

Electric field stimulation of precision-cut lung slices

Von der Fakultät für Mathematik, Informatik und Naturwissenschaften
der RWTH Aachen University zur Erlangung des akademischen Grades
eines Doktors der Naturwissenschaften genehmigte Dissertation

vorgelegt von

Marco Schlepütz, M.Sc.

aus Simmerath

Berichter: Priv.-Doz. Dr. Christian Martin
Univ.-Prof. Dr. Werner Baumgartner

Tag der mündlichen Prüfung: 06. Oktober 2011

Diese Dissertation ist auf den Internetseiten der Hochschulbibliothek online verfügbar.

Acknowledgement

The current thesis was made in the Institute of Pharmacology and Toxicology at the University Hospital Aachen, RWTH Aachen University and it is a pleasure for me to thank all the people who made this dissertation possible.

First, I owe my deepest gratitude to Priv.-Doz. Dr. Christian Martin for being my supervisor and mentor. I would like to thank him for his guidance, support, promotion and trust during the whole time. He always had an open door facilitating my work tremendously, and our discussions were always inspiring.

I would also like to thank my second examiner Univ.-Prof. Dr. Werner Baumgartner for his readiness to survey my doctoral studies and his constant interest in my work.

This thesis would not have been possible without the head of the institute Univ.-Prof. Dr. Stefan Uhlig, who provided the requirements to conduct this study. He supported my work strongly with his productive ideas and he promoted my career by giving me the opportunity to attend international conferences as well as to realize a stay in Montreal.

I am grateful to all collaborative partners, who facilitated my work on the species comparison including Sophie Seehase, Dr. Katherina Sewald and Prof. Dr. Armin Braun at the Fraunhofer ITEM in Hannover, Dr. Christina Schlumbohm from the DPZ in Göttingen, Verena Lambermont and Prof. Dr. Boris W. Kramer at the Maastricht University Medical Center, as well as Dr. Jan Spillner, Dr. Alberto Perez-Bouza, Dr. Till Braunschweig, Univ.-Prof. Dr. Rüdiger Autschbach and Univ.-Prof. Dr. Knüchel-Clarke at the University Hospital Aachen.

Kindly, I thank Prof. Dr. James G. Martin, who invited and welcomed me at the Meakins-Christie Laboratories (McGill University, Montreal) to learn the culturing of airway smooth cells, and Dr. Paul-André Risse, who took care of me during the stay.

I am thankful to the German academic exchange service (DAAD) for financial support to attend the ATS International conference 2010 in New Orleans.

Further, I am indebted to many of my colleagues, who were always willing to help and assist me. In this regard I am highly thankful to current and former members of the pulmonary pharmacology group, by name Marc Bernau, Christoph Burghaus, Hanna Czajkowska, Constanze Dassow, Hiltrud Königs, Anke Kowallik, Dennis Lex, Ulrike Maitas, Oliver Pack, Marion Peters, Annette Rieg, Nadine Ruske, Xhina Schneider, Stephanie Siegl, Ulrike Uhlig, Eva Verjans and Yang Yang. Special thanks are due to Kathleen Reiss and Ulf Soppa for careful proofreading the manuscript.

To all my friends, not mentioned by name but knowing that they are meant, I am deeply thankful for having an open ear and having motivated me during this study. Especially, I want to thank my girlfriend Sandra Dohmen for her enduring encouragement.

Finally, I profoundly feel obliged to my parents, Inge and Hermann-Josef, as well as my brother Tino, who reliably support me wherever possible.

II List of abbreviations

A	Current amplitude
AHR	Airway hyperresponsiveness
ASM	Airway smooth muscle
ATP	Adenosin triphosphate
B	Pulse duration
BDNF	Brain-derived neurotrophic factor
BSA	Bovine serum albumin
cAMP	Cyclic adenosine monophosphate
CBF	Ciliary beat frequency
cGMP	Cyclic guanosine monophosphate
CGRP	Calcitonin gene related peptide
COPD	Chronic obstructive pulmonary disease
CPI	PKC activated phosphatase inhibitor
DAG	Diacylglycerol
4-DAMP	4-diphenylacetoxy-N-(2-chloroethyl)piperidine hydrochloride
EAR	Early allergic response
EC ₅₀	Half-maximal effective concentration
EF ₅₀	Half-maximal effective frequency
EFS	Electric field stimulation
ELISA	Enzyme linked immunosorbent assay
eNANC	Excitatory NANC
F	Frequency
G	Basic rhythm
GDNF	Glial-derived neurotrophic factor
GFL	GDNF family ligand
GFR	GDNF family receptors
G protein	Heterotrimeric guanine nucleotide-binding protein
GPCR	G protein coupled receptor
HDM	House dust mite
HMGB1	High-mobility group box 1
IAA	Initial airway area
IC ₅₀	Inhibitory concentration of half-maximal effect
i.p.	Intraperitoneal
i.tr.	Intratracheal
Ig	Immunoglobulin
IL	Interleukin
iNANC	Inhibitory NANC

IP ₃	Inositol (1,4,5)-trisphosphate
LABA	Long acting β -agonists
LAR	Late allergic response
L-NAME	N _ω -nitro-L-arginine methyl ester
L-NNA	N _ω -nitro-L-arginine
log IC ₅₀	Decadic logarithm of IC ₅₀
LT	Leukotriene
MBP	Major basic protein
MLCK	Myosin light chain kinase
MLCP	Myosin light chain phosphatase
M receptor	Muscarinic acetylcholine receptor
M _R	Muscarinic acetylcholine receptor of type 1-5
NANC	Nonadrenergic noncholinergic
NCX	Sodium calcium exchanger
NGF	Nerve growth factor
NK	Neurokinin
NK _R	Neurokinin receptor of type 1-3
NO	Nitric oxide
NT	Neurotrophin
NTR	Neurotrophin receptor
OVA	Ovalbumin
PBS	Phosphate buffered saline
PCLS	Precision-cut lung slice(s)
PG	Prostaglandin
PKA	Protein kinase A
PKC	Protein kinase C
p75NTR	p75 Neurotrophin receptor
s.c.	Subcutaneous
SABA	Short acting β -agonist
SKF96365	1-(β -[3-(4-methoxyphenyl)propoxy]-4-methoxyphenethyl)-1H-imidazole
SP	Substance P
SQ29548	[1S-[1 α ,2 α (Z),3 α ,4 α]-7-[3-[[2-[(phenylamino)carbonyl]hydra-zino]methyl]-7-oxabicyclo [2.2.1]hept-2yl]-5-heptenoic acid
SR	Sarcoplasmic reticulum
T _C 1-cells	Type 1 cytotoxic T-cells
T _H 1-lymphocyte	T helper lymphocyte type 1
T _H 2-lymphocyte	T helper lymphocyte type 2
TNF	Tumor necrosis factor
TP	Thromboxane prostanoid

TR	Train rhythm
Trk	Tropomyosin-related kinase
TRP	Transient receptor potential
TW	Train width
TXA	Thromboxane
U46619	9,11-dideoxy-9 α ,11 α -methanoepoxy prostaglandin F _{2α}
VIP	Vasoactive intestinal polypeptide

1 Introduction

1.1 Importance and principal structure of the lung

The function of the mammalian lung is the exchange of gases (oxygen \leftrightarrow carbon dioxide) with the environment. Air enters the body via the upper respiratory tract (nose, mouth and throat) and gets into the lung - the lower respiratory tract. Beginning with the trachea, the lower respiratory tract branches at the main bronchus into the left and right lung harboring two and three lobes, respectively. From the hilus, the lobar intrapulmonary bronchi then branch further into terminal bronchioli, respiratory bronchioli, alveolar ducts and end in the alveolar sacs (figure 1). The tracheobronchial tree including the terminal bronchiole is considered as the air conducting part, whereas the part distal is considered as the respiratory part, which represents a gas exchange area of 50-100 m² in humans (84).

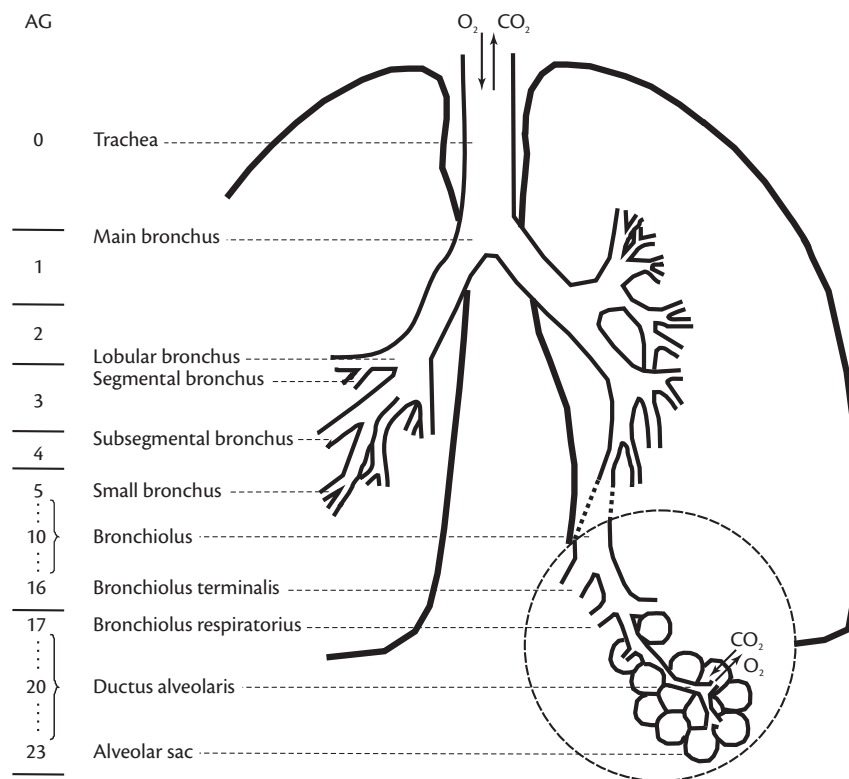

Figure 1: The tracheobronchial tree of the human lung. Air rich in oxygen (O₂) enters the lung via the trachea and is conducted by the airways down to the alveoli, where the gas exchange against carbon dioxide (CO₂) from blood takes place. On the left, the airway generation (AG) referring to its according anatomical structure is depicted. The figure was modified according to Klinke and colleagues (84).

Mammalian tracheobronchial branching architectures are complicated and cannot be idealized to one branching system. Branching of conducting airways in humans is considerably asymmetrical and asymmetry may have an important effect on airflow. Three idealized branching patterns are commonly recognized for different species: (i) monopodial (at the branching point a small segment may branch from the main, or parent stem), (ii) dichotomous (the parent segment may divide into

two equal daughter segments) and (iii) polychotomous (the parent segment may divide into many daughter segments) (83).

A cross-section of a conducting airway reveals a concentric anatomic structure (figure 2). The airway lumen is faced by a single cell layer, the epithelium, lying on the basal membrane. The airway smooth muscle (ASM) cells form a thin bundle around the airway. The purpose of ASM in the airways remains contentious, but certainly contraction of ASM is responsible for the excessive airway narrowing observed in asthma (77). In humans, ASM are found down to the respiratory bronchioles, whereas cartilage is only interspersed in the conducting airways.

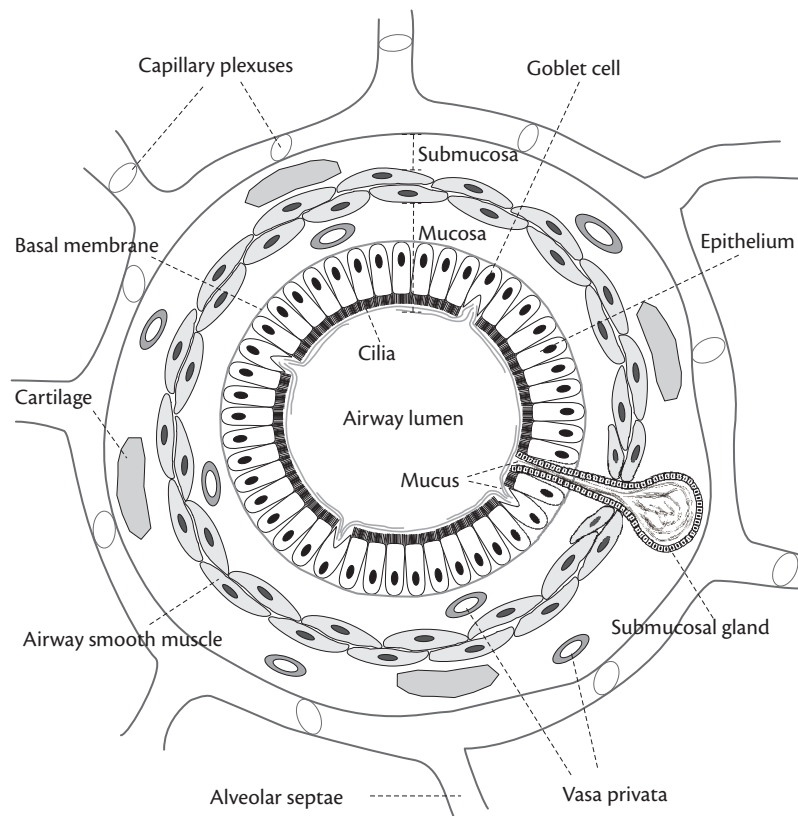

Figure 2: Cross-section of an airway. The concentric structure possesses a single cell layer – the epithelium which is ciliated - facing the airway lumen and lying on the basal membrane. A thin bundle of airway smooth muscle cells follows. The vasa privata provide the lung with blood, whereas the gas exchange of oxygen and carbon dioxide takes place at capillary plexuses. Tethering forces are conducted by the alveolar septae. For more details please see the text.

