Abstract:

Knowing running speed, particularly by means of easy-to-apply tests and low cost, is important to the definition of race strategy and of the most appropriate training throughout the preparation period. The aim was to compare the agreement and reproducibility of critical velocity (CV), anaerobic threshold (AT), and the time trial on the track for the determination of the running speed in a 10-km race in amateur runners. A cross-sectional study was conducted with 34 runners of both genders aged 42.4±11.0 years. We measured their CV, assessed their body composition and AT. Participants also performed a simulated trial on a 10-km running track and an official 10-km race. The delta of the comparisons and the standard error of estimate between the running velocities determined by the CV, AT, and the simulated time trial on the track ranged from 0.55 to -0.79 km/h and 0.14 to 0.59 km/h, respectively. Furthermore, CV and AT were compared to the 10-km running speed. Good agreement and reproducibility were observed between the velocities determined by the CV, AT, and the simulated time trial on the track with the real-time of a 10-km official race.

Key words: *critical velocity, anaerobic threshold, running, endurance*

Introduction

Long-distance street running races have increased in popularity in recent years in several countries (Anthony, et al., 2014; Gómez-Molina, et al., 2017; Knechtle, Nikolaidis, Zingg, Rosemann, & Rüst, 2016), especially among recreational practitioners, who aim to improve their physical fitness and health, but are also motivated by the achievement of better performances, which requires coaches and physical education professionals to identify the determining factors of performance enhancement (Santos, et al., 2012). Consequently, the interest of scientific community has been increased in studying different factors that may affect performance (Ogueta-Alday & Gacia-López, 2015).

Some authors have so far presented a series of potential physiological variables traditionally investigated as predictors or determinants of performance in long-distance races, such as maximum oxygen uptake (VO_{2MAX}), anaerobic threshold (AT), critical velocity (CV), running economy, maximum aerobic velocity, velocity associated with VO_{2MAX}

and AT, among others (da Silva, Sotero, Simões, & Machado, 2015; Denadai, Ortiz, Stella, & Mello, 2003; Ogueta-Alday & Gacia-López, 2015; T. M. Santos, et al., 2012; Smith & Jones, 2001; Souza et al., 2014). However, due to the detriment of distance and duration of a race, performance seems to be influenced not only by the physiological variables, but also by anthropometric parameters, race strategy, age, gender, and supplementation strategy and they should also be considered (Santos, et al., 2017).

Santos et al. (2017) state that during races, endurance runners generally adopt different pacing strategies, such as either higher or lower speed in different moments. Nevertheless, some runners try to maintain the same rhythm from the beginning to the end of the race, which does not mean the same physiological demand, particularly due to the terrain relief, climate changes, and the accumulated strain throughout the race (Thiel, Foster, Banzer, & de Koning, 2012). Thus, it seems clear that the intensity of the race undergoes significant variations during events from medium- (5, 10, or 15-km) to

long-distance races (half- or full-marathons), which requires the interaction between different energy systems (Thiel, et al., 2012). In this sense, knowing running speed is interesting for the establishment of the best race strategy (Lima-Silva, et al., 2010) as well as for quality training designs; knowledge of running speed can also be used as a parameter for the definition of training intensities and volumes throughout the periodization.

Studies analyzed running speed during a 10-km race and identified an association between physiological parameters and running speed (Bertuzzi, et al., 2014; Lima-Silva, et al., 2010), by both field methods and laboratory tests. Among the laboratory methods, the anaerobic threshold (AT) seems to be a good predictor of running speed because it represents the moment of transition from the predominance of aerobic energy production to the anaerobic energy production (Faude, Kindermann, & Meyer, 2009) and has been described in some studies with runners (da Silva, et al., 2015; Souza, et al., 2014, 2011) since AT corresponds to an intensity of effort that can be maintained with a stable state of oxygen and lactate consumption (Wakayoshi, et al., 1992, 1992).

Regardless of the method, it seems clear that getting to know running speed is of vital importance, especially if the insight can be obtained by means of easy-to-apply, low-cost and accurate tests. So, the present study aimed to compare the agreement and reproducibility of critical velocity, anaerobic threshold, and the simulated time trial on the track for the prediction of running speed in a 10-km official race in amateur runners. We hypothesized that the critical velocity and the trial on the track would be more efficient than the anaerobic threshold in predicting the 10-km race speed in amateur runners.

