1. These samples comprised
139 tracheal secretions, aspirates, pharyngeal washes, sputum as well as bronchioalveolar lavages
140 collected from children and adults in the years 2014 to 2016. From these 64 samples, we were
141 able to PCR-amplify and sequence the entire HBoV1 capsid-coding region (2016 bp) in 29
142 samples, *i.e.*, in 45.3% of all samples (exemplified in Fig. 1A; full DNA sequences are shown in
143 the Supplementary Dataset). Typically, failure to amplify or fully sequence the capsid gene
144 correlated with low viral titers in the original sample below 1×10^6 viral genomes (vg) per ml.

145 Interestingly, alignment of these 29 capsid DNA sequences with the HBoV1 reference sequence
146 that was first reported by Allander *et al.* in 2005 (GenBank: DQ000495; note that this is not the
147 sequence that is utilized in current HBoV1 vectors) showed differences in 32 nucleotide
148 positions. As summarized in Supplementary Table 1 and Fig. 1B, the newly analyzed
149 sequences carry between four and 19 mismatches with this reference sequence, corresponding
150 to an average of 12.7 nucleotide differences per variant (368 variations in total, divided by 29
151 samples). Accordingly, their overall DNA sequence identity to DQ000495 is 99.1 to 99.8%, or

152 99.4% on average. Moreover, we noted that the mutations cluster in 14 of the 32 positions,
153 namely, 441, 445, 714, 984, 1140, 1168, 1170, 1176, 1188, 1308, 1758, 1767, 1768 and 1785
154 (numbers are nucleotide positions in the HBoV1 *vp1* capsid gene), where more than half of the
155 29 sequences differed from the reference.

156 On the protein level, these point mutations translated into substitutions at four positions in the
157 671 aa HBoV1 VP1 capsid protein, as compared to the DQ000495 reference (Fig. 1C). Each of
158 the 29 sequences differed in one to three positions, namely, 68, 149, 474 or 590 (numbers are
159 aa positions in VP1), corresponding to identities of 99.6 to 99.9% (99.8% on average). Hence,
160 the majority of nucleotide exchanges was silent on the VP1 protein level. Again, we observed a
161 clustering of the mutations, most notable at aa position 149 (red in Fig. 1B-C) where 100% of all
162 analyzed sequences carry a threonine instead of the alanine reported by Allander and
163 colleagues (26). The second striking difference is seen at position 590 (orange in Fig. 1B-C)
164 where we detected a serine instead of a threonine in 15 out of the 29 sequences. In addition,
165 sample V1541706 carries asparagine instead of aspartate at position 68, and samples VK11443
166 and VK12783 have a replacement of serine with asparagine at position 474.

167 Next, we performed a phylogenetic analysis of all 29 DNA sequences together with 21 publicly
168 available HBoV1 sequences from 14 countries and four continents. Additionally, we included the
169 related viruses HBoV2, 3 and 4 (GenBank: NC012042, NC012564 and NC012729, respectively)
170 as well as the non-primate bocaviruses, canine minute virus (NC004442) and bovine parvovirus
171 1 (NC001540), which we collectively defined as outgroup. This analysis confirmed that all 29
172 HBoV1 *vp* sequences cluster together with the 21 public sequences and are clearly distinct from
173 the outgroup (bootstrap value of 99) (Fig. 1D).

174 *Correlation of HBoV1 capsid sequence diversity and virus infectivity*

175 In addition to the primary sequence, we analyzed the viral load in the original set of 64 HBoV1-
176 positive patient samples that we had collected. By using quantitative (q)PCR, we succeeded at

177 measuring the viral load for 39 samples, comprising the 29 for which we had previously
178 obtained the full capsid sequence (see above) as well as 10 others where this information was
179 lacking. The values obtained ranged from 1.82×10^3 to 6.13×10^{10} vg/ml, with a median of
180 3.91×10^6 vg/ml (Fig. 2A). Prior work had defined a cutoff of 1×10^6 vg/ml above which symptoms
181 of HBoV1 infection manifested in outpatients or inpatients (27). Accordingly, we can classify 15
182 of the 39 samples as having a viral load below this cutoff, while the other 24 are above.

183 As described above, HBoV1 VP1 aa position 590 is a hotspot for a change from threonine in
184 DQ000495 to serine. In line with this, we noted that roughly half of the samples whose viral load
185 we had determined carry a serine at this position. We thus correlated the occurrence of either
186 threonine or serine with viral load for 31 of the 39 samples. This subset was selected based on
187 the criteria that we could read over 90% of the complete capsid sequence and that we could
188 unanimously identify position 590 as threonine or serine. Remarkably, this analysis showed that
189 HBoV1 variants carrying a serine (T590S, n=17) have a ~18-fold lower viral load than those with
190 the originally reported threonine (T590, n=14) (Fig. 2B). In detail, the average viral load for the
191 T590S variant was 5.55×10^8 vg/ml, in contrast to 1.02×10^{10} vg/ml for variant T590.

192 Among the analyzed samples, several had been collected from the same patient(s) at various
193 time points, which allowed us to study dynamic changes in the HBoV1 capsid sequence and
194 measure alterations in the viral load during the course of an infection. The results are depicted
195 in Fig. 2C for patient A (four time points over a period of 15 weeks) and Fig. 2D for patient B
196 (five time points over a period of three weeks). Changes at the nucleotide level over time were
197 observed at positions 804, 873, 1140, 1168, 1170, 1701, 1767, 1768 and 1785. Two examples
198 that were identified in both patients and that are illustrated in Fig. 2C-D are a gradual change of
199 thymine to cytosine at position 1140, or a change of guanine to adenine at position 1170.
200 Intriguingly, while these two mutations were silent on the protein level, we found that the gradual
201 replacement in both patients over time of the nucleotide sequence 5'-AA-3' at position

202 1767/1768 by 5'-CT-3' resulted in an exchange of threonine at aa position 590 to serine, *i.e.*, the
203 same mutation that we had already observed and highlighted before. Congruent with the data in
204 Fig. 2B, we measured a consistent drop in viral loads over time that concurred with the
205 accumulation of the T590S mutation. This is evidenced by a reduction of viral loads in patient A,
206 from 3.11×10^9 vg/ml at the earliest time point to 7.46×10^3 vg/ml at the latest (week 15) (Fig. 2C,
207 E). Likewise, the viral loads in patient B dropped from 1.57×10^{10} vg/ml to 3.91×10^6 vg/ml over
208 the course of three weeks (Fig. 2D-E).

209 *Dissection of the impact of changes in the vp ORF using recombinant HBoV1 vectors*

210 To further study the impact of the observed natural or, introduced later in this work, synthetic
211 point mutations in the HBoV1 capsid, we harnessed a streamlined system for production of
212 recombinant HBoV1 gene transfer vectors that we have established recently (24). Its hallmark is
213 the ability to package rAAV vector genomes encoding a reporter into HBoV1 capsids, by triple-
214 transfecting HEK293T cells with three plasmids expressing all necessary factors including the
215 HBoV1 capsid proteins, and by purifying the resulting vector particles via iodixanol density
216 gradient centrifugation. Specifically, here, we used an AAV vector genome expressing *Gaussia*
217 luciferase (Gluc), which is a secreted protein that is easily detected in the supernatant of
218 cultured cells. For the latter, we used primary human airway epithelia (pHAE) based on findings
219 by others and us that these are highly susceptible to HBoV1 transduction (24, 28).

220 In total, we studied 18 HBoV1 capsid variants using this system, which comprised seven from
221 our collection that had high viral loads between 3.4×10^9 and 6.1×10^{10} vg/ml and that exemplified
222 the roughly equal distribution of either serine or threonine at position 590 (Fig. 3A-B; samples
223 V1500812, V1602382, V1502611, V1512195, V1541706, V1613007 and VK11443). As
224 compared to DQ000495, they differ in five to 18 nucleotides, or one to three amino acids. As
225 two references, we included DQ000495 as well as GQ925675, *i.e.*, the HBoV1 capsid variant
226 that has been used in all recombinant HBoV1 vector preparations reported to date (24, 25, 29).