Removal of particles or microorganisms from the lung is achieved by mucociliary clearance, i.e. the mucus – produced by goblet cells or submucosal glands – forms a continuous layer, to which the foreign bodies stick, that is transported by the beating cilia towards the upper respiratory tract (84). Cilia and mucus are not found in the alveoli as they would impair the gas exchange. At this site, protection against foreign particles is achieved by alveolar macrophages. They phagocytize the foreign particles and enzymatically degrade them or, if this is not possible, the macrophages migrate ameboidly towards the conducting airways and are then removed by mucociliary clearance (84).

The vasa privata originate from the systemic circulation and provide the lung with blood. In contrast in the pulmonary circulation, the pulmonary artery and vein branch out and form capillary plexuses at alveolar sites where gas exchange takes place between air and blood (129). Tethering forces of the parenchyma, pulmonary pressure and partially also cartilage keep the airways in an open uncollapsed state. The parenchyma consists of alveolar ducts, alveolar sacs, alveoli and the airspaces contained within these structures. In the inflated lung the parenchyma constitutes approximately 80-90% of the lung volume and consists of around 70% airspace and 30% gas exchange tissue which surrounds the airspace (106).

1.2 Autonomic innervation of the lung

The mammalian nervous system is divided into the central- and peripheral nervous system. The central nervous system is comprised of the brain and the spinal cord, whereas the peripheral nervous system consists of all somatic and autonomous nerves including ganglions. The somatic nervous system mediates between the organism and its environment. It is associated with conscious perception, voluntary body movements via skeletal muscles and rapid signalling. In contrast, the autonomous nervous system mediates between the organism and its organs. It is responsible for body homeostasis and the regulation of organ functions depending on the environmental conditions. It functions unconsciously and involuntarily. Both, the somatic and the autonomous nervous system, contain afferences and efferences (figure 3). Afferences are all neural pathways originating in the periphery (e.g. skin, organs) and running to the central nervous

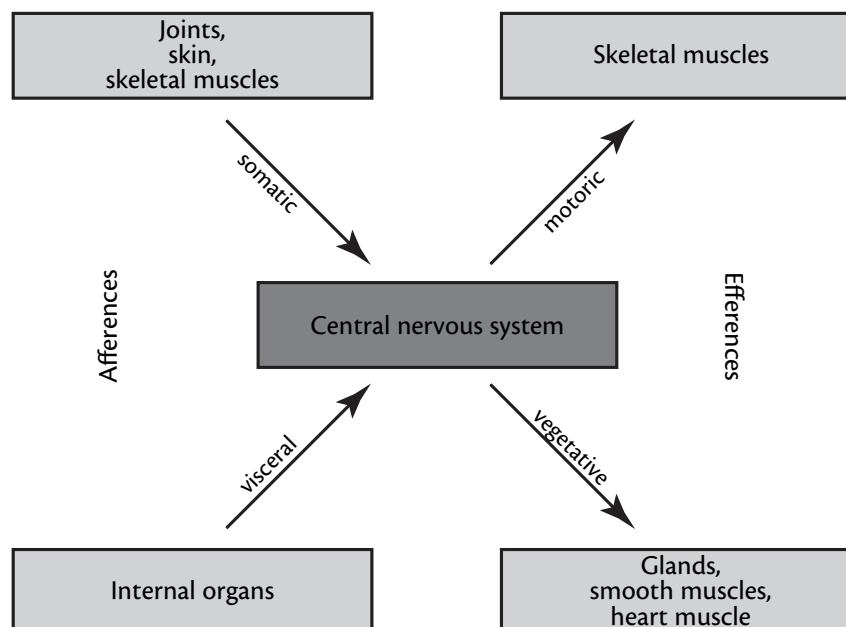

Figure 3: Interconnections between the peripheral and central nervous system. The peripheral nervous system (light grey) contains both afferences and efferences. Signals originating in the periphery are conducted via the afferences to the central nervous system (brain + spinal cord; dark grey), become integrated and are then fed back to the periphery via efferent nerves resulting in an adaptation of the organism to the stimulus. The upper panels reflect the somatic nervous system and the lower panels the autonomous nervous system.

system. By contrast, efferences are all neural pathways running from the central nervous system to the periphery (e.g. voluntary muscles, smooth muscles, vessels or glands) (51).

The autonomous nervous system is further subdivided into the sympathetic and parasympathetic nervous system as well as the enteric nervous system innervating the intestinal wall. Usually, an organ is innervated by both sympathetic and parasympathetic nerves antagonizing each other. Sympathetic nerve fibers are associated with the spinal cord (thoracic vertebrae 1-12 and lumbar vertebrae 1-4), whereas parasympathetic nerve fibers originate from the brain stem and the sacral vertebrae 2-4 (51). In the lung, sympathetic fibers are associated with the thoracic vertebrae 1-5 and parasympathetic fibers with the 10th cranial nerve (Nervus vagus) (129). With respect to the neurotransmitter involved at the neuromuscular synapse there exist three types of nerves: sympathetic noradrenergic nerves, parasympathetic cholinergic nerves and nonadrenergic noncholinergic (NANC) nerves (9; 32; 49). Moreover, nerve fibers are distinguished by their conduction velocities into C- (0.3-2 m/s), A δ - (3-8 m/s) and A δ / γ -fibers (10-50 m/s) (97; 174).

Figure 4: Innervation of the airway smooth muscle (ASM). The ASM is innervated by cholinergic, adrenergic and nonadrenergic noncholinergic nerves (NANC) (9; 142). Excitatory and inhibitory components run side by side, in which excitatory mechanisms lead to ASM contraction and inhibitory mechanisms to ASM relaxation. The excitatory cholinergic innervation is present in the airways from the trachea down to the peripheral bronchi. Bronchoconstriction via excitatory NANC is mediated via subepithelial C-fiber sensory afferents that release tachykinins (neurokinin (NK) A and B, and substance P (SP)). Next to the noradrenergic inhibitory system originating from the adrenal medulla or sympathetic ganglia, inhibitory NANC innervation has been confirmed, in which vasoactive intestinal polypeptide (VIP) and nitric oxide (NO; diffusing through ASM membrane and activating intracellular soluble guanylyl cyclase) are involved as neurotransmitters. Except for the cholinergic nerve component which seems to be present in all mammals, the innervations of the ASM show a considerable variability among different species. ACh, acetylcholine; β , β -adrenoceptor; M, muscarinic acetylcholine receptor; NE, norepinephrine; NKR, NK receptor; VR, VIP receptor. The figure was modified according to Andersson and Grundström (9).

The autonomic nerves regulate many aspects of airway function, e.g. ASM tone, mucus secretion and bronchial microcirculation (143). Upon activation, the nerves release their inherent neurotransmitters, which then have a post-junctional effect on their end organ. With respect to the ASM, neurotransmitters initiate bronchoconstriction or relaxation (figure 4). Bronchoconstrictive neurotransmitters are for instance acetylcholine, which is released by parasympathetic cholinergic nerves, and the tachykinins substance P (SP), neuropeptide K, neurokinin (NK) A or B, which are released from excitatory NANC (eNANC). ASM relaxation is caused by β_2 -receptor stimulation after activation of sympathetic adrenergic nerves or by the release of vasoactive intestinal polypeptide (VIP) or nitric oxide (NO) from inhibitory NANC (iNANC) (9; 59).

Innervation of the ASM differs between species as well as within species along the tracheobronchial tree. Spina and colleagues (158) studied the sensory nerve functions of different species and found that the relative tissue content of the neuropeptides calcitonin gene related peptide (CGRP) and SP was much higher for guinea pigs than for rabbits and marmosets, which had equal levels. In some cases the same neuropeptides can even have opposing effects: Whereas SP or NK A cause relaxation of tracheal preparations from Sprague-Dawley and Wistar rats, they lead to contraction of tracheal preparations from Fischer 344 rats (42; 56; 81; 165). Within guinea pigs, cholinergic nerves dominate over tachykinergic at the trachea, whereas tachykinergic nerves dominate at the bronchus (8). The human lung contains ASM constrictive cholinergic and eNANC nerves, and ASM relaxation is mainly due to iNANC nerves whereas sympathetic adrenergic nerves may play only a minor role (32).

1.3 Mechanisms of neurally induced ASM contraction

The parasympathetic nervous system is the dominant bronchoconstrictor mechanism in all mammals (14). Acetylcholine is released from nerve terminals and binds to muscarinic (M) receptors at different sites throughout the lungs. The M_1 receptor is localized on parasympathetic ganglia and is thought to primarily facilitate cholinergic neurotransmission by nicotinic acetylcholine receptors. M_2 receptors on the pre-synaptic nerve terminals control acetylcholine release in a feedback manner, limiting excessive acetylcholine liberation. Moreover, M_2 and M_3 receptors are found on the ASM cells. M_3 receptor activation leads to ASM contraction, a process facilitated by M_2 receptors by counteracting cAMP-mediated relaxant pathways (21). Regarding eNANC innervation released tachykinins bind to NK receptors located on the ASM. SP binds principally to the NK_1 receptor, whereas NK A and NK B bind to NK_2 and NK_3 receptors, respectively (6). Both, M and NK receptors belong to the family of heterotrimeric guanine nucleotide-binding protein (G protein) coupled receptors (GPCR). M_3 and NK_{1-3} preferentially couple to the $G_{q/11}$ protein (6; 21). Receptor stimulation results in dissociation of the G protein and subsequent activation of the phospholipase C by $G_{\beta\gamma}$. Phospholipase C hydrolyzes phosphatidylinositol-4,5-bisphosphate to diacylglycerol (DAG) and inositol (1,4,5)-trisphosphate (IP_3) (5). Then IP_3 binds to the IP_3 receptor at

the sarcoplasmic reticulum (SR) causing the release of calcium from intracellular stores (115) and resulting in a 10000-fold increase in intracellular calcium concentration (72). In a resting (relaxed) ASM cell the intracellular free calcium ion concentration is approximately 100-200 nM (147). The elevated intracellular calcium concentration causes the formation of the calcium/calmodulin complex, which activates the myosin light chain kinase (MLCK). The contractile apparatus of the ASM consists of actin and myosin filaments and accessory and regulatory proteins. Phosphorylation of the myosin light chain by MLCK enhances its intrinsic adenosine triphosphatase activity and subsequent mechanical interactions with actin. Finally, this results in the sliding of the myosin molecule along the actin filament (72).

ASM contraction can also occur after increases of cytosolic calcium concentration due to calcium entry from extracellular sites via voltage gated calcium channels, the reverse mode of the sodium calcium exchanger (NCX), voltage independent influx via transient receptor potential (TRP) channels or activation of the ryanodine receptor at the SR (72; 115; 147). However, these mechanisms are beyond the scope of neurally induced ASM contraction and are therefore not explained in detail here.

Another mechanism leading to ASM contraction operates by the inhibition of the myosin light chain phosphatase (MLCP). Thereby, the dephosphorylation of the myosin light chain is prevented and ASM contraction is promoted. Inhibition of MLCP is due to activation of the Rho-kinase pathway in response to $G_{12/13}$ stimulation (62; 186) or due to DAG formation after $G_{q/11}$ stimulation. DAG activates the protein kinase C (PKC) (5). PKC in turn phosphorylates the following protein PKC activated phosphatase inhibitor (CPI)-17, which functions as inhibitor of the catalytic subunit of MLCP (62; 186).

Pharmacologically, ASM contraction can be inhibited by receptor antagonists which is also of clinical relevance, e.g. tiotropium in chronic obstructive pulmonary disease (COPD) (134). A variety of anticholinergics, such as atropine, 4-DAMP, AQ-RA, gallamine, DAU 5884, methoctramine, pirenzepine, AF-DX 116, ipratropium or tiotropium have been developed and show different specificity concerning the M receptor subtypes (62). Selective antagonists of the NK receptors are for instance aprepitant, SR140333, LY303870, CP99994, and RP67580 for NK_1 , GR94800, GR159897, MEN10627, SR48968 and MEN11420 for NK_2 or SR142802, SB223412 and PD157672 for NK_3 (6).

1.4 Mechanisms of neurally induced ASM relaxation

ASM relaxation is caused either by sympathetic or iNANC signalling. In sympathetic signalling, norepinephrine functions as neurotransmitter binding to β -receptors on the ASM (19). In iNANC signalling, VIP or NO are involved as neurotransmitters binding to the VIP receptor on ASM or interfering with the cyclic guanosine monophosphate (cGMP) pathway in ASM, respectively

(22; 101; 116; 178). Both, the β -receptor and the VIP-receptor belong to the family of GPCRs coupling to the G_s protein (6). Upon dissociation of G_s , in response to receptor stimulation, the membrane bound adenylyl cyclase becomes activated catalyzing the formation of cyclic adenosine monophosphate (cAMP) from adenosine triphosphate (ATP) (5; 20; 98). Increased cAMP levels are responsible for ASM relaxation due to several mechanisms: On the one hand, cAMP may promote the efflux of calcium to the extracellular space via NCX or via calcium-ATPases into the SR. On the other hand cAMP may activate the protein kinase A (PKA) (85). The PKA leads to phosphorylation of the MLCK preventing MLC phosphorylation (58) or PKA attenuates RhoA phosphorylation (92), which decreases Rho association with its downstream target Rho kinase (44).