Methods

Sample and ethical criteria

A cross-sectional study was conducted with a convenience sample of 34 runners, of both genders (20 males). The study was approved by the Research Ethics Committee of the Catholic University of Brasília – UCB and each participant signed an informed consent form.

Inclusion criteria

Amateur runners from a running club from Brasília, Brazil, were invited to participate in this study. The eligibility criteria were: to have participated in at least one 10-km competition and being asymptomatic of any health problem. They should have uninterrupted training experience of at least six months, sign the informed consent form, participate in all study's tests, and not be taking any medication that could change their heart functions.

General procedures

The participants attended testing on four days and on one day they participated in an official 10-km race. During their visits, the following tests were performed: i) body composition assessment and maximum treadmill test; (ii) 400-meter running track test; (iii) 2000-meter running track test; (iv) 10-km simulated time trial on the running track; and v) 10-km run in an official race. The tests i, ii, and iii were performed in a random order. All track tests were conducted on the official track under similar climatic conditions (air temperature = 21 – 26 °C, relative humidity = 45 – 63%), with at least 48-hour interval between the tests. Athletes were instructed to participate in the study under conditions of total recovery, hydration, and nourishment. The experiment was completed in two weeks. Before each track test, the athletes were instructed to perform a moderate-intensity warm-up exercise followed by stretching.

Body composition analysis

Body fat was measured using dual-energy X-ray absorptiometry (DXA). Volunteers were asked to remove any metallic items they were wearing, such as rings, jewelry, belts, and watches (because such objects affect readings of the values of the estimated variables). Next, volunteers were placed in the horizontal decubitus dorsal position on the DXA apparatus for the full-body analysis. The equipment used was a Lunar DPX-IQ with version 4.6A software. Before using, the DXA equipment was duly calibrated, according to the manufacturer recommendations, and cut line adjustments were predefined. All analyses were performed by the same measurer.

Maximum treadmill test

A maximum treadmill test (MTT) was performed as an incremental exercise test with two-minute stages and increments of 0.5 km/h. The initial velocity was individualized between 8 and 9 km/h on the treadmill (Brudden Equipments LTDA and Line Movement, model RT 400, São Paulo, BRA). These tests were performed at an air temperature maintained between 21 and 23 °C and relative humidity between 40 and 60%. The test was conducted until voluntary exhaustion or any other ending criteria such as blood pressure $\geq 260/115$ mmHg, rating of perceived exertion (RPE) >19 on the Borg 6-20 scale, or S-T segment electrocardiogram with depression or elevation greater than 2 mm. During each test, heart rate (HR) was measured continuously as well as blood pressure (BP), RPE, ventilation (VE), oxygen uptake (VO_2), carbon dioxide release (VCO_2), oxygen ventilation equivalent (VE/VO_2), carbon dioxide equivalent (VE/VCO_2), and respiratory exchange ratio (RER). Each subject was instructed to avoid caffeine, alcohol, and strenuous exercise 48 hours before the experi-

ments, as well as to eat normally and avoid foods not usual in their daily intake.

Maximum oxygen uptake (VO_{2MAX}) was determined using a breath-by-breath method (Cortex and Metalyzer 3B from Cortex Biophysik – GER) and it was valid when at least two of the following criteria were met: $RER > 1.15$, VO_2 plateau $\Delta VO_2 \geq 150$ ml at the last minute, $HR < 10$ bpm of 220 and age, and/or $RPE \geq 19$. Anaerobic threshold (AT) was determined based on VE/VO_2 and VE/VCO_2 , measured at the point where VE/VO_2 increased disproportionately compared to the increase in VE/VCO_2 (Ferreira, et al., 2013).

The maximum treadmill test was used to determine the maximum heart rate (MHR) at the highest HR found in the test. Intensity at which the AT was used to determine the oxygen uptake at the AT (AT_{VO_2}), running speed at the AT (AT_{SPEED}), heart rate at the AT (AT_{HR}), and rating of perceived exertion at the AT (AT_{RPE}).