227 Furthermore, we selected nine variants that were described by Principi *et al.* in 2015 and that
228 differ from DQ000495 in one to six amino acids (27). As the original sequences were not
229 available to us as molecular clones, we recapitulated only non-synonymous substitutions that
230 cause aa changes by successive overlap-extension PCR using DQ000495 as template
231 (Supplementary Table 2 and 3). Of these nine capsids, seven were associated with high viral
232 loads between 5×10^8 and 7.5×10^9 vg/ml in the study by Principi and colleagues (27). The
233 remaining two variants from this study, named KPLGr1 and KPLGr2 here, represent two groups
234 of patient-derived HBoV1 capsid sequences that were identical within each group and that were
235 associated with low viral loads of 4.5×10^4 or 6.3×10^4 vg/ml, respectively. They were interesting
236 since KPLGr1 carries the T590S mutation, while KPLGr2 has T590, thus representing the
237 distribution of these two residues and making these two variants useful as additional controls.
238 Altogether, this set of 18 capsid variants was composed of six carrying T590 and 12 with
239 T590S.

240 *Titration of recombinant vectors based on HBoV1 capsid mutants*

241 To produce vectors based on the aforementioned 18 HBoV1 capsid variants, we performed
242 three independent runs using three 15 cm² dishes each, following our triple-transfection and
243 iodixanol purification scheme (24). Titration by quantitative (q)PCR revealed titers for the 54
244 (18×3) individual stocks between 6.51×10^8 to 6.61×10^{11} vg/ml (data not shown), with an
245 average of 9.65×10^{10} vg/ml. The majority of capsid variants yielded titers in a range of 2×10^{10} to
246 2×10^{11} vg/ml, with the notable exception of KPLMI-30 and KPLMI-3503 whose average titers
247 were 1.13×10^{10} or 2.15×10^9 vg/ml, respectively. In contrast, KPLGr1 and KPLGr2 that had been
248 associated with low viral loads in patients before (27) consistently produced well in our hands.

249 We subsequently pooled all three independent preparations per capsid variant and further
250 purified and concentrated them using Amicon Ultra-15 filter units. Final titers per nine 15 cm²
251 dishes per capsid variant were between 4.11×10^{10} to 2.4×10^{11} vg/ml (average of 1.1×10^{11} vg/ml,

252 Fig. 3C), again with the exception of KPLMI-30 and KPLMI-3503, which yielded 1.7×10^9 or
253 4.67×10^8 vg/ml, respectively. Titers for the 16 capsids that produced well were determined twice
254 since these stocks were used in later transduction experiments (see below). On average,
255 concentration using the Amicon Ultra-15 filters had resulted in a vector particle recovery of 42%.
256 Interestingly, we noted a highly significant difference between the HBoV1 capsids depending on
257 the presence of a threonine or serine at position 590. While the average titer of the six T590
258 variants was 6.66×10^{10} vg/ml, it was 1.59×10^{11} vg/ml for all capsids with the T590S mutation,
259 *i.e.*, 2.39-fold higher ($p=0.0003$, Fig. 3D). Of note, for this calculation, we excluded the two low
260 producers KPLMI-30 and KPLMI-3503 as they were obvious outliers. To facilitate the
261 comparison of candidates and to highlight their differences throughout this work, five candidates
262 were randomly chosen (including the two references DQ000495 and GQ925675) and colored.

263 *Comparison of the transduction efficiency of all HBoV1 capsid variants in pHAE*

264 To measure and compare the transduction efficiency of the 16 HBoV1 capsid variants that
265 produced well, we used pHAE from five different donors (labeled 171469, 171476, 171834,
266 171905, 171975 in the following). Each capsid was tested twice per donor ($n=10$ for each
267 variant) and compared to two negative controls (two wells of untransduced cells). Per transwell,
268 we applied 3×10^8 vg, which corresponds to a multiplicity of infection (MOI) of 600 based on a
269 count of roughly 5×10^5 cells per transwell. As the Gluc reporter that was encoded by all vectors
270 is secreted from the cells, we could collect cell culture supernatant at three successive time
271 points (day 6, 9 or 12 post-transduction) and thus analyze the kinetics of transduction.

272 Two general observations were, firstly, that the overall transduction efficiencies varied
273 substantially between the donors, as best illustrated by the up to 10-fold differences in luciferase
274 light units between donors #171476 and #171905 (Fig. 4A, also shown in Fig. 4D). Secondly,
275 we noted donor-dependent relative differences in the performance of the various capsids. This
276 is exemplified by variant KPLMI499 (yellow bars) that gave robust luciferase expression in

277 donors 171905 and 171975, but was less efficient in the other donors, 171469, 171476 and
278 171834 (Fig. 4A, also shown in Fig. 4D). For these two reasons, the raw data for all five donors
279 are depicted individually in Fig. 4A-B.

280 Despite the donor variability, it was noteworthy that the two published variants, DQ000495 and
281 GQ925675, were consistently among the top performers in all five donors. Furthermore, the
282 HBoV1 reference sequence DQ000495 (green bars in Fig. 4A) that was originally reported in
283 2005 significantly outperformed GQ925675 (orange bars) in the pHAE derived from donor
284 171467 (Fig. 4A, also shown in Fig. 4D). This is intriguing considering that, to our best
285 knowledge, the less efficient GQ925675 forms the basis for all recombinant AAV/HBoV1 vectors
286 that are currently in use by us and others. Next to these two historic controls, also capsid variant
287 V1512195 (blue bars, Fig. 4A and 4D) performed remarkably well in most cells, albeit we again
288 noted some degree of donor dependency (*e.g.*, in donor 171975, where it ranked second to
289 last). In contrast, capsid variants V1613007, KPLMI-246, KPLMI-253, KPLMI-311, V1500812
290 (all in gray) and V1502611 (pink bars) were frequently among the least efficient of all capsid
291 variants, also with a few donor-specific exceptions (*e.g.*, the good performance of capsids
292 V1500812 and V1502611 in donor 171469, Fig. 4A). Besides, we measured a steady increase
293 in luciferase transgene expression for all 16 capsids and all five donors from day 6 to 12 post-
294 transduction (data not shown), congruent with prior notions of AAV/HBoV1 kinetics in this cell
295 culture model (24).

296 Next, we compared transduction efficiencies at day 12 based on the presence of T590 (six
297 variants) versus T590S (twelve variants) (Fig. 4B). We found no significant differences between
298 the two groups in their transduction abilities, but observed trends in donors 171834, 171469 and
299 171476, where variants with T590 had a slight advantage. *Vice versa*, the S590 variant tended
300 to perform better in donors 171905 and 171975. Notably, as exemplified in Fig. 4C, we
301 concurrently observed differences in the cellular composition of the pHAE cultures that might

302 have influenced the transduction efficiency and specificity of the HBoV1 variants. In particular,
303 sample 171834 showed a much higher proportion of Mucin-positive goblet cells versus Tubulin-
304 positive ciliated cells, as compared to samples 171905 and 171975 where ciliated cells
305 predominated. An overview of the differential efficiency of selected variants in each of the five
306 pHAE cultures is shown in Fig. 4D.