NO activates the soluble guanylyl cyclase forming cGMP, which activates the protein kinase G (PKG). PKG causes smooth-muscle relaxation by mechanisms that are still being defined and that include reduction in cytosolic calcium (by enhanced calcium export and/or by reduction in IP_3 receptor-mediated calcium-mobilization) and dephosphorylation of MLC (by activation of MLCP and/or by sequestration of MLCK in a phosphorylated form, which is inaccessible for calcium/calmodulin complexes) (20).

ASM relaxation can be influenced pharmacologically. With respect to β -receptors, a variety of antagonists and agonists are established. Antagonists are for instance the β -blockers, propranolol and arterenol. Agonists have clinical relevance in the treatment of asthma and are for instance salbutamol, isoproterenol, indacaterol, salmeterol or formoterol, which are classified as short or long acting β -agonists (SABA/LABA) depending on their duration of action (125). Moreover, direct blocking of catecholamine release from adrenergic nerves can be achieved by the application of guanethidine (52). Small peptides resembling the growth hormone releasing factor are considered as antagonists at the VIP-receptor (6; 63; 182). NO-signalling is antagonized by NO synthase inhibitors such as N_{ω} -nitro-L-arginine methyl ester (L-NAME) (139) or N_{ω} -nitro-L-arginine (L-NNA) (102; 103).

1.5 Electric field stimulation (EFS) of lung tissue preparations in organ baths

Application of an electric field across isolated airway preparations results in activation of intrinsic nerves, the release of neurotransmitters, and response of the ASM to these neurotransmitters (52). Previously, EFS has been studied in three types of airway preparations, i.e. tracheal strips, bronchial strips and parenchymal strips (52), which were mounted in organ baths and faced by parallel platinum electrodes. The electrodes can be wire or flat stock placed parallel to the preparation or ring electrodes placed at each end of the tissue (52). These models have been extremely useful for understanding the neural control of airway tone in different species e.g. mouse, rat, guinea pig, ferret, cat, dog, horse or human (8; 11; 49; 57; 61; 71; 80; 93; 104; 125; 183; 184; 190), and continues to do so (25; 125). However, the organ bath method has some disadvantages: First, it can be applied

only to relatively large airways and preparations from the lower airways of smaller mammals are difficult to obtain. For example in rats, studies of the innervation are characterized only down to the eighth generation (52). However, innervation is unevenly distributed along the tracheobronchial tree. For instance, in guinea pig trachea cholinergic nerves predominate over tachykinergic nerves, whereas the latter predominate in the bronchus (8). *In vivo* parasympathetic vagal stimulation and tantalum roentgenography showed a higher bronchospasm in intermediately sized airways compared to larger airways in dogs or cats. Therefore, methods to examine smaller sized airways in different species are needed (124). Second, organ bath methods are often performed under either isometric or isotonic conditions and require a muscle preload. This creates potential problems: the preload is artificial and may influence the result or even damage the smooth muscle (52). Furthermore, contractions are not auxotonic as *in vivo*, where the ASM shortens against an increasing load imposed by the attachments of the surrounding lung parenchyma, parallel elastic elements (i.e. extracellular matrix) and mucosal folding (34; 52; 96). More recently, some of these problems have been solved by the development of servo-controlled force-length transducers that adjust airway preparations to match a muscle length that was determined before the specimen was prepared (25; 26). Third, the smaller the airways are the smaller is the amount of smooth muscle and quantification of weak contractions requires very sensitive equipment. Spiral tissue preparations, used to increase contractions, are hampered by misalignment of the smooth muscle from the longitudinal axis and force generation is lost to the coil (52). Fourth, organ bath experiments require a relatively large buffer volume, generally more than 5 mL. This is disadvantageous, if expensive substances have to be tested and/or a high throughput of experiments is intended. Fifth, in whole tissue preparations (i.e. parenchymal strips) contractions from airways or vessels cannot be distinguished (52).

1.6 Precision-cut lung slices (PCLS)

PCLS are a relatively new *in vitro* method in pulmonary research. PCLS are lung tissue slices of uniform thickness of 200 - 300 μm , which are prepared from agarose instilled lungs by means of a Krumdick tissue slicer and which are viable for at least 72 h under cell culture conditions (111; 159). In 1996, Martin and colleagues (111) described the preparation and study of airway responses in PCLS for the first time. Originally developed for rats, the PCLS method has been adopted to other species such as mice (34; 68), guinea pigs (145), horses (181), sheep (151), non-human primates (155) and humans (145; 163; 188). Depending on the species 10 to more than 50 slices can be obtained from one animal. Therefore, this method is very economical in terms of experimental costs and animal use, thus contributing to Russell's and Burch's (149) 3Rs (refinement, reduction, replacement) of animal protection: The PCLS Method has the potential to (i) refine the multiple physiological measurements, (ii) reduce the number of animals by a factor of 10 to 50 and (iii) replace animals when human lung tissue is used (110).

PCLS have been extremely useful in pharmacological (69; 107; 145; 152; 188; 189) and toxicological studies (68; 127; 128) because they resemble the intact respiratory tract of the *in vivo* situation in morphology and functionality. Some advantages of the PCLS method are that airway contractions are somehow auxotonic as the airways are embedded in the surrounding tissue (34), that contractions of vessels and airways can be distinguished (108), that only small buffer volumes are needed, that many slices can be obtained from an individual so that different conditions can be tested at the same subject and that small airways are accessible allowing to study the complete tracheobronchial tree down to the peripheral lung (111; 152; 189). Even biochemical analysis can be performed on PCLS, i.e. gene expression profiles can be analysed after reverse transcription polymerase chain reaction (38) or intracellular calcium fluxes can be measured in multiphoton microscopy (39; 145).

Small airways are defined by their inner diameter being less than 2 mm in human and less than 780 μm in rat airways (189; 191). As a result of their relative inaccessibility, the role of small airways is difficult to assess and maybe because of these problems small airways have been considered as a silent zone in the past. Since in PCLS the airway diameter is easily accessible, this method offers a novel way to study airway responses in peripheral airways (110). The smallest airways being analyzed by Wohlsen and colleagues (189) in PCLS from rat were of 50 μm in diameter, corresponding roughly to the terminal bronchioles. Bronchoconstriction in PCLS has been studied in response to exogenously administered mediators of the early allergic response (e.g., methacholine, histamine, serotonin, thromboxane (TXA), leukotriene (LT), endothelin) and in response to allergens after passive or active sensitization (34; 189). Smaller airways in PCLS are more reactive to methacholine, serotonin, the thromboxane prostanoid (TP) receptor agonist U46619 and allergens in lungs of different species (112; 188; 189). Different explanations for these longitudinal differences in airway responsiveness are possible: for instance, heterogeneous receptor distribution along the airways, as shown for VIP (33; 137), tachykinin (55), SP (132), and histamine (28) or varying ASM thickness (thickness is more pronounced in small than in large airways) (48), which might result in differences in airway reactivity (120; 162). This last argument is contradicted by findings that endothelin contracted airways independent of their size (112), while small airways react stronger to methacholine and TXA (111; 112). Given the importance of small airways for asthma and COPD (160; 188; 189), the possibility to study different airway generations in PCLS is of clinical relevance.

Mucociliary clearance is an important defense mechanism that clears foreign particles and chemicals from the airways to maintain healthy lungs. A key parameter determining the rate of mucus clearance is the ciliary beat frequency (CBF). The density (cilia per cell and number of ciliated cells) and length of cilia are greater in the trachea than in small airways and this correlates with an increase in mucus transport and CBF toward the oropharynx (41). Hence, beside broncho- and vasoconstriction, measuring the CBF has been addressed in PCLS from mice, rats and humans (41; 187; 188). CBF in those species varied from 23.1 - 26.5 Hz in mice to 12.7 - 15.6 Hz in rats and

4.8 - 12.9 Hz in humans. Although species variation may occur, PCLS serve as a suitable model to examine regulation of CBF in response to physiological parameters (e.g. temperature) (41) or drug interference (e.g. cAMP elevating agents such as roflumilast), which have shown beneficial effects in COPD or asthma (187).

Overall, as results obtained from PCLS are predictable for responses of the entire intact lung (110), PCLS are of great use in pulmonary toxicology and pharmacology, i.e. development of drugs for asthma and COPD. Certainly, human PCLS provide a unique opportunity to save animals and to get clinically relevant data at the same time.

1.7 Asthma and COPD

Bronchial asthma and COPD have a high personal as well as societal, and economical impact (177). Chronic lower respiratory tract diseases are the fourth-leading cause of death and the major cause of sickness in the United States (123). Worldwide, they are currently the fifth-leading cause of death and the World Health Organization projects they will become the third-leading cause by 2030 (154). Therefore, it is critical to understand their underlying pathogenic mechanisms in order to develop new treatment strategies.

Both asthma and COPD are characterized by airway obstruction, which is variable and reversible in asthma but is progressive and largely irreversible in COPD. In asthma, airway obstruction is mainly due to bronchoconstriction, edema and plasma exudation, whereas in COPD mucosal inflammation, fibrosis, emphysema and mucus hypersecretion are responsible for obstruction (19). In both diseases, the respiratory tract is chronically inflamed (table 1), which is mediated by increased production of multiple inflammatory proteins, including cytokines, chemokines, adhesion molecules, inflammatory enzymes and receptors (19). Moreover, acute episodes of exacerbation are observed with increasing intensity of inflammation in both diseases (19). Ultimately, chronic inflammation leads to airway remodelling which affects the whole respiratory tract from central to peripheral airways that are less than 2 mm in internal diameter in humans, the so called small airways (177).

Asthma is an allergic disease, in which mast cells become activated and initiate the early allergic response (EAR) within minutes and the late allergic response (LAR) within hours leading to the typical asthma symptoms: wheezing, coughing, chest tightness and shortness of breathing (170). In the EAR, inhaled allergens activate mast cells, by cross-linking surface bound immunoglobulin (Ig) E, that degranulate and sequester preformed (histamine, proteoglycans, serine proteases, tumor necrosis factor (TNF)) or newly synthesized mediators (prostaglandins (PG), cysteinyl LT, TXA, platelet activating factor, cytokines). These mediators interact and lead to bronchoconstriction (17; 18; 170). The LAR appears frequently 4 - 6 hours after the EAR and

depends on leukocyte (eosinophils, mast cells and T-lymphocytes) recruitment due to mast cell-derived mediators such as TNF- α and different chemokines as well as the expression of adhesion molecules on leukocytes and vascular endothelial cells (170). Those leukocytes initiate the second phase of bronchoconstriction, mucus secretion and airway swelling. Moreover, they cause tissue destruction, launch and maintain the chronic inflammation (170). T helper lymphocytes type 2 (T_H2-lymphocytes) have a central role in regulating the inflammatory response in allergy through the release of interleukins (IL). IL-4 and IL-13, stimulate B-lymphocytes to produce IgE, IL-5 attracts eosinophils and IL-9 stimulates mast-cell proliferation (18).

Table 1: Characteristics of asthma and COPD in chronic inflammation of the lower respiratory tract (modified from Barnes (17; 18))

Character	Asthma	COPD
Airway smooth muscle	Increased	Minimal increase
Basement membrane	Thickened	No change
Fibrosis	Subepithelial	Peribronchiolar
Alveolar disruption	No	Existent
Airway vessels	Increased	No change
Epithelium	Often shed	Pseudostratified
Goblet cells	Increased	Increased
Mast cells	Increased and activated	Normal
Eosinophils	Increased	Normal
Neutrophils	Normal (severe: increased)	Increased
Dendritic cells	Increased	Uncertain
T lymphocytes	T _H 2 type	T _H 1 and T _C 1 type
B lymphocytes	IgE producing	Increased
Cytokines	IL-4, IL-5, IL-13, TNF- α	TNF- α
Chemokines	CCL11, CXCL8	CCL2, CXCL1, CXCL8
Lipid mediators	LTD ₄ , LTB ₄ , PGD ₂	LTB ₄
Oxidative stress	Yes	Yes
Steroid response	Sensitive	Resistant

CCL, CC-chemokine ligand; COPD, chronic obstructive pulmonary disease; CXCL, CXC-chemokine ligand; IL, interleukin; LTB₄, leukotriene B₄; LTD₄, leukotriene D₄; PGD₂, prostaglandin D₂; T_C1, type 1 cytotoxic T cell; T_H, T helper cell; TNF, tumor necrosis factor.

In contrast to asthma, in COPD, inhaled cigarette smoke and other irritants activate epithelial cells and macrophages to release chemotactic factors that attract monocytes (differentiating into macrophages in the lung), neutrophils, T helper lymphocytes type 1 (T_H1-lymphocytes) and type 1 cytotoxic T cells (T_C1-cells) (18). These cells, together with macrophages and epithelial cells, release proteases, e.g. matrix metalloproteinase 9 causing elastin degradation and emphysema. Neutrophil elastase also causes mucus hypersecretion. Epithelial cells and macrophages release transforming growth factor- β , which stimulates fibroblast proliferation, resulting in fibrosis in the small airways (18).