Critical velocity

For the determination of the CV, the times of the 400 m and 2,000 m tests on an official athletics track were recorded. Participants were instructed to run the set distances, alone, in the shortest possible time. The CV was calculated as the linear relation between distance and race time, corresponding to the slope of the linear regression line. The tests were performed at 08:00 a.m. or 7:00 p.m.

10-km simulated time trial on the track

The 10-km simulated time trial on the track took place on an official running track, with all involved in a single session, which began at 9:00 a.m. Each volunteer was identified, and a group of referees counted laps until completing 10-km. From the 5th lap, a table was placed with water next to the track, so the athletes could hydrate themselves. Hydration occurred *ad libitum*.

10-km race

The 10-km race chosen to compose this study was the Race of the Physical Education Professional, certified by the Brazilian Athletics Confederation, held in Brasilia-DF at approximately 1,080 meters above sea level. The race started at 07:00 a.m.; air temperature was 17.3°C and 53% relative humidity. The slope along the course was around -1.0 to 0.9%. A timing system was used via a chip positioned in the sneakers of each runner.

Statistical analysis

Initially, the normality of the data was verified through the Shapiro-Wilk's test. Data are presented like mean and standard deviation. The independent t-test was used to compare the means according to gender. The paired t-test was used to compare the means of the 10-km running speed with the CV, AT, and the simulated time trial on the track. The Bland-Altman plot was used to evaluate the concordances between the velocities established in the 10-km race with the CV, AT, and the simulated time trial on the track. The upper and lower limits of agreement for the Bland-Altman analysis were established with an alpha of 95% (± 1.96 standard deviation). In order to evaluate the reproducibility between the velocities established in the 10-km race with the CV, AT, and the simulated time trial on the track, the intra-class correlation coefficient (ICC) and the Cronbach's alpha were calculated. The ICC values were interpreted as poor if $< .40$, moderate if between $.40$ and $.75$, and excellent if $> .75$, according to the scale of reliability levels proposed by Fleiss (1999). Also, the values of total error (ET), standard error of estimate (SEE), and absolute and relative delta were calculated. The value of $< .05$ was adopted to indicate significant differences. The SPSS program, version 18.0 was used for the analyses.

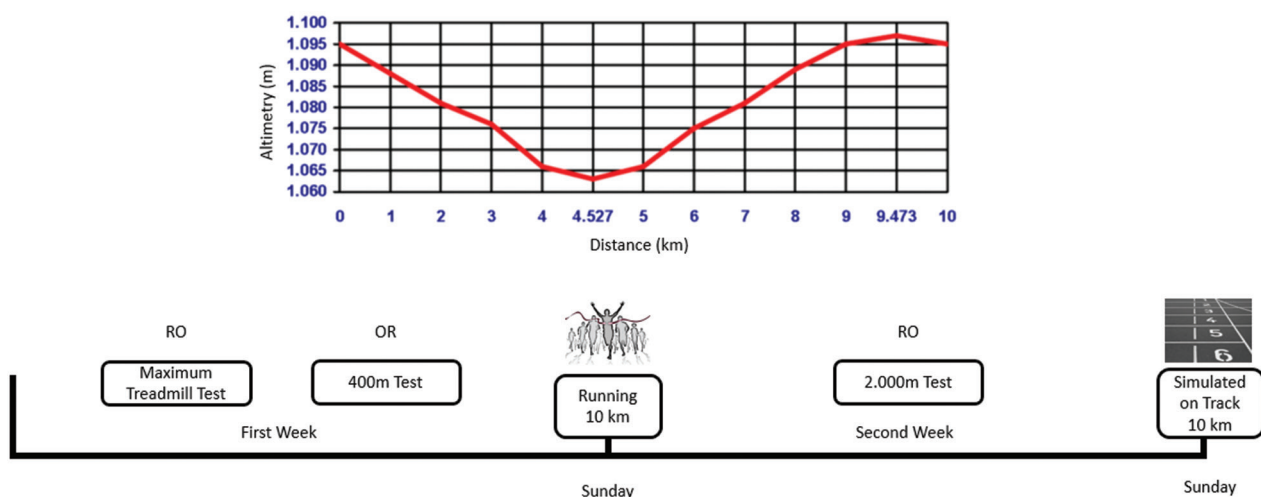

Figure 1. Schematic drawing of the study.

Results

Table 1 shows the results of the characterization of the sample for the total group and stratified according to gender.