307 Finally, we separately tested the two HBoV1 variants that had yielded the lowest titers during
308 vector production (Fig. 3C), KPLMI-30 and KPLMI-3503, in direct comparison to DQ000495
309 (Fig. 4E). For this, we used pHAE derived from two donors, one from the group of five that we
310 had also used above (171476), while the other was used only in this experiment (171427).
311 Moreover, owing to the limiting vector yields, we had to reduce the MOI from 600 to 200,
312 corresponding to 1×10^8 vg per pHAE filter. Consistently, we found that these two HBoV1
313 variants mediated very low transduction that was 10- to 100-fold below the DQ000495 reference
314 at all time points (Fig. 4E). Together, this implies that the multiple nucleotide and/or aa
315 differences in these two capsids as compared to the HBoV1 reference (Fig. 3A-B and
316 Supplementary Table 3) impact both, the ability to be produced as recombinant vector and to
317 mediate robust transgene expression, at least in pHAE.

318 *Packaging and transduction efficiency of HBoV1 tyrosine mutants*

319 An alternative approach to identify HBoV capsids with improved properties that complements
320 screening of natural HBoV variants is rational engineering of the viral capsid. To this end, the
321 modification of surface-exposed tyrosine residues in the viral capsid is especially promising as
322 these residues play important roles in assembly, ubiquitination and degradation, as well as in
323 transcription and transduction of parvoviruses (30-36). Accordingly, we mutated six different
324 tyrosine residues in the VP1 capsid protein to phenylalanine that we had originally predicted by
325 structural modeling to be located on the HBoV1 capsid surface (Fig. 5A), namely, Y276, Y403,
326 Y484, Y523, Y595 and Y657 (all VP1 aa numbering). To study the effect of each mutation on

327 particle assembly and transduction, we packaged two transgenes, *yfp* (yellow fluorescent
328 protein) or Gluc, into the different capsid variants. All mutants yielded largely comparable vector
329 amounts (data not shown), implying that none of the studied tyrosine mutations affects vector
330 production.

331 Next, to assess the ability of these mutants to transduce pHAE, they were added to the apical
332 surface of transwells at a MOI of 2×10^4 . This higher MOI (versus 600 before) was used as we
333 expected a lower infectivity for at least some of the tyrosine mutants, and as we wanted to be
334 able to measure all transduction efficiencies in the same experiment and under identical
335 conditions. Transductions were performed in the presence or absence of proteasome inhibitors,
336 to study whether the Y-to-F mutations had circumvented capsid ubiquitination and thereby
337 alleviated HBoV1's dependency on proteasome inhibition. Interestingly, we found that
338 transduction of two of the six mutants was impaired at all time points (day 3 to 14, Fig. 5B),
339 namely, Y484 (~6.8-fold reduction compared to wild-type HBoV1) and Y595 (~4.5-fold
340 reduction). In contrast, the other four mutants were indistinguishable from the wild-type control.
341 Moreover, the Y484F mutation had actually increased the dependency of the cognate capsid on
342 proteasome inhibitors, because this capsid was inert in their absence. In this respect, it differs
343 from the Y595F mutant that showed a similarly reduced potency in the presence of proteasome
344 inhibitors, but that, unlike the Y484F variant, remained active also without these inhibitors (albeit
345 at reduced efficiency, akin to all other variants).

346 Of note, after the completion of these experiments, the capsid structure of HBoV1 has been
347 determined by cryo electron microscopy (37). The HBoV1 capsid structure revealed that of the
348 six tyrosines that we studied here, only three are indeed located on the capsid surface, *i.e.*,
349 Y276, Y403 and Y595 (Fig. 5C). In addition, the hydroxyl group of Y276 is inaccessible for
350 potential phosphorylation. In contrast, Y484, Y523, and Y657 are not exposed on the capsid
351 surface. Most notably, mutation of Y484, which is located on the inside of the capsid, had

352 yielded the strongest phenotype, implying a mode of action that differs from the anticipated
353 phosphorylation and ubiquitination (see Discussion).

354 *Differential inhibition of HBoV1 capsid variants by human immunoglobulins*

355 To determine the effect of anti-HBoV1 antibodies on the functionality of the different HBoV1
356 capsid variants, we first performed an Enzyme Immuno Assay (EIA; Fig. 6A). For this purpose,
357 microtiter plate wells were coated with the different capsid variants (antigens) at four different
358 dilutions (only 8- and 16-fold dilutions are shown, as they resulted in a linear signal). Next, the
359 reactivity of a human serum pool positive for HBoV1 antibodies was measured. We detected
360 small differences typically within 1.3 OD between the variants in their ability to bind HBoV1-
361 specific antibodies, except for GQ925675, which showed a 2- to 4-fold reduced binding.
362 Surprisingly, for reasons as-of-yet-unknown, capsid variant VK11443 that differs only in one
363 nucleotide from GQ925675 and has an identical aa composition did not show the same
364 reduction in antibody binding. Also notable are the two capsid variants KPLMI-30 and KPLMI-
365 3503, which resulted in an OD of 3.10 and 0.10, respectively (at 8-fold dilution). Notably, the low
366 viral titers of both KPLMI-30 and KPLM-3503 (close to the background) limit the ability of qPCR-
367 based analysis that requires encapsidated genomes to reliably estimate the amount of viral
368 capsids. Thus, the slightly higher OD value measured for KPLMI-30 as compared to the other
369 variants (differences between 0.72 and 2.54 ODs) might result from the technical challenge to
370 quantify the proper amount of virus solution used in the EIA. The differential reactivity of these
371 two variants with human antibodies is interesting in view of their strikingly reduced viral titers
372 and transduction ability in pHAЕ (Fig. 3C and 4E, respectively). Based on the titer reduction, we
373 speculated that these variants might have a defect either in assembly or genome packaging. To
374 resolve these possibilities, we studied viral VP expression by Western blot analysis (Fig. 6B). All
375 variants expressed VP1/VP2/VP3 proteins (without evidence for additional protein species) in
376 the expected 1:1:10 stoichiometry, which shows that capsid protein expression is not limiting.

377 Thus, the absence of signal in the EIA for KPLMI-3503 viral particles implies that this variant
378 might have an assembly defect. By contrast, the high signal for KPLMI-30 in combination with
379 the low measured viral titers hints at an impairment in genome packaging. Notably, we do not
380 rule out the possibility that subtle differences in VP protein composition not detected by Western
381 blotting may have contributed to the variations in transduction or packaging ability, a theory that
382 could be studied with other, more sensitive methods. Besides, we did not detect variations in the
383 length of the encapsidated vector DNAs (data not shown), implying that genome integrity is not
384 responsible for the differences in titer or transduction.

385 Concerning the T590S variation, the EIA assay did not reveal obvious differences between the
386 T and S groups in their binding to human anti-HBoV1 antibodies, which implies that aa position
387 590 does not confer a differential reactivity to HBoV1 capsid antibodies in human sera.

388 It is known for AAV vectors that antibody binding does not always result in neutralization of virus
389 transduction (38). To test whether this applies to HBoV1 as well and to compare our different
390 variants in a functional assay (transduction ability), we performed *in vitro* neutralization assays
391 using commercially available, pooled human immunoglobulins (IVIg). This mix of IgG antibodies
392 from healthy individuals has previously been shown to potently reduce the activity of the
393 standard GQ925675 vector, in line with its large seroprevalence in the human population (24).

394 Due to the limited availability of pHAE, we selected seven HBoV1 variants for the assay with
395 equal T/S590 distribution, including the GQ925675 and DQ000495 reference strains. To this
396 end, we mixed 5×10^9 vg per capsid variant (corresponding to a MOI of 1×10^4 vg per well) with
397 six different IVIg concentrations and incubated these mixtures for 1 h at 37°C, before adding
398 them to pHAE from two different donors (Fig. 6C). These IVIg concentrations were shown in
399 pilot studies to result in a reduction or complete inhibition of transduction with GQ925675 (data
400 not shown). Comparison of Gluc expression from the different HBoV1 variants at day 5 and 10
401 showed no obvious differences between the two groups (T or S at position 590) in their

402 transduction abilities in the presence or absence of IVIg, which supports the previous notion that
403 this variation does not confer increased resistance to neutralizing antibodies. Still, contradicting
404 this trend is the KPLGr2 variant, which differs only in aa position 590 from KPLGr1 but shows a
405 higher resistance to IVIg, despite its stronger binding to antibodies in the EIA assay (Fig. 6A).