Airway hyperresponsiveness (AHR) and airway remodelling in asthma

AHR is defined as an exaggerated airway narrowing in response to many different stimuli, e.g. histamine, methacholine or adenosine (15; 170). In everyday life, increased bronchial responsiveness may occur following allergen exposure, upper respiratory tract viral infection or industrial chemical contact (15). Depending on the trigger, various types of asthma exist, that are for example extrinsic (allergic) asthma, intrinsic asthma, exercise-induced asthma, aspirin-sensitive asthma and occupational asthma (35; 64).

Airway remodelling is a consequence of chronic airway inflammation and refers to structural changes in the lung. These are thickening of the airway wall, hyperplasia of goblet cells, hypertrophy of submucosal glands, increased vascularity of the airway wall, ASM hypertrophy, ASM hyperplasia and subepithelial fibrosis (table 1) (13; 170). The airway wall thickening may explain incomplete reversibility of airway obstruction in asthmatics, whereas altered goblet cells and submucosal glands explain mucus hypersecretion and mucus plugging (170). Moreover, the increased vascularity is responsible for amplified plasma protein leakage into the lung (170). The neural function is also influenced in asthma and a separate chapter is dedicated to that topic (chapter 1.9).

1.8 Animal models of asthma

As a consequence of the continuous increase in prevalence and morbidity in asthma, there is an urgent need to develop new drugs for therapy. In general, animal models provide a surrogate for humans to test hypotheses concerning a disease. The strengths of animal models include: (i) being genetically homogenous and well defined study subjects; (ii) the ability to use invasive, *in vivo*, experimental methods to identify potential mechanisms; (iii) the accessibility of tissue for *in vitro* studies; (iv) the ability to control and manipulate environmental and/or genetic factors; and (v) the ability to develop and test pharmaceuticals for human use (1). With regard to allergic asthma, an ideal animal model should develop first an EAR, second a LAR, third non-specific AHR to various stimuli, fourth eosinophilic and neutrophilic bronchial inflammation, fifth changes in mucus secretion and quality, sixth alterations in airway and lung histology and seventh spontaneous increase in resistance of airways after prolonged or repeated allergen exposure (83; 166). However, so far there is no animal known with a natural disease course perfectly mimicking human asthma and no animal model is available that completely reproduces the multiple features of human asthma (table 2) (83). Hence, all established models are approaches to reflect particular aspects of human asthma.

Animal models of asthma are distinguished into three groups: (i) animals having naturally occurring recurrent airway obstruction, e.g. cats (idiopathic asthma: wheezing, cough and cyanosis) (1; 83) and horses (heaves) (1), (ii) animals having an AHR before any provocation in the laboratory

Table 2: Asthma symptoms in selected animal models compared to human asthma (referring to (1; 83; 144))

Symptom	Mouse	Rat	Guinea pig	Rabbit	Cat	Dog	Pig	Sheep	Horse	Monkey	Human
Naturally sensitive	-	-	-	-	+/-	+	-	+	+	+	+
EAR	-	+	+	+/-	+	+	+/-	+	-	+/-	+
LAR	+	+	+	+	-	+	+	+	-	+	+
AHR	+	+/-	+	+	+	+	-	+	+	+	+
Inflammation	+	+	+	+/-	+	+	+	+	+	+	+
Eosinophilia	+	+	+	-	+	-	+	+	-	+	+
Neutrophilia	-	-	-	-	-	+	+	-	+	-	+
Remodelling	-	+	-	-	+	+	-	+	-	-	+

EAR, early allergic response; LAR, late allergic response; AHR, airway hyperresponsiveness

occurs (73; 135) and (iii) animals developing reversible airway obstruction and/or increased airway responsiveness only after challenge, among which are small laboratory animals (e.g mouse, rat and guinea pig) (144) but also large animals (e.g. sheep). Remarkably, sheep may also develop a natural sensitivity, when they encounter the allergen *Ascaris suum* in their natural environment (2) and the use of an anthelmintic is therefore required during sensitization of sheep with for instance house dust mite (HDM) (24).

Concerning the latter of the three groups, sensitization of the animal is a prerequisite for studying airway responses. In general, animals are sensitized with an allergen, which is commonly ovalbumin (OVA) (60; 75; 91; 117; 185) or HDM (23; 24; 27; 157), by repeated allergen challenge over days to weeks to establish an adaptive immune response by the animal. Many sensitization protocols have been developed in which the allergen is applied either intraperitoneally, subcutaneously, intratracheally/intralobularly or by aerosolization. In some cases, an adjuvant such as aluminium hydroxide or heat inactivated *Bordetella pertussis* organisms may be required to induce T_H2-lymphocyte driven immune responses and ultimately the production of IgE (87).

The rat exhibits many features of airway allergy and allergic asthma that are similar to those of humans (table 2) (87). Therefore, the ability to extrapolate to humans is one of the advantages of this species. Similarities between rats and humans include (i) EAR and LAR after an allergen challenge, (ii) responses after a nonspecific challenge with methacholine, acetylcholine, or serotonin, (iii) IgE production and (iv) an accumulation of inflammatory cells (87). The ability to produce EAR, LAR and AHR makes the rat favorable over the mouse model (87), which is advantageous when genetic modifications or gene knock-outs are required to study the involvement of distinct endogenous proteins in the pathomechanisms of asthma (94). AHR, airway inflammation and obstruction can be easily reproduced in rats, although this may depend on the rat strain: Wistar rats are prone to

sensitization with OVA, producing similar but less pronounced effects compared to those observed in Brown Norway rats (87). In contrast, Sprague Dawley rats do not develop an allergic reaction or an increase in IgE production under the same conditions and usually serve as a control group for Brown Norway rats (87). Singh and colleagues (157) studied the allergic airway response in three rat strains in response to HDM and found that Brown Norway rats develop strong and Sprague Dawley rats moderate hallmarks of asthma, whereas Lewis rats were relatively unresponsive. Moreover, Schneider and colleagues (153) reported that there is no pulmonary inflammation and no rise in IgE after an allergen challenge in Fisher and Lewis rats.

1.9 Neurogenic inflammation and neuronal plasticity

Airway inflammation associated with asthma may affect neuronal activity at several points along the neural reflex pathway, including the function of the primary afferent nerves, integration within the central nervous system, synaptic transmission within autonomic ganglia and transmission at the level of the postganglionic neuroeffector junction (172). Functional changes within autonomic nerves of the lung are termed neuronal plasticity (143). As nerves regulate many pulmonary functions, altered neuronal regulation in and due to inflammation is crucial to understand. It affects the ASM tone, airway secretions (e.g. mucus hypersecretion), blood flow by vascular dilation, microvascular permeability and the migration and release of inflammatory cells (16). These effects are attributed to actions of neuropeptides and tachykinins. All these insights led to the concept of neurogenic inflammation (143). The basis for this term is twofold: the biological effects produced by tachykinins in the airways in general are proinflammatory and provide a neurogenic contribution to the overall inflammatory process and the stimuli that elicit tachykinin release in the airways include mediators of inflammation (178). For instance, inflammatory mediators such as bradykinin, platelet-activating factor, LTD₄, lipoxin A₄, PG and histamine activate and/or sensitize capsaicin sensitive afferents (99). Hence, capsaicin desensitization reduces bronchoconstriction, vasodilation and AHR in experimental animal models (guinea pig, pig and sheep) after allergen exposure (99). In human, capsaicin led to abolished nasal irritation by lactic acid and hypertonic saline as well as absent skin flare response to allergen, pointing to the involvement of sensory nerves in allergy (99). This is supported by the finding of increased levels of neuropeptides including SP in the lungs of asthmatic patients and elevated levels of NK A in bronchoalveolar lavage fluids of asthmatic patients following airway allergen challenge (143).

The underlying mechanisms of qualitative changes in nerve functions include enhanced reflex activity, increased mediator release, enhanced sensitivity of the ASM to neuropeptides and tachykinins as well as increased receptor-density on both ASM cells and airway neurons. Moreover, quantitative changes in sensory and/or motor neurons are also debated in the context of asthma (143). LTs or TXA, for example, are inflammatory mediators enhancing acetylcholine release by activating afferent sensory nerve fibres and by directly facilitating ganglionic neurotransmission

and acetylcholine release from vagal nerve terminals (4; 7; 21; 116; 167; 176) (figure 5). Another mechanism leading to an increased cholinergic outflow is neuronal M_2 receptor dysfunction as acetylcholine induced feedback inhibition of acetylcholine release is prevented. Neuronal M_2 receptor dysfunction has been reported to contribute to AHR in human asthma patients, antigen challenged animals, virus infected animals, ozone exposed animals, and animals exposed to organophosphate pesticides (131). In antigen challenged animals, eosinophils are recruited to airway nerves, where they degranulate and release major basic protein (MBP), which functions as a natural occurring M_2 receptor antagonist (76) (figure 5). There is also a possible role of the inflammatory cytokine TNF- α to inaugurate M_2 dependent hyperreactivity, because TNF- α directly inhibits M_2 receptor gene expression *in vitro* (130). Moreover, vagally induced AHR in guinea pig after OVA sensitization (130) or viral infection (131) is abolished by etanercept (a human dimeric fusion protein consisting of the p75 TNF receptor 2 dimer linked to the fragment crystallizable (F_c) of IgG₁), and M_2 receptor expression is reconstituted by etanercept in neuroblastoma cells, which were treated with a supernatant of virus-infected tracheal epithelial cells (131).

The functional plasticity of neurons is under close control of neurotrophins (NT) (143). *Trophe* originates from the Greek and means nourishment. Therefore, in the context of nerves, neurotrophism describes a nutritive, target-derived factor that promotes growth and survival of neurons (142). NTs are small proteins of about 13 kDa regulating neuronal structure and function, i.e. neurogenesis, neuronal differentiation/survival, neuronal plasticity and neuronal conduction (142). The NT family classically consists of four conserved members of similar structure and function: nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), NT3 and NT4/5. Those bind to tropomyosin-related kinase (Trk) receptors with different affinities. NGF preferentially binds to the Trk A receptor, BDNF and NT4 to the Trk B receptor, whereas NT3 binds with high affinity to the Trk C receptor and lesser affinity to Trk A and B. Moreover all NTs bind to the low-affinity p75 neurotrophin receptor (p75NTR) (142). Originally, NTs were reported to be involved in neurodegenerative disorders (e.g. Alzheimer's disease), brain tumors and spinal cord injury repair (142). However, there are several sources of NTs in the lung and their receptors are present at different sites. These lung components include nerves, immune cells, epithelial cells, fibroblasts, ASM, vascular smooth muscle, vascular endothelial cells and distinct immune cells (142). Accordingly, NTs have the potential to affect pulmonary function and structure at all sites. The current knowledge on NTs with respect to their importance in asthma is summarized in table 3.

Another neurotrophic factor is the glial-derived neurotrophic factor (GDNF). Primary sensory nerves are modulated by GDNF and GDNF family ligands (GFLs, e.g. neurturin, artemin, and persephin). GDNF and GLF selectively interact with the GDNF family receptors (GFR α 1-4) (97). Neurotrophic factor receptor expression has been largely characterized in neurons during development and in neonatal animals. In contrast, there is little information regarding neurotrophic

Figure 5: Irritation of nerves in inflammation and asthma. Chronic inflammation leads to epithelial shedding activating sensory nerves, which release tachykinins. Tachykinins in turn activate inflammatory cells or facilitate acetylcholine (ACh) release from parasympathetic nerves. Increased ACh outflow can also be due to muscarinic acetylcholine receptor (M₂) dysfunction, tropomyosin related kinase receptor (Trk_R) stimulation and leukotriene (LT), prostaglandin (PG) or thromboxane (TXA) stimulation of parasympathetic nerves. M₂ dysfunction results from the natural antagonist major basic protein (MBP) released by eosinophils or from inhibited M₂-gene expression by tumor necrosis factor (TNF). Neurotrophic factors may originate from different sources inducing a phenotypic switch in nerves (Neurotrophin (NT)-3 induces inhibitory nonadrenergic noncholinergic nerves (iNANC) to produce substance P (SP)) or activating immune cells. For example, nerve growth factor (NGF) activates eosinophils and type 2 helper T-lymphocytes (T_H2-cell). T_H2-cells release IL-5, that attracts eosinophils, or IL-4, that stimulates B-lymphocytes (B-cell) to produce immunoglobulin (Ig) E and IgG₁. IgE binds to the surface of mast cells, which get activated and degranulate if allergen is bound by IgE. Increased neurotransmitter (ACh, SP, neurokinin A (NKA), calcitonin gene related peptide (CGRP)) release results in increased airway smooth muscle (ASM) contraction, mucus hypersecretion and increased vascular leakage by binding to muscarinic (M_R) or neurokinin receptors (NKR) on ASM, goblet cells, submucosal glands or vessels. ↑, increased; →/+, activating, ⊥, inhibiting. For more details, please see the text.