As seen in Table 1, only age, MHR, AT_{HR} , and AT_{SPEED} did not differ between men and women.

Table 2 presents the values of mean velocity of the 10-km race and of the simulated time trial on the track, as well as the AT and CV velocities determined in laboratory and field tests, respectively.

Only the velocities determined by the CV and the AT were similar to the time of the 10-km race in women. The simulated time trial on the track differed from the 10-km race velocity in the total group and both genders. For the total group and men, the CV, AT, and the simulated time trial on the track differed from the 10-km race velocity.

Figures 2 to 4 show the agreement values established using the Bland-Altman plot, with values presented for the total group and stratified by gender for the estimated velocities in the CV and AT tests, mean velocity established in a simulated time trial on the track with the velocity of the 10-km race.

As seen in Figures 2 to 4, comparisons using the Bland-Altman plot showed that all residual scores

were within the range of agreement defined at ± 1.96 standard deviation for comparisons between the CV, AT, and the simulated time trial on the track with the 10-km race.

Table 3 presents the indicators of concordances, reproducibility, values of the errors of the comparisons of the velocities determined by the CV, AT, and the simulated time trial on the track with the 10-km race velocity for the total group and stratified by gender.

As seen in Table 3, the CV delta analysis overestimated the velocity of the 10-km race, while the deltas of the AT and simulated time trial on the track underestimated the 10-km race velocity. The agreement and reproducibility between the velocities calculated by ICC and Cronbach's alpha presented high values and considered excellent for the CV, the AT, and the simulated time trial on the track, according to the classification of the reference range established in ≥ 70 . Moreover, the total error and standard error estimate were mostly less than 1 km/h for the CV and simulated time trial on the track, and close to 1.5 km/h for the AT.

Figure 5 shows the delta percentage of the difference between the velocity determined by the

Figure 4. Agreement between the mean velocities established in a simulated time trial on the track and in a 10-km race. A – total group, B – males, and C – females.

CV, the AT, and the simulated time trial on the track and the 10-km race velocity.

As shown in Figure 5, the percentage difference showed that the CV presented the lowest delta in relation to the velocity of the 10-km race, with 2.6% for women and 4.8% for men, both overestimating the velocity of the 10-km race. On the other hand, both the simulated time trial on the track and the CV showed a tendency to underestimate the velocity of the 10-km race (between 5.0 and 6.0%, respectively).

Discussion and conclusion

The main results of the present study showed good agreement and reproducibility between the velocities determined by the CV, AT, and simulated time trial on the track with the real-time of a 10-km official race. These results corroborate the findings of another study (Souza, et al., 2014), which analyzed the predictive capacity of the AT determined in the laboratory and Montreal Test (MT) (Léger & Boucher, 1980) for performance

Figure 5. Delta percentage of the difference between the velocities determined by the CV, AT and simulated time trial on the track, and the 10-km race.

at distances of 1.5, 5.0 and 10.0 km. The authors found that performance prediction from the AT determined in both protocols (laboratory and MT) was dependent on the running distance. Also, physiological indexes obtained in a laboratory test that was able to predict performance in the 1.500 m, 5.000 m and 10.000 m tests were similar to indexes obtained in MT, and indexes derived from MT had higher ability to predict performance than indexes derived from laboratory tests in the three distances analyzed.

Our results also partially corroborate the findings of another study (Santos, et al., 2012) that associated VO_{2MAX} , the velocity at which VO_{2MAX} and CV were achieved with the performance in the 3.6-km ascending race, 10 km and 21 km in men and women. The authors found that CV presented high and significant association with all the distances studied, proving to be an adequate predictor of aerobic performance. However, they pointed out that the indirectly estimated VO_{2MAX} was the variable with the best association with race performance in the 10-km and 21-km races. In the present study, our focus was on the comparison of velocities determined by field and laboratory methods, although we verified the association between VO_{2MAX} and the actual running speed in the 10-km race. Here, our results diverge from previously reported study, since the highest correlations were found between the official running speed of 10 km and the CV ($R=.93$) and the simulated time trial on the track ($R=.97$) to the detriment of comparisons with VO_{2MAX} ($R=.88$) and the velocity at which VO_{2MAX} was reached ($R=.89$). On the other hand, we believe that these divergences cannot be understood by the simple metrical comparison of Pearson's linear correlation, nor used to indicate greater or less predictive or explanatory capacity. Although correlation is a strong indicator of association between two variables, in this case, there is a certain limitation, since the units and magnitudes of the measurements are different, therefore, it is not possible to use tests that measure the comparison between the means, its variance and error size.