406 *Analysis of evolutionary selection pressures on HBoV1*

407 Intrigued by our finding that the natural T/S590 variation has a profound impact on viral titer, we
408 asked whether this site was subject to a positive selection pressure. To address this question,
409 we used several methodologies comprising MEME, SLAC, FEL and FUBAR (see Methods).
410 Indeed, we found one site (using MEME) under "positive selection" (moderately significant with
411 $p=0.51$), namely, the abovementioned aa 590 (Fig. 7A). However, a positive selection of T/S590
412 was not supported by the other methods used, which showed a neutral selection pressure at
413 this position. Thus, albeit it is implied by the MEME results, we cannot firmly conclude that the
414 observed substitution at this site has an impact on intra-species transmission and adaptation of
415 HBoV1.

416 Finally, we analyzed the conservation of the aa 590 residue in the VR-VIIIIB by comparing the aa
417 composition of this region to other primate BoV (Fig. 7B). Notably, the Gorilla bocavirus (GBoV)
418 described by Kapoor *et al.* (39) is genetically most closely related to HBoV1 (on both, the
419 nucleotide and amino acid level). Accordingly, the VR-VIIIIB of HBoV1 is also most homologous
420 to the one in GBoV, with both carrying a threonine at position 590, in contrast to an asparagine
421 in HBoV2-4. Also interesting in this context is the profound ability of GBoV to transduce human
422 airway epithelial cells that we have reported recently (24). Together, this may hint towards an
423 inter-species transmission of HBoV1/GBoV.

424

425

426 **DISCUSSION**

427 The present work was fueled by a string of recent publications showcasing the great potential of
428 recombinant gene transfer vectors derived by packaging of AAV vector genomes into HBoV1
429 capsids (22, 24, 25, 40). Most recently, these reports have inspired us to engineer similar
430 vectors based on alternative BoV, *i.e.*, HBoV2-4 and Gorilla Bocavirus (GBoV), leading to our
431 discovery of their favorable properties for gene transfer into various primary human cells (24). At
432 the same time, this work by others and us has revealed a series of gaps in our current
433 understanding of fundamental BoV biology, whose resolution will not only benefit our knowledge
434 of the bocaviral life cycle but also promises to foster the development of next-generation BoV
435 gene therapy vectors.

436 In the first part of this work, we aimed to study the natural variation in HBoV1 isolates.
437 Specifically, we focused our attention on the capsid (*vp*) ORF, which is the determinant of virus
438 tropism and the subject of extensive research in viral vector development. Therefore, we
439 amplified and sequenced 29 full-length *vp* sequences from patient samples collected in
440 Heidelberg and Cologne. Despite the high degree of sequence conservation among the HBoV1
441 isolates, which is in line with previous reports (41), we detected an interesting hotspot for
442 variation in VP1 at aa position 590 in around 50% of analyzed patient samples. This change
443 results from a conversion of two nucleotides (5'-AA-3') at positions 1767-1768 in *vp1* to 5'-CT-3'.
444 Interestingly, a previous study by Principi and co-workers, who analyzed samples from Milan
445 (Italy), also showed this high prevalence of the T590S variation (27). The additional collection of
446 several samples from the same individual over time allowed us to also follow the course of
447 infection in two patients. Surprisingly, we found dynamic changes at the 590 aa position, starting
448 with a clear abundance of threonine that was gradually replaced by a serine (see Fig. 2C-D).
449 The emergence and persistence of the T590S switch could be explained by different events: (i)
450 a *de-novo* change of two adjacent nucleotides during virus evolution, which is, however,

451 unexpected in view of the estimated mutation rate of primate bocaviruses (9×10^{-4}
452 mutations/site/year) (42, 43), or (ii), as previously proposed by Martin and colleagues (44), a
453 secondary infection with another strain, which might have a replication or immunological
454 advantage and thus dominated over time. Another, rather rare scenario also reported in the
455 above-mentioned study is the co-infection with two strains during the same primary event that
456 have different kinetics or immunoreactivity. To conclusively identify the proper scenario, deep
457 sequencing analysis of samples from different time points has to be performed to detect even
458 minor quantities of specific variants. Interestingly, as opposed to the study by Principi *et al.*, the
459 T590S change was concomitant with a decrease in overall virus load (27). However, these
460 varying study outcomes may have resulted from different time and end points in sample
461 collection. At this point, it thus remains equally possible that the observed decrease at the
462 endpoint of sample collection truly reflects a biological property of T590S or that a secondary
463 infection has happened in these patients. Consequently, a firm conclusion regarding the
464 persistence or spread of 590S *versus* T590 variants and on their possible positive selection
465 cannot be drawn until more samples have been collected and analyzed during symptomatic and
466 asymptomatic periods.

467 In addition to the prominent T590S mutation, we detected additional aa changes resulting from
468 single-nucleotide polymorphisms (SNP): D to N (aa position 86), S to N (aa position 474) and a
469 dominant A-to-T mutation (aa position 149) in all variants (as compared to the DQ000495
470 reference strain). To experimentally unravel the role of these naturally occurring SNPs or
471 singletons in the *vp* ORF on the producibility and transduction ability of HBoV1, independent of
472 the exact collection time points and sample types, we made use of a previously established
473 recombinant vector system in which rAAV genomes are packaged into BoV capsids (22, 24). To
474 this end, we selected variants from patient samples with approximately equal T/S distribution
475 (Fig. 3A-B) and packaged a rAAV-Gluc vector into each capsid. The high aa identity of the

476 HBoV1 variants in our study prompted us to include additional synthetic mutants into our screen
477 that either (i) recapitulate several natural HBoV1 variants reported by Principi *et al.* (27) or (ii)
478 were rationally designed, based on a previously published HBoV1 structure by Gurda *et al.* (45).
479 During packaging of the rAAV-Gluc genomes into the different HBoV1 *vp* variants, we gained
480 significantly higher titers with the ones harboring a serine at aa position 590 (see Fig. 3C-D),
481 which was surprising as it is diametrically opposed to the decrease observed in the patient
482 material. Hence, these findings allow us to conclude that the decrease in 590S viral load in
483 patient material does not result from a reduced ability to produce viral progeny (Fig. 2B).
484 Moreover, the consistently higher viral titers obtained using 590S variants indicate a direct effect
485 of the variation on capsid assembly and/or genome packaging. Interesting in this context and
486 supporting this hypothesis is that T/S 590 lies in the capsid VR-VIII B (also called “HI loop”, Fig.
487 8A-B). This region belongs to the surface-exposed, hypervariable regions and was linked to
488 particle assembly and genome packaging in AAV (46), hinting at a similar function in the BoV
489 context. In addition to its role in particle assembly, the VR-VIII B is crucial for the externalization
490 of the VP1u region during endosomal escape and thus contributes to particle infectivity (46).
491 Accordingly, to test whether the *vp* variations studied in this work affected the transduction
492 ability of HBoV1, pHAЕ grown on transwells were transduced from the apical side with an equal
493 number of viral particles. Transgene expression was followed over time by measuring the
494 secreted reporter Gluc in the medium. Intriguingly, nearly all tested variants displayed high
495 transduction abilities (except for KPLMI-3503, KPLMI-30, HBoV1 Y595F and HBoV1 Y484F).
496 Moreover, their activity was dependent on the transwell composition and thus varied among
497 pHAЕ cultures, consistent with our prior observations with various primate BoV vectors (24).
498 When we compared transduction abilities in the context of the T590S variation, we did not
499 observe significant differences between the two groups. This is in line with a previous study
500 using recombinant AAVs, which showed that swapping of the complete HI loop between
501 serotypes with high sequence identity affects their producibility but not transduction ability (46).