Table 3: Neurotrophins and their potential function in asthma (modified from (142))

Components	NT expressed	NTR expressed	Effects and importance
<i>Structure:</i>			
Nerves	NGF; BDNF; NT3	TrkA; TrkB; p75NTR	↑NGF: induced TrkA, NK1 and SP expression/content; ↑Neuronal plasticity; ↑Cholinergic outflow (BDNF); Neurally-mediated AHR (NGF, BDNF); ↑Neurotransmitter release (NT3)
ASM	NGF; BDNF; NT3; NT4	TrkA; TrkB; TrkC; p75NTR	↑NGF, BDNF, TrkA, TrkB, p75NTR with inflammation; Contractility (↑with NGF, BDNF, NT4; ↓with NT3); ↑AHR (NGF); Airway remodelling; ↑Cell proliferation (NGF)
Epithelium	NGF; BDNF; NT3; NT4	TrkA; TrkB; p75NTR	↑BDNF ↑NGF with inflammation (allergic asthma); Airway remodelling: ↑airway thickening, ↑cell survival
<i>Immune Cells:</i>			
Monocytes/ macrophages	NGF; BDNF; NT3	TrkA; TrkB	↑NGF and BDNF with allergen challenge
T-lymphocytes	NGF	TrkA	↑BDNF with allergen challenge; NGF produced by CD4 ⁺ and CD8 ⁺ T-lymphocytes; ↑NGF by T _H 2-lymphocytes
B-lymphocytes	NGF; BDNF; NT3	TrkA; p75NTR	↑NGF, BDNF and NT3 with allergen challenge
Eosinophils	NGF; BDNF; NT3; NT4	TrkA	↑NGF with airway inflammation
Mast cells	NGF; BDNF; NT3	TrkA; TrkB; p75NTR	Allergen-induced IgE-mediated NGF release

↑, increase; ↓, decrease; AHR, airway hyperresponsiveness; ASM, airway smooth muscle; BDNF, brain-derived neurotrophic factor; CD, clusters of differentiation; IgE, immunoglobulin E; NGF, nerve growth factor; NT, neurotrophin; NK, neurokinin; NTR, neurotrophin receptor; p75NTR, p75 neurotrophin receptor; SP, substance P; T_H2, type 2 T helper lymphocyte; Trk, tropomyosin-related kinase receptor

factor receptor expression in adult vagal afferent neurons of differing phenotypes, especially with respect to airway-specific neurons (97). Recently, Lieu and colleagues (97) showed the expression of GFR α 1-3 and their corresponding co-signalling molecule RET in jugular neurons innervating the lung of guinea pig, but their physiological importance remains undetermined.

The mechanisms by which neurotrophic factors alter airway function are a current focus of biomedical research. Udem and coworkers (173) were the first to report a phenotypic change in airway tachykinergic innervation associated with allergen challenge and that NGF is a potential mediator for this effect. NGF increases SP expression in airway neurons and changes the neuronal phenotype so that large, capsaicin-insensitive nodose neurons with fast-conducting A δ fibers provide a component of the tachykinergic innervation (74). AHR, as shown after ozone exposure, may then result from enhanced release of acetylcholine from parasympathetic nerves, since tachykinins bind to NK receptors on these nerves, or tachykinins, i.e. SP, cause eosinophils to release MBP blocking the M₂ receptor on cholinergic nerves (179; 180) (figure 5). Recently, Pan and colleagues (138) found that the iNANC phenotype changed to a cholinergic phenotype in guinea pigs after repeated allergen challenge and that this change was mimicked by NT3 (figure 5). Physiologically, this could imply an exaggerated airway contraction, because an airway relaxant pattern is switched to a constrictive one, but the proof for that is yet missing. Furthermore, evidence is given by an electrophysiological study on airway parasympathetic ganglia from guinea pigs that synaptic transmission is directly potentiated by NGF, i.e. by binding of NGF to Trk receptors on neurons (figure 5). Using single cell recording, direct application of NGF caused a lasting decrease in the cumulative action potential after hyperpolarization and increased the amplitude of excitatory postsynaptic potentials in response to nicotinic stimulation, which was blocked by the tyrosine kinase inhibitor, K-252a, implicating Trk receptor involvement (65). NTs also exhibit profound effects on immune cells residing in airways and lung tissue, which has been termed immunological plasticity (143). In this regard, neurotrophins act as amplifiers of the locally occurring immune dysbalance. For instance, when splenic mononuclear cells from allergen-sensitized mice were stimulated with different concentrations of OVA *in vitro*, there was a T_H2-mediated immune response, characterized by elevated IL-4 and IL-5 production as well as increased IgE and IgG₁ synthesis (30).

The modulatory effect of nerves on inflammation or rather immune cells has been termed the inflammatory reflex (169). The modulatory effect can be either anti- or pro-inflammatory, and the role of tissue macrophages may be central to this issue. Neural anti-inflammatory regulation of tissue macrophages is local, fast and integrated through the central nervous system. Acetylcholine, originating from parasympathetic nerves, inhibits the release of cytokines from macrophages via activation of the α 7-nicotinic acetylcholine receptor present on their surface and subsequent inhibition of gene transcription (169; 171). This action is anti-inflammatory, because macrophages typically secrete pro-inflammatory cytokines such as TNF, IL-1, IL-6 or high-mobility group box 1

(HMGB1) during inflammation (171). Epinephrine and norepinephrine from sympathetic nerves predominately inhibit TNF release but can, under certain circumstances, stimulate TNF release, while SP stimulates cytokine synthesis amplifying the local inflammatory response and mediating pain (169).

2 Aim of the study

Irritation of nerves plays an important role in chronic inflammatory lung diseases such as asthma and COPD. Up to date, peripheral airway innervation is poorly characterized in the mammalian lung. The PCLS method is a relatively new method in pulmonary research and has been established for different species. It allows the study of large to small airways along the tracheobronchial tree and has been useful to characterize airway responses to exogenously applied mediators of the EAR and LAR. However, intrinsic activation of PCLS by stimulation of nerves has not been studied yet. Before, *in vitro* organ bath studies on lung innervation have been performed by EFS on tracheal strips, bronchial strips and parenchymal strips; a method that does not allow to access small airways, especially when small laboratory animals are used. Parenchymal strips do not allow to differentiate between airway and vascular smooth muscle contractions. Furthermore, studies on lung tissue in organ baths are performed under either isometric or isotonic conditions, whereas the *in vivo* situation is more auxotonic - as present in PCLS.

Therefore, the aim of the study was to combine the PCLS method with EFS and to establish a tool for the examination of peripheral airway innervation. It was the first aim to develop EFS of PCLS for one animal species, namely the rat, to specify EFS conditions that specifically activate nerves and exclude direct electric ASM stimulation. Neurally-evoked airway responses should be addressed pharmacologically to resolve types of innervation in peripheral airways. Since small airways respond to exogenous mediators, e.g. methacholine, differently from large airways, airways of different size should be addressed in EFS of PCLS.

After establishing the model of EFS of PCLS, lungs from allergic rats should be studied to prove if nerves contribute to a possible AHR. Allergen and methacholine provocation of PCLS should also be investigated in the allergic rat model to evaluate a possible EAR and an unspecific AHR, respectively.

Finally, EFS of PCLS should be transferred to different species, to characterize their types of innervations, i.e. parasympathetic cholinergic, sympathetic adrenergic and/or NANC. The final aim was to compare PCLS from animals to those from humans to identify suitable animal models that allow predictions for pharmacological interventions.

3 Materials and Methods

3.1 Animals

Harvesting of lungs from laboratory animals was approved by the local ethic committee (reference number 8.87-51.05.20.09.245). Balb/c mice (21 - 23 g) were from Harlan Winkelmann (Borchen, Germany), Wistar rats (200 - 300 g) from Janvier (Le Genest St. Isle, France) or Harlan Winkelmann (Borchen, Germany), Brown Norway rats (180 - 250 g) from Janvier (Le Genest St. Isle, France) and Dunkin Hartley guinea pigs (340 - 550 g) from Charles River (Sulzfeld, Germany). Lungs from adult marmoset monkeys (*Callithrix jacchus*) were obtained from the German Primate Center (Göttingen, Germany). Sheep lungs were taken from adult Texel sheep kept at the Maastricht University Medical Center (Maastricht, Netherlands). Care and housing conditions of the animals complied with the regulations of the European Parliament and the Council Directive on the protection of animals used for scientific purposes (2010/63/EU) and the National Institutes of Health Guide for the Care and Use of Laboratory Animals.

3.2 Human material

Human PCLS were prepared from patients undergoing lobectomy due to cancer. After pathological inspection, cancer free lung tissue was used. The experiments were approved by the local ethics committee and all patients gave written informed consent.

3.3 Chemicals

Acetylcholine, aluminium hydroxide, atropine, bovine serum albumin (BSA), capsaicin, 4-diphenylacetoxy-N-(2-chloroethyl)piperidine hydrochloride (4-DAMP), ipratropium bromide, magnesium sulphate, methacholine, neostigmine, N_ω-nitro-L-arginine methyl ester (L-NAME), OVA grade V (≥ 98% purity), propranolol hydrochloride, Ruthenium red, SKF96365 (1-(β-[3-(4-methoxyphenyl)propoxy]-4-methoxyphenethyl)-1H-imidazole) and standard laboratory chemicals were purchased from Sigma (Steinheim, Germany). Custom *Bordetella pertussis* antigen was supplied by Lee laboratories (Grayson, Georgia, USA). Low-melting agarose was delivered by Gerbu (Gaiberg, Germany). Penicillin-streptomycin was obtained from Gibco (Darmstadt, Germany). [1S-[1α,2α(Z),3α,4α]]-7-[3-[[2-[(phenylamino)carbonyl]hydrazino]methyl]-7-oxabicyclo [2.2.1]hept-2yl]-5-heptenoic acid (SQ29548) and 9,11-dideoxy-9α,11α-methanoepoxy Prostaglandin F_{2α} (U46619) were provided by Biomol (Hamburg, Germany). Substances for cell culture were obtained from PAA laboratories (Cölbe, Germany).

3.4 Cell culture medium

The cell culture medium always comprised 2 mM CaCl_2 , 1 mM MgSO_4 , 5 mM KCl, 116 mM NaCl, 1 mM NaH_2PO_4 , 17 mM glucose, 26 mM NaHCO_3 , 25 mM HEPES (4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid), 1 mM sodium pyruvate, 2 mM glutamine, amino acids (PAA laboratories, M11-002, 1:50), vitamins (PAA laboratories, N11-002, 1:100) and 1% (v/v) penicillin-streptomycin. During slicing, the medium was not supplemented by pyruvate, glutamine, amino acids, vitamins and penicillin-streptomycin.

3.5 Preparation of PCLS

PCLS were prepared as previously described (188; 189) and as depicted exemplarily for the rat in Figure 6. Briefly, whole lungs of mouse, rat, guinea pig and marmoset were filled via the trachea with low-melting agarose (at 37°C), whereas only separate lobes of sheep and human were filled with low-melting agarose via the main bronchus. The agarose concentration was always 1.5% (w/v) in cell culture medium, except for mouse and rat (0.75% (w/v)). The filled lung tissue was cooled

Figure 6: Preparation of precision-cut lung slices (PCLS) from rat. **A.** After anaesthesia the rat is tracheotomized and thoracotomy is performed so that the lung lies collapsed in the thorax. **B.** Low-melting agarose (0.75% (w/v)) is filled into the lung via the trachea and solidified on ice. **C.** The lung is removed en bloc from the animal. **D.** The lobes of the lung are separated, cut into pieces perpendicular to the tracheobronchial tree and tissue cores containing the airway are punched. **E.** PCLS are cut from the cores by means of a modified self build Krumdieck tissue slicer. **F.** PCLS are taken in culture and are viable for at least 72 h.

on ice to harden the agarose. Then, tissue cores (10 mm in diameter) with a penetrating airway in its center were prepared by a rotating sharpened metal tube. Since the lungs from mice were too small for tissue coring, the left and right lung were separately embedded in 3% (w/v) agarose before cutting. PCLS were cut perpendicular to the airway by means of a Krumdieck tissue slicer (Alabama Research and Development, Munford, AL, USA). PCLS were taken in culture and incubated at 37°C and 5% carbon dioxide atmosphere. In order to wash out the agarose and to remove cell debris as well as released mediators, the medium was changed every 30 min after PCLS preparation and every hour for the next two hours. Thereafter, the medium was changed once daily. Only slices with an airway free of agarose, beating cilia and an intact and relaxed ASM layer were used in experiments one day after preparation.

3.6 Videomicroscopy

The PCLS under study was placed into a cavity of a standard laboratory 12- or 24-well plate and mounted on the stage of an inverted Leica DMIL microscope (Leica Microsystems, Wetzlar, Germany). The airway area was then monitored by means of a SensiCam 365KL digital camera (Visitron Systems, Munich, Germany) at a frame rate of 0.36 Hz in experiments with EFS and 0.2 Hz in all other experiments. Camera control and image analysis were achieved by Optimas 6.5 software (Optimas, Bothell, WA, USA). The airway area before the first stimulation was defined as 100% initial airway area (IAA) (figure 9 B, C).