The CV, when compared to the velocity established by the AT and the simulated time trial on the track, showed the lowest absolute and delta percentages, the highest CCI and Cronbach's alpha, as well as the lowest SEE concerning the time of a 10-km official race. Also, the paired *t*-test showed that the velocities determined by the CV and AT were similar to the time of the 10-km race in women, showing that the CV and AT for females already presented themselves as good predictors of running speed in a 10-km race. However, in studies of this nature, we cannot rule out or accept the viability of an instrument only by the absence or presence of significant difference established through the paired *t*-test, since other important tests and calculations are needed that can help establish the instrument's possible agreement and reproducibility as well as greater credibility. In the present study, comparisons using the Bland-Altman plot showed that all residual scores were within the range of agreement. Moreover, the agreement and reproducibility between the velocities calculated by CCI and Cronbach's alpha were considered excellent for the CV, AT and the simulated time trial on the track, according to the classification of reference established in the literature (Fleiss, 1999). Furthermore, the absolute and percent delta values, as well as the total error and standard error of estimate were considered low in the present study. The results also showed that the CV presented the smallest delta percentage in relation to the running speed of the 10-km race, overestimating the running speed of the 10-km race by 2.6% for women and by 4.8% for men. Alternatively, the simulated time trial on the track and the AT underestimated the running speed of the 10-km race by between 5.0% and 6.0%, respectively. Finally, the total error and standard error of estimate were mostly less than 1 km/h for the CV and the simulated time trial on the track and close to 1.5 km/h for the AT, which allows us to infer that the velocities determined through the CV, AT and simulated time trial on the track showed good reproducibility and agreement about the running speed of 10-km race.

Demonstrating the predictive capacity of CV with other important variables such as aerobic performance (Hughson, Orok, & Staudt, 1984; Kranenburg & Smith, 1996), lactate and ventilatory thresholds (Moritani, Nagata, Devries, & Muro, 1981; Smith & Jones, 2001; Wakayoshi, et al., 1992, 1992), swimming (Garatachea, et al., 2006; Wakayoshi, et al., 1992) and cycling (Hiyane,

Simões, Sílvia, & Campbell, 2006) performance is not new in literature. Another study evaluated the validity of the CV for determining the effects of training on the anaerobic threshold in endurance runners and confirmed that the CV had good validity for the determination of the AT before, but not after a four-week training program (Denadai, et al., 2003). The authors report that there was a loss of sensitivity between the AT and the CV to identify the adaptations induced by the training, justifying that the mechanisms that determined the adaptations in lactate responses and the CV may not be the same (Denadai, et al., 2003). This difference in pre- and post-training moments can be explained by the principle of biological individuality, since the adaptations acquired through training may be different depending on individual aspects such as age, gender, rest time, genetic aspects, and food, among others.

Thus, the extrapolation of the results of the present study should be applied with caution throughout a training program. Although the velocities determined by the CV, AT and the simulated time trial on the track showed good applicability and are useful tools for physiologists and endurance runners' coaches in determining the pace, race strategy and choice of training intensities throughout the periodization, their use should be one of the variables used as a parameter for the training and the race strategy, since other equally important variables should be considered. Also, both the CV and the simulated time trial on the track can be used as a low-cost, easy-to-apply, and reliable tool for use in endurance runners.

The limitation of the present study was the non-performance of all the tests at the same time of day. However, the distribution of the tests was randomized, except for the race and the 10-km simulated time trial. Besides, there were no great climatic variations during the tests. Another limitation is the impossibility of ensuring that the athletes complied with the recommendation not to perform vigorous exercises 48 hours before each experiment, though, messages were sent and phone calls were made to the athletes remembering the need to follow the recommendations before the tests.

We concluded the measurement of the CV determined on the track with only two distances (400 m and 2,000 m), the AT determined in laboratory conditions and the simulated time trial on the track were valid to estimate running speed in a 10-km race, once a good agreement was observed.