502 Hence, we concluded that the T/S variation affects the virus titers by playing a role in particle
503 assembly and/or genome packaging but does not determine infectivity. By contrast, mutation of
504 the tyrosine residue to phenylalanine at aa position 595, which flanks the VR-VIIIB in the HBoV1
505 capsid, resulted in a 4.5-fold reduction in virus infectivity. Importantly, this residue is highly
506 conserved among primate BoVs except for HBoV4, where it can be naturally replaced by a
507 phenylalanine (*e.g.*, HBoV4 strain FJ973561).

508 An even stronger phenotype (6.8-fold reduction in infectivity) was obtained when Y484, located
509 between VR-VI and VR-VII, was mutated to a phenylalanine. This residue lies inside the capsid
510 and is also highly conserved among primate BoVs, indicating an important role in the BoV
511 infection pathway, most likely perhaps for capsid assembly. Further analysis of Y484 in the wild-
512 type HBoV1 capsid structure showed a potential hydrogen bond of the side chain's hydroxyl
513 group to the backbone (A435) of VR-V situated above this residue. Thus, an intriguing working
514 hypothesis for future work is that the removal of the hydroxyl group by mutation to phenylalanine
515 could alter the conformation of VR-V, which is a potential determinant of host tropism, and result
516 in reduced virus infectivity or vector transduction efficiency.

517 The best performers in our transduction assays were DQ000495 and HBoV1 Y523F, which
518 consistently mediated comparable or higher transduction than the standard BoV vector
519 GQ925675 and thus represent promising candidates for a future application as viral vectors. In
520 contrast to the favorable effect of S590, two of the reconstructed mutants (KPLMI-30 and
521 KPLMI-3503) resulted in 64- and 239-fold lower average viral titers, respectively, despite the
522 presence of the S590 residue. The EIA assay revealed the presence of assembled particles for
523 KPLMI-30 but not KPLMI-3503, despite the presence of free VP proteins (compare Fig. 6A and
524 B), which implies a defect in genome packaging, particle assembly and/or antibody recognition,
525 respectively. This hypothesis is supported by the localization of the different residues in both
526 variants. In KPLMI-30, the two residues SA (at aa 396-397) are located on the capsid surface at

527 the 5-fold canyon (Fig. 8C-D), *i.e.*, a region surrounding the 5-fold axis channel, which serves as
528 a portal for viral genome packaging (37, 47). By contrast, in KPLMI-3503, aa residues 534-536
529 (KPD) are on the inside of the capsid between the HI loop and VR-VIII that is located on the
530 sides of the 3-fold protrusions, *i.e.*, the determinants of antibody recognition and infectivity in
531 other parvoviruses (37) (Fig. 8E-F). Thus, we speculate that these residues might have led to
532 structural changes that either negatively influenced capsid assembly or interfered with antibody
533 binding. The latter would, however, not explain the 239-fold reduced viral titers. Consequently,
534 at this point, the exact mechanisms underlying our observations remain unknown and our
535 assumptions require experimental validation. For instance, to unanimously determine whether
536 aa 534-536 affect particle assembly or impact genome packaging, a different antibody
537 recognizing a conformational epitope should be used in future experiments. Finally, it is
538 interesting that the transduction ability of both mutants was severely compromised in pHAE (Fig.
539 4E), which seems to be at odds with the high titers ($\sim 5 \times 10^9$ vg/ml) at which these mutants were
540 detected in the original report (27). Here, it is important to mention again that only nucleotide
541 changes that cause an aa change were transferred into our expression constructs. Thus, the
542 effect of silent mutations that might have led to changes in different, as-of-yet unknown ORFs
543 within *vp2* cannot be assessed in this setting.

544 In the last part of this work, we asked whether the T590S variation affects the serological
545 reactivity of the HBoV1 capsid, which might have resulted in the emergence and/or persistence
546 of this mutation in the clinical samples. This question is also important for the application of viral
547 vectors in gene therapy, where pre-existing neutralizing antibodies significantly lower the
548 therapeutic benefit. To this end, we pursued two independent approaches: (i) EIA to assess the
549 binding of antibodies in HBoV1-positive sera to the HBoV1 *vp* variants, and (ii) a functional
550 assay in which the impact of a pool of human antibodies (IVIg) on the transduction abilities of
551 the HBoV1 variants was studied.

552 Interestingly, we found only small differences between the variants in the EIA, except for the
553 GQ925675 variant that showed 2- to 4-fold reduced binding to serum antibodies (Fig. 6A). This,
554 however, did not directly correlate with the results from the transduction assays, where
555 GQ925675 had no benefit compared to the other tested variants (Fig. 6C). This discrepancy
556 was also observed in previous reports using AAV vectors and indicated that antibody binding is
557 not always linked to particle functionality (38). The *in vitro* neutralization assay also did not
558 reveal any correlation between the T/S590 variation and the susceptibility of the HBoV1 capsid
559 to neutralization by pooled human IgG. One exception is the Gr2 variant, which was more
560 resistant to neutralization as compared to the other variants and which differed from Gr1 only in
561 the presence of S590. This led us to the conclusion that T/S590 mostly affects the efficiency of
562 virus production, yet it remains to be determined how this variation affects virus spread or
563 latency.

564 The higher resistance of the KPLGr2 variant in this work is remarkable and would be of
565 advantage for the future application of this variant as a viral vector. Thus, it would be now
566 interesting to (i) validate the immune-escaping ability of KPLGr2 by testing its reactivity to
567 different patient sera, and (ii) to include other variants that have the same aa sequence as
568 KPLGr2, namely, V1512195, V1502611 and V1500812 but that differ substantially in their
569 nucleotide composition. These variations have led to different transduction abilities in pHAE
570 (Fig. 4A and 4D), which might be a result of alternative, as-of-yet undiscovered ORFs that could
571 also influence the immunoreactivity. Thus, it should be highly rewarding to additionally study the
572 abovementioned variants and the other BoV capsids reported in this work as it will further enrich
573 our knowledge of bocaparvovirus biology and support efforts to breed optimal viral vectors for
574 human gene therapy.

575

576

577 **MATERIALS AND METHODS**

578 **Plasmids and cloning procedures.** The HBoV1 helper plasmid pCMVNS*Cap (GenBank:
579 GQ925675) was previously described (9, 48) and kindly provided by Ziyang Yan. The DQ000495
580 *cap* sequence was ordered as gene block from IDT (Leuven, Belgium). The gene block and
581 HBoV1 *cap* sequences from clinical samples were amplified using primers #1 and #2 in
582 Supplementary Table 2 (both with overhangs containing BsmBI restriction sites). The PCR
583 product was cloned using a Golden Gate reaction into a previously described acceptor plasmid
584 (pCMVNS*ΔVP-2xBsmBI) (24) lacking the *cap* sequence.

585 All other synthetic variants reported in this work were generated by introducing mutations using
586 overlap-extension (OE-)PCR as previously described (49). For each change, two PCR reactions
587 were performed using overlapping primers (forward and reverse) containing the mutation(s) of
588 interest (#5 to #36 in Supplementary Table 2) and two common external primers (#3 and #4 in
589 Supplementary Table 2) with restriction sites (BstBI / EagI) that allow for the cloning of the end
590 products into pCMVNS*Cap (see Supplementary Tables 3 and 4 for an overview of the
591 nucleotide changes introduced).

592

593 **Phylogenetic analysis.** Phylogenetic analysis of HBoV1 *cap* sequences was performed in
594 MEGA7.0.26 (Pennsylvania State University, PA, USA). The evolutionary history was inferred
595 using the Maximum Likelihood method. The percentage of replicate trees in which the
596 associated taxa clustered together in the bootstrap test (500 replicates) are shown next to the
597 branches. Only bootstrap values above 70% are displayed.