3.7 EFS of PCLS

EFS of PCLS were carried out in cavities of standard 12-well plates in a reaction volume of 1 mL cell culture medium. The PCLS (10 mm in diameter) were placed between two platinum electrodes of 12 mm distance and were weighted down by a Teflon ring (9 mm outer diameter x 6 mm inner diameter x 4 mm height) (figure 9 A). The electric field was applied by a HSE Stimulator II (Hugo Sachs Electronics, March Hugstetten, Germany), which allowed serial rectangular stimuli. The electric stimuli are defined by the basic EFS conditions frequency, pulse duration, current amplitude, train width and train rhythm. Their meaning is depicted in figure 7.

Figure 7: Basic conditions of electric field stimulation (EFS). The electric stimuli are described by the basic rhythm ($G = 1/\text{frequency}$ (F), pulse duration (B), current (A), train width (TW) and train rhythm (TR).

The standard provocation protocol comprised the following setting: train rhythm TR = 60 s, train width TW = 2.5 s, frequency F = 50 Hz, pulse duration B = 1 ms and current A = 200 mA (equal to 40 V). The standard stimulation train lasted 3.3 min.

3.8 Realization of response curves for the basic EFS conditions

The basic EFS parameters frequency, pulse duration, current and train width (figure 7) were systematically examined by stimulating the PCLS repeatedly and modulating only one parameter while the others were kept constant at the values noted above (chapter 3.7). Frequency, pulse duration, current and train width were examined at 0.4 - 100 Hz, 0.1 - 5 ms, 1 - 200 mA and 0.5 - 20 s, respectively. Recovery between the repetitive stimulations lasted until the airway had relaxed to its initial state (3 - 5 min), except for frequency-response curves in species comparison where recovery lasted 1 min.

3.9 Examination of large and small airways in EFS of PCLS

PCLS from rat containing differently sized airways ranging from $3.8 \times 10^3 - 1.2 \times 10^6 \mu\text{m}^2$ (0.07 - 1.2 mm in diameter) were stimulated by EFS. The first stimulation train was conducted without additive and the second train was carried out in the presence of 10 μM neostigmine given 15 min in advance.

3.10 Pharmacological interventions

3.10.1 Drugs

Distinct drugs were used to characterize airway innervation in EFS of PCLS and exogenous activation of PCLS. The relevance of each drug for neural activation, neural specification or receptor signalling is specified in table 4.

3.10.2 Application of magnesium

PCLS were repeatedly stimulated by EFS. The first stimulation train took place without magnesium sulphate. After 30 min the second stimulation occurred either in the absence or presence of 10 mM magnesium sulphate to block neuronal calcium entry. Magnesium sulphate was present 30 min prior to stimulation. After the last stimulation 10^{-4} M acetylcholine or methacholine were added to examine airway contractility in the presence of 10 mM magnesium sulphate. In the experiments on PCLS from rat 10 μM neostigmine was present at all times.

Table 4: Drugs and their importance

Substance	Function	Effect
Acetylcholine	Muscarinic receptor agonist	ASM contraction
Atropine	Muscarinic receptor antagonist	Inhibition of ASM contraction
Capsaicin	Vanilloid receptor agonist	Activation of sensory neurons
4-DAMP	Muscarinic receptor antagonist	Inhibition of ASM contraction
Ipratropium	Muscarinic receptor antagonist	Inhibition of ASM contraction
L-NAME	NO synthase inhibitor	Lack of NO release
Magnesium	Competes with Ca ²⁺ at synapse	Neuromuscular block
Methacholine	Muscarinic receptor agonist	ASM contraction
Neostigmine	Acetylcholine esterase inhibitor	Increased cholinergic stimulation
Propranolol	Adrenergic β -receptor antagonist	Inhibition of ASM relaxation
Ruthenium red	NSCC/TRP channel antagonist	Diminished eNANC response
SKF96365	TRP channel antagonist	Diminished eNANC response
SQ29548	TP receptor antagonist	Reversed U46619 agonistic effect
U46619	TP receptor agonist	ASM contraction; Modulation of cholinergic transmission

ASM, airway smooth muscle; 4-DAMP, 4-diphenylacetoxy-N-(2-chloroethyl)piperidine hydrochloride; L-NAME, N_o-nitro-L-arginine methyl ester; NO, nitric oxide; eNANC, excitatory nonadrenergic noncholinergic nerve; NSCC, non-selective cation channel; SKF96365, 1-(β -[3-(4-methoxyphenyl)propoxy]-4-methoxyphenethyl)-1H-imidazole; SQ29548, [1S-[1 α ,2 α (Z),3 α ,4 α]]-7-[3-[[2-[(phenylamino)carbonyl]hydrazino]methyl]-7-oxabicyclo[2.2.1]hept-2yl]-5-heptenoic acid; TRP, transient receptor potential channel; U46619, 9,11-dideoxy-9 α ,11 α -methanoepoxy Prostaglandin F_{2 α}

3.10.3 Characterization of EFS-induced neural airway responses

Cholinergic response: Each PCLS from rat was exposed to three stimulation trains. The first stimulation train was carried out in the absence of any additive, the effect of acetylcholine esterase inhibition (10 μ M neostigmine) was examined in the second train and the role of acetylcholine receptors (10 μ M atropine) was studied in the third train. All drugs were added 15 min prior to stimulation. In all other species than rat, the use of neostigmine as cholinergic response amplifier was not required and therefore skipped. Exceptionally in guinea pigs, PCLS were not stimulated repeatedly but separate PCLS were activated either in the presence or absence of atropine.

Sympathetic response: This response in EFS of PCLS was proven by the β -blocker propranolol. A first stimulation train was performed without propranolol as control and a second followed 15 min after the installation of 10 μ M propranolol.

Excitatory NANC response: The unspecific TRP-channel inhibitors SKF96365 (30 μM) and Ruthenium red (10 μM) were used to validate eNANC responses in EFS of PCLS. Control stimulations were performed without these inhibitors. SKF96365 or Ruthenium red were allowed to equilibrate 15 min before the first EFS train was performed.

Inhibitory NANC response: This response in EFS of PCLS was validated by the NO synthase inhibitor L-NAME. A first stimulation train was performed without L-NAME as control and a second followed 15 min after the installation of 100 μM L-NAME.

3.10.4 Concentration dependent antagonism of anticholinergics

Rat PCLS were exposed to eight consecutive stimulation trains. The first stimulation train was carried out in the absence of any additive and from the second train 10 μM neostigmine was present throughout the whole experiment. In the third to eighth EFS trains the muscarinic antagonist (atropine, ipratropium or 4-DAMP) was increased cumulatively to match concentrations of 10^{-11} – 10^{-6} M. All newly installed drug concentrations were equilibrated for 15 min prior to stimulation.

3.10.5 Effect of the TP receptor antagonist SQ29548

PCLS from rats were repeatedly stimulated by EFS. The first stimulation train occurred at 10 μM neostigmine. The second stimulation occurred either in the absence or presence of 10 μM SQ29548 to block TP receptors. SQ29548 was applied 15 min prior to stimulation. After the second stimulation 10 μM U46619 was added to prove receptor blocking by SQ29548 and to verify a priming of acetylcholine release by U46619 in a following third EFS train. Airway responses during U46619 application were monitored at a frame rate of 0.1 s^{-1} for 15 min.

3.11 Exogenous activation of airway responses in PCLS

3.11.1 Application of methacholine

Cumulative concentration-response curves with methacholine were performed on PCLS for various purposes. In general, methacholine was maintained at concentrations of 10^{-8} – 10^{-4} M each for 5 min.

The effect of magnesium on ASM was studied by addition of methacholine in the presence or absence of 10 mM magnesium sulphate. PCLS from rat were preincubated with magnesium sulphate 30 min before addition of the first methacholine concentration. If EFS was performed at 10 mM magnesium, afterwards 10^{-4} M methacholine was added in the magnesium group as in the

control group to exclude an effect of magnesium on the ASM itself.

AHR was evaluated by provocation of PCLS from OVA sensitized or saline treated rats with methacholine (10^{-8} – 10^{-4} M).

3.11.2 Application of capsaicin

Excitatory NANC nerves were triggered by application of 10 M capsaicin on the PCLS. The airway area was monitored by videomicroscopy to quantify the response.

3.11.3 Application of U46619

The effect of atropine on U46619 evoked ASM contraction was evaluated. Herein, a concentration-response curve was conducted with U46619 (10^{-8} – 10^{-4} M) in the presence or absence of 10 μ M atropine. Preincubation of atropine occurred for 15 min before addition of the first U46619 concentration. U46619 was cumulatively added every 5 min.

3.12 Active sensitization of rats

3.12.1 Sensitization protocol

Sensitization of male Brown-Norway rats was approved by the “Landesamt für Natur Umwelt und Verbraucherschutz Nordrhein-Westfalen” (TVA-10599G1). The sensitization scheme was in accordance to Glaab and colleagues (60) and was performed as depicted in figure 8.

Figure 8: Acute sensitization model for rat. At day 0 animals received ovalbumin (OVA) or saline subcutaneously (s.c.). Aluminium hydroxide (Al(OH)₃) and heat-inactivated *Bordetella pertussis* (*B. pertussis*) organisms served as adjuvants. Sensitization was boosted at day 7, 14 and 21 by intratracheal (i.tr.) installation of OVA/saline. Precision-cut lung slices (PCLS) were prepared on day 22 and measurements were conducted the following day. Serum samples were collected at the beginning and end of the sensitization. i.p., intraperitoneal; for further please see the text.

At day 0, rats received a subcutaneous injection of 1 mg OVA in 250 μ L saline or saline only adsorbed to 20 mg aluminium hydroxide. In some animals 6×10^9 heat-inactivated *Bordetella*

pertussis organisms were administered intraperitoneally as adjuvants. The sensitization was boosted by intratracheal application of 100 μ L 0.3% (w/v) OVA in saline or saline only on day 7, 14 and 21. For intratracheal applications the animals were sedated with pentobarbital sodium (50 mg/kg_{bodyweight}). Preparation of PCLS was performed on day 22 as described in chapter 3.5. Serum samples were collected on day 0 and 22 for the determination of IgE titers.

3.12.2 EFS of PCLS from sensitized animals

EFS were performed on PCLS from OVA sensitized and control animals. EFS comprised the standard stimulation protocol (chapter 3.7) as well as the accomplishment of response curves for the frequency, pulse duration, current and train width (chapter 3.8).

3.12.3 Allergen provocation of PCLS from sensitized animals

PCLS from OVA sensitized or saline treated rats were provoked by 0.1% (w/v) OVA and airway area was monitored for 20 min each 15 s.

3.12.4 Quantification IgE

IgE levels in serum samples were determined by enzyme linked immunosorbent assay (ELISA) according to Glaab and coworkers (60). Briefly, F96 Maxisorp NUNC-Immuno Plate (NUNC, Roskilde, Denmark) were coated with a mouse monoclonal antibody against rat IgE (MCA193, AbD Serotec, Wiesbaden, Germany) in a concentration of 0.1 μ g/well. The plates were incubated at room temperature overnight, washed five times with 0.05% (v/v) Tween 20 supplemented phosphate buffered saline (PBS; 137 mM NaCl, 2.7 mM KCl, 8.1 mM Na₂HPO₄, 1.5 mM KH₂PO₄, pH 7.2; sterile filtered) and blocked with 1% (w/v) BSA in PBS for 1 h. After aspiration of the blocking solution and washing, serum samples (diluted in PBS, 0.05% (v/v) Tween 20, 1% (w/v) BSA) and standard antibody (rat IgE κ , PRP07A, AbD Serotec, Wiesbaden, Germany) in the range of 15.625 – 1000 ng/mL were incubated for 1 h. Following an additional washing, 100 μ L of peroxidase conjugated detection antibody (mouse anti rat κ/λ LC:HRP, MCA1296P, AbD Serotec, Wiesbaden, Germany) at a concentration of 0.5 μ g/mL was added per well and incubated for 1 h until a further washing was performed. Then, 100 μ L/well of 3,3',5,5'-Tetramethylbenzidine (TMB) substrate solution were applied and enzymatic substrate conversion was carried out for 15 min in the dark. The reaction was stopped by 50 μ L/well of 1 M sulphuric acid and absorbance was measured in an ELISA plate reader (Genios Tecan, Salzburg, Austria) at 450 nm. Wavelength correction was measured at 550 nm to correct for optical imperfections in the plate.

3.13 Statistics

Non-linear regression, Spearman or Pearson correlation, and statistical analyses were performed using GraphPad Prism 5 (GraphPad Software, Inc., La Jolla, USA) or JMP 9 (SAS Institute, Cary, NC, USA). Homoscedasticity was checked by the Bartlett test. Unpaired data were either compared by the Mann-Whitney test or the Steel-Dwass test (if variances were unequal) or by the t-test or the Tukey test (if variances were equal). Paired data were analyzed by the paired t-test or linear mixed model analysis followed by the Tukey test. The statistical test used is indicated in the legends of the table or figures. The half-maximal effective frequencies (EF_{50}) were calculated by four parameter logistic regression and compared by the F-test. $P < 0.05$ was always considered significant.

4 Results

4.1 EFS of PCLS from rats - Design and Development of EFS setup

4.1.1 Setup and basic conditions

Classic organ bath apparatuses were not applicable for the EFS of PCLS, because PCLS are very thin and force development due to bronchoconstriction is small, so that the use of force transducers was not practicable. In PCLS, airway responses are typically monitored by videomicroscopy (111).

Figure 9: Setup for electric field stimulation (EFS) of precision-cut lung slices (PCLS). **A.** Device: PCLS of 10 mm in diameter were placed between two platinum electrodes, which are 12 mm apart. PCLS were kept in place by a Teflon ring (9 mm outer diameter x 6 mm inner diameter x 4 mm height). The electric field was applied by an electric stimulator connected to the electrodes. The electrodes were placed in a standard 12-well plate that was placed on the stage of an inverted microscope to follow bronchoconstriction by videomicroscopy. **B.** Photograph of a PCLS. AW, airway; PA, pulmonary artery; PV, pulmonary vein. **C.** Initial and minimal airway area in response to a single electric stimulation ($F = 50$ Hz, $B = 1$ ms, $A = 200$ mA, $SD = 2.5$ s, at $10 \mu\text{M}$ neostigmine) is depicted. The airway area was used for quantification.

A device was designed that allows the EFS of PCLS in a cavity of a standard 12-well plate (figure 9 A). Two platinum electrodes were held by a movable plastic carrier that fits exactly into a cavity and keeps the electrodes 12 mm apart. The electrodes were connected to a HSE Stimulator II allowing serial rectangular pulses. PCLS (10 mm in diameter) were placed between the electrodes, weighted down by a Teflon ring (which was figured out to be crucial to that the PCLS does not float and to establish tethering forces) and reduction in airway lumen area became apparent after electric stimulation (figures 9 C and 10). The bronchoconstriction was reversible, as long as the Teflon ring was used (figure 10).

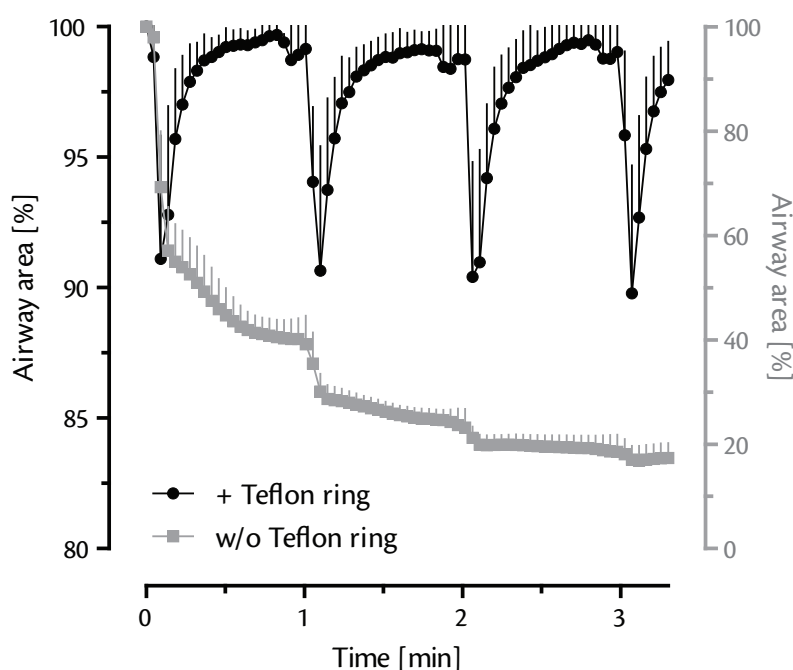

Figure 10: Role of the Teflon ring in electric field stimulation evoked bronchoconstriction in PCLS. PCLS were either loosely (right y-axis) placed between the electrodes or weighted down by a Teflon ring (left y-axis). The latter approach yielded reversible and reproducible airway responses. Data are shown as mean + SD of 6 PCLS from 2 rats in the first group or 10 PCLS from 6 rats in the group with the Teflon ring. EFS conditions were $F = 50$ Hz, $B = 1$ ms, $A = 200$ mA, $TW = 2.5$ s and $TR = 60$ s.

Since the PCLS setup differed in geometry from organ bath studies, the basic EFS conditions (frequency, pulse duration, current and train width) were evaluated initially. Airway contractions increased in a frequency-dependent manner up to 50 Hz, (figure 11 A) with a half maximal response (EF_{50}) at (16.7 ± 4.9) Hz. Bronchoconstriction also became stronger with pulse duration, current and train width. A plateau response for pulse duration was reached at pulses ≥ 1 ms (figure 11 B). At 200 mA (corresponds to 40 V), the maximal current output of the stimulator, airways contracted about 35% (figure 11 C). Maximal ASM contraction occurred if train width lasted 10 s or longer (figure 11 D). However, the recovery phase to reach the initial airway area lasted longer at $TW = 10$ s (figure 11 D) and contractions persisted in presence of 10 mM magnesium ($(8.0 \pm 3.4)\%$ -IAA at $TW = 10$ s vs. $(1.4 \pm 0.6)\%$ -IAA at $TW = 2.5$ s; mean \pm SD; $p = 0.036$ in Mann-Whitney test), suggesting unspecific non-neural stimulation at this train width. As a consequence

Figure 11: Determination of the basic EFS parameters to stimulate PCLS from rat. Except of the parameter that was changed in panel A-D, the stimulation settings were always $F = 50$ Hz, $B = 1$ ms, $A = 200$ mA, $TW = 2.5$ s. **A.** Frequency dependency of airway contraction by EFS. Data are shown as mean \pm SD of 11 PCLS from 5 rats; $EF_{50} = 16.7 \pm 4.9$ Hz. Effect of pulse duration (**B**) and current (**C**) on airway contraction by EFS. Data are shown as mean \pm SD of 6 PCLS from 6 rats. **D.** Train width was increased to show maximal airway contraction in response to EFS of PCLS. Data are shown as mean \pm SD of 6 PCLS from 6 rats.

of these results, it was decided to carry out the following experiments with the Teflon ring in place, at a frequency of $F = 50$ Hz, a pulse duration of $B = 1$ ms, a current of $A = 200$ mA and a train width of $TW = 2.5$ s. These conditions resulted in reproducible airway contractions (figure 12).

4.1.2 Cholinergic interventions

To examine the role of cholinergic nerves in the EFS-induced bronchoconstriction, PCLS were stimulated in the presence of neostigmine to enhance acetylcholine concentrations in the synaptic cleft and atropine to block post-synaptic acetylcholine receptors. In the presence of neostigmine ($10 \mu\text{M}$), EFS contracted airways to $(49.2 \pm 11.0)\%$ -IAA compared to $(84.1 \pm 5.3)\%$ -IAA without neostigmine (figure 12). With neostigmine still present, atropine nearly completely abolished the

EFS-induced airway contractions (figure 12) indicating that airway contractions in rat PCLS mainly depend on muscarinic receptors.

Figure 12: Cholinergic mediation of EFS-triggered airway contraction. The same PCLS was stimulated repeatedly (at $F = 50$ Hz, $B = 1$ ms, $A = 200$ mA, $TW = 2.5$ s, $TR = 60$ s): the entire time course for a single experiment with one slice is shown on the abscissa. The time course of airway area in successive EFS trains ($4 \times$ EFS in 3.3 min) is depicted on the left (**A**) and the statistical evaluation based on the minimal airway area shown as bar graphs on the right (**B**). The top lane shows the results of EFS without any addition to the incubation medium. The middle lane shows the results from EFS experiments in the presence of the acetylcholine esterase inhibitor neostigmine ($10 \mu\text{M}$). The bottom lane shows EFS experiments in the presence of neostigmine plus the muscarinic receptor antagonist atropine ($10 \mu\text{M}$). C, control EFS; N, neostigmine + EFS; N + A, neostigmine + atropine + EFS; n.s., not significant; **, $p < 0.01$; ***, $p < 0.001$ in the Tukey multiple comparison test; data are shown as mean - SD (A) or mean + SD (B) from 5 independent experiments.

After validation of the cholinergic response to EFS, the setup was further developed for the testing of anticholinergic drugs. Repeatable EFS of PCLS was reversible and reproducible for at least seven consecutive stimulations after neostigmine addition, allowing successive stimulations while increasing drug concentrations at the same time (figure 13; for clarity each single spike represents the mean train of four times EFS, i.e. the total of eight stimulations mean that 28 EFS trains occurred within in each PCLS, underlining the high reproducibility) Atropine, ipratropium and 4-DAMP showed a concentration-dependent reduction in airway contraction upon EFS. Plotting the mean minimal airway area obtained against the logarithmic antagonistic concentration revealed sigmoidal inhibition curves with significant different values of half-maximal inhibitory concentrations (IC_{50}). Ipratropium with a decadic logarithmic (\log) IC_{50} of (-10.0 ± 0.4) M was more

Figure 13: Increasing concentrations of anticholinergic drugs block airway contractions in repeated EFS of PCLS. The same PCLS was stimulated repeatedly at $F = 50$ Hz, $B = 1$ ms, $A = 200$ mA, $TW = 2.5$ s and $TR = 60$ s, i.e. a 1 min interval represents the mean course of 4 x EFS during 3.3 min. Drugs tested were added and equilibrated for 15 min prior to the according EFS train. Data are presented as mean - SD of 5 rats. **A.** Neostigmine increased airway contractions were reproducible for at least seven consecutive trains. Atropine **(B)**, ipratropium **(C)** and 4-DAMP **(D)** were cumulatively add in consecutive EFS trains to match indicated concentrations (10^{-11} M - 10^{-6} M). In B-D like in A, neostigmine was present throughout the whole experiment beginning from the second EFS train.

Figure 14: Ipratropium is more potent to block EFS evoked bronchoconstriction in PCLS than atropine or 4-DAMP. The mean minimal airway areas obtained in figure 13 are plotted against the decadic logarithmic (log) concentration of atropine, ipratropium or 4-DAMP. Curves were compared by performing extra sum-of-square F-test on top, bottom, slope and half-maximal inhibitory concentration (IC₅₀). Significant differences at an α -level of *, $p < 0.05$ and **, $p < 0.01$ were found for the log IC₅₀ values of ipratropium and atropine or 4-DAMP, respectively; data are shown as mean \pm SEM ($n = 5$) in the graph and mean \pm SD in the curve analysis table.

potent to block airway response than atropine or 4-DAMP which showed equal log IC₅₀ values of (-8.8 \pm 0.4) M and (-8.4 \pm 0.3) M respectively (figure 14).

4.1.3 Effect of magnesium to prove neural activation

The effects of magnesium concentrations high enough to block voltage-gated calcium entry in neuronal cells (40; 53) were examined to verify that the EFS evoked airway contractions were due to neural stimulation. 10 mM magnesium sulphate totally abolished the EFS-induced contractions in the presence of 10 μ M neostigmine (figure 15 A-C). In contrast, airway contraction by exogenously added acetylcholine was not affected by magnesium sulphate (figure 15 A-C) and 10 mM magnesium sulphate did not alter the concentration-response curve of methacholine-induced bronchoconstriction (figure 15 D).

Figure 15: Effect of magnesium on airway contractions by EFS and acetylcholine derivatives. A. First and second train: 4 x EFS ($F = 50$ Hz, $B = 1$ ms, $A = 200$ mA, $TW = 2.5$ s, $TR = 60$ s) in 3.3 min in the presence of $10 \mu\text{M}$ neostigmine; third train: addition of $100 \mu\text{M}$ acetylcholine; $n = 6$. The entire time course for a single experiment with one slice is shown on the abscissa. **B.** The same experiments as in panel A with the addition of 10 mM MgSO_4 30 min prior to the second train; $n = 5$. **C.** Summary of the minimal airway area obtained in the experiments shown in panel A and B as bar chart. EFS, electric field stimulation; ex. ACh, exogenous acetylcholine; n.s., not significant in t -test of selected pair of columns; **, $p < 0.01$ in Mann-Whitney test of selected pair of columns; data are shown as mean - SD (A, B) or mean + SD (C). **D.** Cumulative concentration-response curves of methacholine-induced airway contraction in PCLS were recorded in the absence or presence of 10 mM MgSO_4 . MgSO_4 was added 30 min before the first addition of methacholine. Data are shown as mean \pm SD of 8 PCLS for each condition from 5 animals. A shared concentration-response curve was suitable to fit the data, because there was no statistical difference at $p < 0.05$ (F-test) in any parameter of the 4-parameter logistic equation between the two data sets.

4.1.4 Response of different airway sizes

Since small airways respond stronger to methacholine than larger ones (111), the response of small and large airways were analyzed to EFS (figure 16).