598

599 **Cell culture and patient material.** HEK293T were grown in Dulbecco's Modified Eagle's
600 Medium (DMEM) with GlutaMAX™ (Thermo Fisher Scientific, Waltham, MA, USA), supplied
601 with 10% fetal bovine serum (FBS) and 100 U/ml penicillin-streptomycin (both Merck/Sigma-

602 Aldrich, Darmstadt, Germany). Polarized human airway epithelial cells were generated as
603 previously described (24) from resected bronchial tissue and were obtained from Lung Biobank
604 Heidelberg (member of the German Center for Lung Research, DZL), at University Hospital
605 Heidelberg, Germany. The cells were grown on ThinCerts (Greiner Bio-One, Frickenhausen,
606 Germany) and differentiated at an air-liquid interface in PneumaCult ALI Basal medium
607 supplemented with PneumaCult ALI 10× Supplement (both from StemCell, Vancouver,
608 Canada).

609

610 **Recombinant virus production.** Pseudotyped BoV/AAV vectors were produced in HEK293T
611 cells as previously described (24) using a triple plasmid transfection of (i) one of the BoV helper
612 plasmids, (ii) a self-complementary (sc)AAV plasmid encoding Gluc (1.912 kb insert size) and
613 (iii) pDGΔVP, a plasmid encoding *rep* from AAV2 and adenovirus helper genes (21). Cells were
614 harvested 72 h post-transfection and the crude cell lysate was processed for iodixanol gradient
615 centrifugation as previously described (24, 50). The virus-containing 40% iodixanol fraction was
616 pulled from the gradient, mixed with 15 mL PBS and applied to an Amicon Ultra-15 (Merck,
617 Darmstadt, Germany) centrifugal filter unit (100,000 nominal molecular weight limit). Several
618 centrifugation steps at 500-1,000×g allowed for buffer exchange and concentration of viral
619 preparations.

620

621 **qPCR analysis of patient samples and recombinant virus titers.** To determine viral titers,
622 alkaline lysis was performed by mixing 10 μL of each virus stock with 10 μL TE buffer and 20 μL
623 2 M NaOH. The mixture was heated up to 56°C for 30 min and then neutralized using 38 μL of 1
624 M HCl. Next, a 1:1,000 working solution was prepared and 5 μL were used in a TaqMan real-
625 time PCR reaction as previously described (50), using the 2× SensiMix II Probe Kit (Bioline,
626 Luckenwalde, Germany) and a probe binding in the promoter region (see Supplementary Table
627 5 for probe/primer combinations).

628 To determine the viral load in patient samples, 2.5 µL of extracted DNA (QIA Symphony kit;
629 Qiagen, Hilden, Germany), were directly mixed with 22.5 µL qPCR mix containing: (i) 12.5 µL
630 SensiMix SYBR No-Rox Kit (Bioline), (ii) 0.25 µL of each forward and reverse primer
631 (Supplementary Table 5) and (iii) 9.5 µL H₂O. The qPCR reaction were measured in duplicates
632 using a Rotor-Gene Q cyclor (Qiagen) and the following conditions: Initial activation (95°C, 10
633 s), followed by 40 cycles of (i) denaturation (95°C, 15 s), (ii) annealing (58°C, 20 s) and (iii)
634 extension (72°C, 20 s). To ensure the detection of different HBoV1 strains, the forward and
635 reverse primers were designed to bind in the relatively constant promoter region.

636

637 **Gussia luciferase assay.** Gluc activity was determined in the cell culture medium as
638 previously described (24). Briefly, 20 µL of the cell medium were incubated with 100 µL assay
639 buffer supplied with Coelenterazine (PJK, Kleinblittersdorf, Germany) at a final dilution of 11.7
640 µM. Gluc activity was detected in a GloMax96 microplate luminometer equipped with an
641 automatic injector (Promega, Madison, WI, USA).

642

643 **Enzyme immunoassay (EIA).** HBoV1 variants selected from the transduction experiments
644 were tested for their reactivity to human serum pools using an in-house IgG EIA. Therefore, 96-
645 well microtiter plates were coated overnight at 4°C in duplicates with 4-, 8-, 16- and 32-fold
646 diluted (in PBS) bocaviral stocks. Then, plates were coated with diluent LOY-X (Labsystems
647 Diagnostics, Vantaa, Finland) three times for 10 min each. A HBoV1-IgG-positive serum pool
648 (1:200) diluted in RED buffer (Kaivogen, Turku, Finland) was pipetted into each well and the
649 plate was incubated at 37°C for 1 h. As control, a 1:200 dilution of a HBoV1-IgG-negative serum
650 pool was used. After five washes with 0.05% Tween-20 in PBS, an HRP-(horseradish
651 peroxidase-) conjugated anti-human IgG (1:2,000; DAKO/Agilent, Glostrup, Denmark) diluted in
652 LOY-X was applied. For the detection of HRP-labeled antibodies, TMB substrate (Merck/Sigma-
653 Aldrich) was added and incubated at room temperature for 20 min. Then, H₂SO₄ (0.5 M) was

654 added to stop the reaction, and absorbances were measured at 450 nm using a MultiScan EX
655 (Thermo Fischer Scientific).

656

657 **Western blot analysis.** Western blotting was performed as previously described (49). Briefly,
658 5×10^5 HEK293T cells were transfected with 2 μg of BoV helper plasmid. Three days post-
659 transfection, the cells were harvested in 300 μL PBS, mixed with an equal volume of 2 \times SDS
660 sample loading buffer and boiled for 5 min at 95°C. The cell lysates were then centrifuged at
661 13,000 rpm and 10 μL from each lysate were separated on 8% SDS-PAGE gels (Biorad,
662 Hercules, CA, USA). Next, the proteins were transferred to a nitrocellulose membrane (NeoLab,
663 Heidelberg, Germany) using semi-dry transfer. For detection of the three capsid proteins (VP1,
664 VP2 and VP3), an in-house produced rabbit polyclonal anti-HBoV1 antibody was used at a
665 1:1,000 dilution. To produce the anti-HBoV1 antibody, rabbits were inoculated with HBoV1 VP3-
666 VLPs (virus-like particles) that were produced in a baculovirus expression system. Serum was
667 obtained on day 120 and tested for HBoV1 IgG by EIA. Immunization of rabbits was performed
668 by GenScript (Piscataway Township, NJ, USA). For further details, see reference (51).

669 For detection of the primary antibody, a HRP-conjugated secondary donkey anti-rabbit antibody
670 (#NA934V; GE Healthcare, Chicago, IL, USA) was used (1:10,000). To visualize protein bands,
671 the Lightning Plus-ECL reagent (PerkinElmer, Waltham, MA, USA) was added and a
672 chemiluminescence imager (Intas ChemoStar, Göttingen, Germany) was used to detect the
673 signal.

674

675 **Transduction of pHAE in the presence or absence of IVIGs.** Primary HAE were incubated
676 from the apical side with the different pseudotyped HBoV1 variants at a MOI of 1×10^4 . To
677 enhance transduction, two proteasome inhibitors were applied to the medium on the basolateral
678 side, as previously described (22, 24), namely, 5 μM doxorubicin hydrochloride (Santa Cruz

679 Biotechnology, Dallas, TX, USA) and 40 μ M ALLN calpain Inhibitor I (G-Biosciences, St. Louis,
680 MO, USA). After 16 h, the virus was removed from the apical compartment and the medium
681 replaced with fresh medium without inhibitors.

682 To perform transductions in the presence of IVIg (Kiovig; Baxalta, Bannockburn, IL, USA), the
683 IVIg solution was diluted to working concentrations of 2, 10, 20, 40, 60 or 200 mg/dl. Next, equal
684 volumes of virus and IVIg solution were mixed and placed at 37°C for 1 h. Positive (PBS,
685 +HBoV1) or negative (+IVIg, -HBoV1) controls for transduction were also included. Transgene
686 expression was measured at 5 or 10 days post-transduction.

687

688 **Flow cytometry analysis.** Characterization of pHAEC cell composition using flow cytometry was
689 performed as previously described (22, 24). Briefly, to stain goblet and ciliated cells, the
690 following primary antibodies were used: goblet cell marker MUC5A/C (#ab3649; Abcam,
691 Cambridge, UK) diluted 1:100 and ciliated cell marker β -Tubulin IV (#T7941; Merck/Sigma-
692 Aldrich) diluted 1:100. Primary antibodies were incubated for 1 h at 4°C, followed by treatment
693 with secondary anti-mouse antibody (AF-647 goat anti-mouse #A21235, Thermo Fisher
694 Scientific) for 30 min at room temperature. Cells were measured on a FACSVerse (BD
695 Biosciences, Franklin Lakes, NJ, USA) and analysis was performed using Flowing Software
696 (version 2.5.1; Turku Centre for Biotechnology, Turku, Finland). Only living cells were used for
697 the analysis.

698

699 **Statistical analysis.** The statistical analysis was performed in PRISM Version 8.0 (GraphPad
700 Software Inc.; <https://www.graphpad.com>). Two data sets in Fig. 2B or 3D were compared using
701 an unpaired two-tailed t-test analysis (for 2B, Welch's correction was applied to account for
702 highly significant differences in variances). The data sets in Fig. 4B were analyzed using a
703 multiple t-test. Statistical significance was determined using the Holm-Sidak method, with alpha

704 = 0.05. Computations assume that all rows are samples from populations with the same scatter
705 (SD). In Fig. 4D, a one-way ANOVA with Dunnett's test was used to compare each data set with
706 the reference (DQ000495.1). Significance is denoted by asterisks above the SD or range bar. *,
707 $p < 0.05$, **, $p < 0.01$, ***, $p < 0.001$, ****, $p < 0.0001$, ns, non-significant.

708

709 **Structural analysis.** For the structural analysis, the model of the HBoV1 VP monomer (PDB-ID:
710 5URF) and the HBoV1 capsid 60-mer was downloaded from the VIPERdb online server
711 (<http://viperdbscripps.edu>) (52). Surface exposed tyrosines were identified by generation of a
712 gray surface representation of the capsid 60-mer followed by the coloration of tyrosine residues
713 in Chimera (53). Similarly, the location of specific residues on the capsid surface such as serine
714 590 were identified. The depiction of the ribbon diagrams of the HBoV1 VP monomer were
715 generated using the 'smooth loop' option in PyMol (54).

716

717 **Selective pressure analysis.** Tests for negative or positive selections were conducted on the
718 Datamonkey server (55). Methods used involve single-likelihood ancestor (SLAC) (56), the
719 fixed-effects likelihood (FEL) (56), the fast, unconstrained Bayesian approximation (FUBAR)
720 (57) and the mixed effects model of evolution (MEME) (58). To reduce the probability of false-
721 positive events, a p-value threshold of 0.1 in SLAC, FEL and MEME and a FUBAR posterior
722 probability threshold of 0.9 were used to identify sites for selection.

723

724 **Ethical approval.** This study was carried out in accordance with the recommendations of the
725 University Hospital Heidelberg with written informed consent from all subjects in accordance
726 with the Declaration of Helsinki. All samples were received and maintained in an anonymized
727 manner. The protocol was approved by the ethics commission at University Hospital Heidelberg
728 under the protocol numbers S-270/2001 (collection of surgical material for lung research) and S-

729 782/2018 (amplification of BoV sequences from patient material and application of derived BoV
730 vectors in pHAE).

731

732 **AUTHOR CONTRIBUTIONS**

733 J.F., K.-P.L. and D.G. conceived the study. J.F. and K.-P.L. generated constructs and
734 performed the majority of experiments. M.A.-M. and Ma.M. generated capsid structures and
735 residue information. M.S.-V. and M.X. designed and performed EIA assays. M.A.S. and Mi.M.
736 provided pHAE. O.S. and P.S. provided extracted DNA from patient material. J.F. and D.G.
737 wrote the manuscript. All authors read the manuscript and approved the final version.

738

739 **CONFLICTS OF INTEREST**

740 D.G. is a co-founder and shareholder of AaviGen GmbH. All other authors declare no competing
741 financial interests.

742

743 **ACKNOWLEDGMENTS**

744 J.F. and D.G. are grateful for funding from the Cystic Fibrosis Foundation (CFF, grant number
745 GRIMM15XX0), the German Research Foundation (DFG, Cluster of Excellence CellNetworks,
746 EXC81) as well as from the Heidelberg Biosciences International Graduate School HBIGS at
747 Heidelberg University. K.-P.L. and D.G. are thankful for a MD stipend to K.-P.L. from the
748 German Center for Infection Research (DZIF, BMBF). D.G. acknowledges additional funding by
749 the DZIF (TTU-HIV 04.803 and 04-815). M.A.S. and M.M. acknowledge funding by the German
750 Center for Lung Research (DZL, BMBF, 82DZL00402). D.G. appreciates further support from
751 the Collaborative Research Center SFB1129 (DFG; TP16; Project number 240245660). M.A.M.
752 and M.M. were supported by NIH R01 GM082946. M.S.V. and M.X. acknowledge funding by the
753 Sigfried Jusélius Foundation and the Life and Health Medical Association, and M.X. by the
754 China Scholarship Council (CSC) and the Finnish-Norwegian Medical Foundation.

931

932 **FIGURE LEGENDS**

933 **FIG 1** Isolation and sequencing of natural HBoV1 capsid variants. **(A)** Representative agarose
 934 gel showing the results of PCR amplification of HBoV1 capsid genes in patient samples. The
 935 expected size of the full-length PCR amplicon was 2016 bp. POS, positive control (HBoV1
 936 helper plasmid); NEG, negative control (H₂O). **(B-C)** Nucleotide (B) and protein (C) sequences
 937 of the HBoV1 capsid variants shown on the left in each panel. The second column depicts the
 938 number of nucleotide (B) or aa (C) differences as compared to variant DQ000495 (shown at the
 939 top). The numbers above each column have to be read vertically and indicate the position of
 940 each nucleotide (B) or aa (C) in the HBoV1 capsid gene or protein (VP1), respectively. A dot
 941 indicates no change. The four colors highlight the corresponding nucleotides and AA in the two
 942 panels. **(D)** Phylogenetic tree of the shown HBoV1 capsid variants derived by applying

943 maximum-likelihood methodology and 500 bootstrap repeats. Bootstrap repeats with a support
944 of over 60% are shown at the nodes. HBoV2 (GenBank NC012042), HBoV3 (NC012564),
945 HBoV4 (NC012729), Bovine Parvovirus (NC001540) and Canine Minute Virus (NC004442)
946 were defined as outgroup. Capsid variants that resulted from this work are marked with a dot.

947

948 **FIG 2** Correlation of HBoV1 capsid sequence and viral load in patient material. **(A)** Results of
949 qPCR titration of viral loads in 39 different patient samples. Shown is the median value ($3.91 \times$
950 10^6 vg/mL). **(B)** Correlation of aa at position 590 (threonine or serine) with viral load in 31
951 selected (see main text for criteria) samples. Shown are means plus range. ns, non-significant.
952 **(C)** Sequencing results of selected regions of the HBoV1 capsid in material taken from patient A
953 (sputum and tracheal secretions) at the four indicated time points (total collection period was
954 about 15 weeks). Also shown are the corresponding viral loads. Letters and colors indicate the
955 aa or nucleotide at each position (green = adenine, blue = cytosine, black = guanine, red =
956 thymine). **(D)** Same as panel C, but data for patient B and material (tracheal secretions)
957 collected over a period of three weeks. **(E)** Viral loads measured for patients A and B (vg/mL)
958 and shown in panels **(C)** and **(D)** are plotted (Y-axis) against the measurement time-points
959 (days; x-axis).

960

961 **FIG 3** Selection and production of recombinant HBoV1 capsid variants. **(A-B)** Nucleotide (A)
962 and protein (B) sequences of the 18 HBoV1 capsid variants shown on the left in each panel.
963 The second column depicts the number of nucleotide (A) or aa (B) differences as compared to
964 variant DQ000495 (shown at the top). The numbers above each column have to be read
965 vertically and indicate the position of each nucleotide (A) or aa (B) in the HBoV1 capsid gene or
966 protein (VP1), respectively. A dot indicates no change. The colors highlight the corresponding
967 nucleotides and aa in the two panels. Panel B also shows the viral loads that were measured for
968 each of the corresponding patient samples. Values marked with an asterisk were taken from

969 Principi *et al.* 2015 (27) and rounded. **(C)** Vector titers (means \pm SD) were determined by qPCR
970 for the shown 18 HBoV1 variants (each produced in nine 15 cm² plates and purified). All
971 titrations were performed twice except for those marked with an asterisk that were performed
972 once. The dotted line represents the average value of 1.1×10^{11} vg/ml. Colored bars represent
973 randomly chosen candidates that are highlighted in the next section of this work. **(D)** Same
974 results as in panel C but sorted by the presence of a threonine (n=6) or serine (n=12) at position
975 590. Shown are means \pm SD. ***, $p < 0.001$ (unpaired t-test).

976

977 **FIG 4** Functional characterization of HBoV1 variants. **(A)** The indicated HBoV1 variants were
978 tested for their transduction abilities in pHAE derived from five different patients (#171834 to
979 #171476). To this end, a rAAV-Gluc genome was packaged into each HBoV1 capsid and pHAE
980 were transduced apically at a MOI of 600. Gluc activity (means \pm SD) was measured in the
981 medium 12 days post-transduction and plotted on the y-axis as arbitrary light units (ALU).
982 Colored bars represent candidates shown in Fig. 3C and are intended to facilitate comparison of
983 candidates between pHAE derived from different patients. **(B)** Same results as in panel C but
984 sorted by the presence of a threonine (n=6, 2 transwells each) or serine (n=12, 2 transwells
985 each) at position 590. Shown are means \pm SD. ns, non-significant (multiple t-test). **(C)** Flow
986 cytometry analysis of untransduced pHAE derived from the indicated patient samples (n=2
987 independent transwells per patient). Cells were stained for cell type-specific markers, *i.e.*, β -
988 Tubulin IV (ciliated cells) and MUC5AC (goblet cells). Blue areas show the percentages of
989 positive cells for the indicated markers. **(D)** Side-by-side comparison of selected HBoV1 variants
990 highlighted in Fig. 3C and 4A. Shown is their transduction ability in pHAE derived from different
991 patients (indicated by the numbers below the x-axis). Transduction efficiency was estimated
992 from the Gluc reporter activity in the medium, which is plotted as ALU on the y-axis (mean \pm
993 SD). *, $p < 0.05$, **, $p < 0.01$, ***, $p < 0.001$, ****, $p < 0.0001$, ns, non-significant (one-way
994 ANOVA). **(E)** Transduction of pHAE with the shown HBoV1 variants at a MOI of 200. Gluc

995 activity (means \pm SD) was measured in the medium 3, 9 and 12 days post-transduction and
996 plotted on the y-axis as ALU. NEG, negative control (untransduced cells).

997

998 **FIG 5** Synthetic tyrosine mutants of the HBoV1 capsid and their transduction properties. **(A)**
999 Shown tyrosine residues (Y) were mutated to phenylalanines (F). Numbers indicate the position
1000 of the aa in VP1. Underlined nucleotides represent mutated residues that result in the
1001 corresponding aa change. **(B)** Gluc activity measured at the indicated time points. pHAE were
1002 transduced with the different tyrosine HBoV1 mutants from panel **(A)** at a MOI of 2×10^4 in the
1003 presence (+) or absence (-) of proteasome inhibitors. N, negative control (untransduced cells);
1004 wt, wild-type HBoV1 capsid (positive control). The dotted line represents the assay background.
1005 **(C)** HBoV1 capsid surface representation with surface-exposed tyrosine residues highlighted in
1006 green and the hydroxyl group colored in red. In variants with an asterisk, the hydroxyl group is
1007 partially inaccessible. This image was generated using Chimera.

1008

1009 **FIG 6** Analysis of the immunoreactivity of HBoV1 capsid variants. **(A)** EIA using pooled human
1010 sera positive for HBoV1. Iodixanol-purified viral stocks (adjusted to an average of 5×10^{10} vg/mL)
1011 of the indicated HBoV1 capsid variants were used to coat the wells of a microtiter plate (8- and
1012 16-fold dilutions). EIA absorbance values (optical density; OD) are plotted on the y-axis. **(B)**
1013 Western blot analysis of the variants shown in panel (A). HEK293T cells were transfected with
1014 the different HBoV1 plasmids to analyze the expression of the three capsid proteins VP1, VP2
1015 and VP3. **(C)** *In vitro* neutralization assay using commercially available human immunoglobulins
1016 (IVIg). Gluc-expressing vectors were pre-incubated with the indicated IVIg concentrations for 1 h
1017 at 37°C and then used to apically transduce pHAE at a MOI of 1×10^4 (5×10^9 vg per well). All
1018 assays were performed in duplicates. Shown are mean Gluc activity levels (light units) plus
1019 range measured at days 5 and 10 post-transduction.

1020

1021 **FIG 7** Selection pressure acting on the intra-host level and comparison of the inter-host genetic
1022 diversity of the VR-VIII B. **(A)** Positive or negative selection pressure acting on the *vp* codons of
1023 the HBoV1 strains in this study. MEME: mixed effects model of evolution; SLAC: single-
1024 likelihood ancestor; FUBAR: fast unconstrained Bayesian approximation methods; FEL: fixed-
1025 effects likelihood. **(B)** Amino acid 590 variation among different primate bocaviruses.

1026

1027 **FIG 8** Structural representation of the HBoV1 T590S variant (GQ925675) as well as of the
1028 HBoV1 variants KPLMI-30 and KPLMI-3503. **(A)** Shown is the HBoV1 capsid surface with the 2-
1029 , 3- and 5-fold symmetry axes as well as the location of the S590 residue (in green). **(B)** Ribbon
1030 diagrams of the VP3 monomer of the HBoV1 S590 variant. The S590 residue is represented by
1031 a green sphere and localizes to the VR-VIII B (HI loop). **(C,E)** Surface representation of the
1032 HBoV1 KPLMI-30 **(C)** or KPLMI-3503 **(E)** capsid. The aa residues 396-397 in KPLMI-30 are
1033 located on the capsid surface and are shown by green spheres, whereas the critical residues in
1034 KPLMI-3503 (534-536) reside inside the capsid and are not visible in the image in panel **(E)**.
1035 **(D,F)** Ribbon diagrams of the VP3 monomer of the HBoV1 variants in panels **(C)** and **(E)**,
1036 respectively. Residue changes as compared to DQ000495 mentioned in panels **(C)** and **(E)** are
1037 shown as green spheres. Images in panels **(A)**, **(C)** and **(E)** are radially colored from blue to
1038 white and red, representing capsid center to surface regions. These images were generated
1039 using Chimera. In panels **(B)**, **(D)** and **(F)**, the capsid VRs from I to IX are indicated. These
1040 images were generated using PyMOL (<http://www.pymol.org/>).