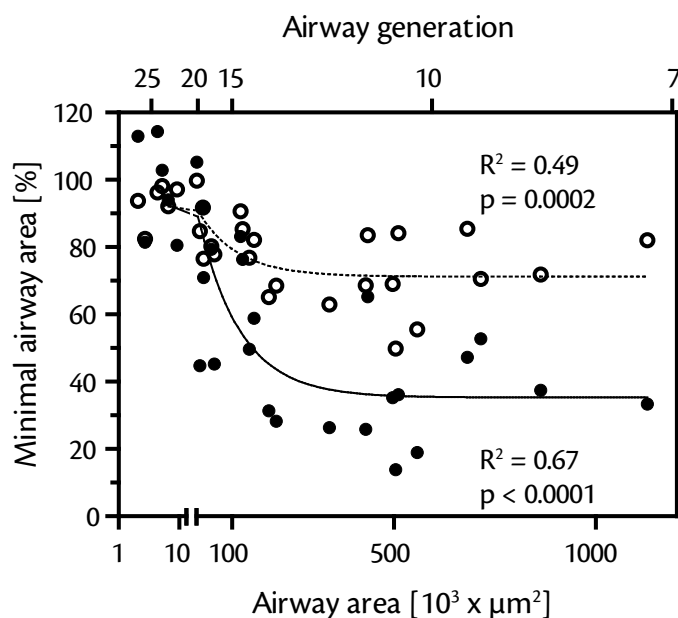

Figure 16: Correlation of airway size with EFS-triggered airway contractions. PCLS were first stimulated in the absence (○) and then in the presence (●) of 10 μM neostigmine, i.e. the data are paired. Rat airway generations are marked on the upper x-axis according to Yeh and colleagues (191). A one phase exponential-decay described the relationship reasonably well. R^2 , goodness of fit; data show the results of 29 PCLS from 5 rats.

EFS were studied in PCLS with airway sizes ranging from 3.8×10^3 - $1.2 \times 10^6 \mu\text{m}^2$ in the presence or absence of neostigmine. Herein, larger airways were more responsive than smaller ones (figure 16). Additionally, the amplification of airway contraction by neostigmine was more pronounced in larger airways.

4.1.5 TP receptor involvement

An interaction between TP receptor signalling and parasympathetic cholinergic acetylcholine release has been shown for dogs, guinea pigs and mice (4; 7; 167; 176), whereas this mechanism has not yet been characterized in rat lungs. Therefore, the influence of the TP receptor antagonist SQ29548 was studied in EFS of rat PCLS. No difference was found for electrically evoked cholinergic airway responses in the presence and absence of a TP receptor antagonist (figure 17). A statistical power calculation based on these results (figure 17 C) indicated that at least 32 experiments were needed to possibly reach significance, indicating that any role of TP receptors would be rather small.

Figure 17: Effect of the thromboxane prostanoid (TP) receptor antagonist SQ29548 on bronchoconstriction induced by EFS or U46619. A. First and second train: 4 x EFS (F = 50 Hz, B = 1 ms, A = 200 mA, TW = 2.5 s, TR = 60 s) in 3.3 min in the presence of 10 μ M neostigmine; third train: addition of 10 μ M of the TP receptor agonist U46619; n = 4. The entire time course for a single experiment with one slice is shown on the abscissa. **B.** The same experiments as in panel A with the addition of 10 μ M SQ29548 15 min prior to the second train; n = 5. **C.** Bar graph summary of the minimal airway area obtained in the EFS trains in panel A and B; n.s., not significant in t-test. **D.** Bar graph summary of the airway area obtained 15 min after U46619 addition in panel A and B; *, p < 0.05 in Mann-Whitney test. EFS, electric field stimulation; ex. U46619, exogenous U46619; data are shown as mean - SD (A, B) or mean + SD (C, D).

The addition of U46619 demonstrated that SQ29548 was capable of blocking TP receptors in the present system (figure 17 D). Moreover, a subsequent EFS train in the presence of U46619 did not increase the response (figure 18).

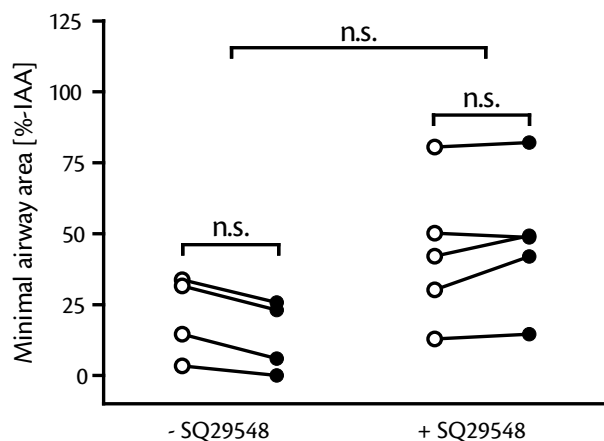

Figure 18: U46619 does not prime the airway response to EFS. A subsequent EFS train was carried out on the same set of PCLS as depicted in figure 17. For both groups ($\pm 10 \mu\text{M}$ SQ29548) no significant (n.s.) difference was found before (open symbols) and after (closed symbols) addition of U46619 ($10 \mu\text{M}$) in the Tukey multiple comparison test.

The influence of TP receptor agonist U46619 and its possible interactions with muscarinic receptors was studied by the use of atropine. The airway responses for cumulative concentration-response curves with U46619 were the same in the presence and absence of atropine (figure 19).

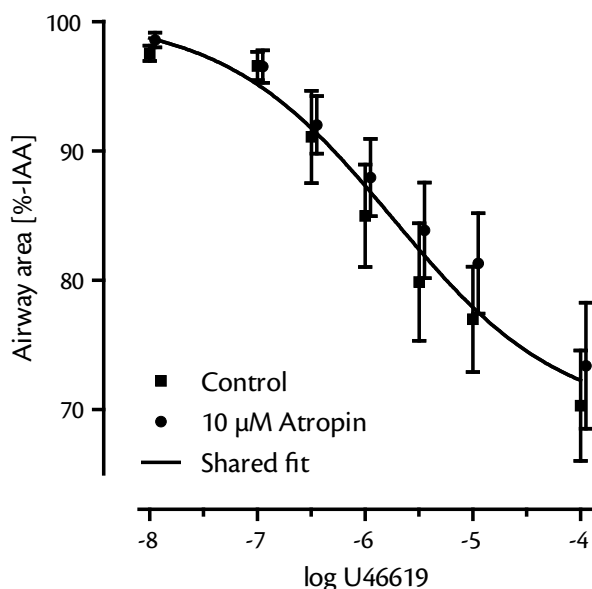

Figure 19: Effect of atropine on airway contraction by U46619. Cumulative concentration response curves of the U46619-induced airway contraction in PCLS were recorded in the absence or presence of $10 \mu\text{M}$ atropine. Atropine was added 15 min before the first addition of U46619. Data are shown as mean \pm SEM of 9 PCLS for each condition. A total of 5 animals were used for the experiment. A shared concentration-response curve was suitable to fit the data, because there was no statistical difference at $p < 0.05$ (F-test) in any parameter of the 4-parameter logistic equation between the two data sets.

4.2 Active sensitization of rats

In the foregoing part, the EFS of PCLS was established in healthy rats. Now this method was used to study the neurally-induced bronchoconstriction of peripheral airways within an experimental rat model of asthma, since nerves may exhibit enhanced reflex activity, increased mediator release, increased receptor-density or quantitative changes during asthma (143). The ASM itself may also display enhanced sensitivity to neuropeptides and tachykinins or possess an increased receptor density (143). The sensitization occurred according to Glaab and colleagues (60), who observed an AHR *in vivo* and an increased number of immune cells (eosinophils, lymphocytes, neutrophils and macrophages) in bronchoalveolar lavage of OVA sensitized animals. Herein, OVA adsorbed to aluminium hydroxide was injected subcutaneously, and some animals also received heat-inactivated *Bordetella pertussis*, to initiate an intended T_H2 -lymphocyte driven immune response.

In order to boost the immune response repeated challenges with allergen were performed intratracheally assuring its deposition in the lung.

4.2.1 Macroscopic observations

During active sensitization, rats were either repeatedly challenged by OVA (sensitized group) or saline (control group) for three weeks. Neither control nor sensitized animals showed wheezing

Figure 20: Ovalbumin (OVA) sensitized rats showed haemorrhages throughout the lung. Rats were actively sensitized to OVA (B, D, F) or received saline in the control group (A, C, E) as described in chapter 3.12.1. **A, B.** The lung lied collapsed in the thorax after thoracotomy. **C, D.** The agarose filled lung was removed en bloc from the animal. **E, F.** PCLS were taken in culture. White arrows indicate haemorrhages.

while sensitization and none of the animals appeared to be heavily sick. When rats were taken for preparation of PCLS, haemorrhages on the surface of the lung became apparent in the sensitized animals after thoracotomy, whereas in control animals haemorrhages were not present (figure 20 A-D). Haemorrhages in sensitized rat were spread throughout the whole lung and were still found in PCLS after the cutting process (figure 20 E, F).

4.2.2 Response of PCLS to allergen provocation

To demonstrate a response to allergen after active sensitization, PCLS were provoked with 0.1% (w/v) OVA for 20 min and airway area was monitored. Only rats from OVA sensitized rats responded with a moderate airway contraction (figure 21 A).

Figure 21: Allergen provocation induces bronchoconstriction in sensitized rat. Rats were actively sensitized to ovalbumin (OVA) or received saline in the control group as described in chapter 3.12.1. Provocation of PCLS was performed by application of 0.1% (w/v) OVA for 20 min. Groups were not further subdivided by *Bordetella pertussis* application, since the adjuvants did not show an effect. **A.** The course of airway behaviour is drawn after application of allergen. **B.** Maximal observed airway narrowing differed in sensitized and control group. Data are shown as mean \pm SEM ($n = 6$, control; $n = 7$, sensitized); **, $p < 0.01$ in Mann-Whitney test.

Although a significant difference was found between the sensitized and control group, it is remarkable that some OVA sensitized rats exhibited very weak if any airway contraction at all upon OVA (figure 21 B).

4.2.3 Response of PCLS to methacholine

Methacholine was applied to study an AHR in sensitized animals. The same concentration-response curve was found for both sensitized and control animals (figure 22), i.e. sensitivity (shared EC_{50}) and maximal contraction (shared bottom) to methacholine were the same, and sensitized animals were not hyperresponsive.

Figure 22: Sensitized animals are not hyperresponsive to methacholine. Rats were actively sensitized to ovalbumin or received saline in the control group as described in chapter 3.12.1. Cumulative concentration-response curves of methacholine were performed on PCLS from sensitized or control animals. Groups were not further subdivided by *Bordetella pertussis* application, since the adjuvants did not show an effect. Data are shown as mean \pm SEM of $n = 7$ animals in sensitized group and $n = 6$ in control group. A shared concentration-response curve was suitable to fit the data, because there was no statistical difference at $p < 0.05$ in any parameter of the 4-parameter logistic equation between the two data sets.

4.2.4 IgE levels in sensitization

During sensitization B-lymphocytes produce specific IgE. Therefore, the IgE levels were determined to evaluate if sensitization with OVA induced the expression of IgE. Moreover, some animals received heat inactivated *Bordetella pertussis* organisms - a common adjuvants to trigger T_H2 -cell response and in further consequence the production of IgE. In line with this, rats, which received *Bordetella pertussis* as adjuvants, had elevated IgE levels three weeks after sensitization in both OVA and saline treated animals (figure 23). However, OVA alone had no effect on the titers of

Figure 23: IgE levels after sensitization. Rats were actively sensitized to ovalbumin or received saline in the control group as described in chapter 3.12.1. Some animals also received heat inactivated *Bordetella pertussis* (*B. pertussis*) organisms as adjuvants at day 0 of sensitization. Data are shown as mean \pm SD. Groups not indicated by the same letter are significantly different according to the Tukey multiple comparison test. +, rats received treatment; -, rats did not receive treatment.

IgE past sensitization (figure 23). Notably, the anti-IgE antibody used in the underlying ELISA only detected total IgE but not anti-OVA specific IgE.

4.2.5 Response of PCLS to EFS

Frequency, pulse duration, current and train width are the basic parameters by which the electric field can be determined. Nerves are differentially activated by changes in the electric field and airway responses are altered. Bronchoconstriction occurred with an increase in each parameter. A shared frequency-response curve with an EF_{50} of (18.9 ± 3.2) Hz was found for OVA sensitized and saline control animals (figure 24 A). Furthermore, no significant differences were observed in response to increasing pulse durations or train widths for both groups (figure 24 B, D). However, the sensitized animals seemed to be less reactive. This was most prominent for the sensitivity to increasing currents (figure 24 C).

Figure 24: Response of PCLS from sensitized and non-sensitized rats to basic EFS parameters. Rats were actively sensitized to ovalbumin or received saline in the control group as described in chapter 3.12.1. Except of the parameter that was changed in panel A-D, the stimulation settings were always $F = 50$ Hz, $B = 1$ ms, $A = 200$ mA, $TW = 2.5$ s. **A.** The frequency-response curve resulted in a shared curve with an EF_{50} of (18.9 ± 3.2) Hz. **B, C** and **D** show the effect of pulse duration, current and train width, respectively, on airway contraction in EFS of PCLS from actively sensitized or control animals. Data are always shown as mean \pm SD ($n = 7$, sensitized group, $n = 6$ control group); *, $p < 0.05$ in unpaired t-test on the area under the curve.

Deriving from the study of the basic parameters above, one can conclude, that the standard stimulation parameters ($F = 50$ Hz, $B = 1$ ms, $A = 200$ mA, $TW = 2.5$ s) as determined during the

development of EFS (chapter 4.1.1) are also appropriate here when examining sensitized and non-sensitized rats. Therefore, the responses of PCLS from either sensitized or saline treated rats were exposed to the standard stimulation conditions. Interestingly, a significant difference was figured out in which PCLS from the OVA treated rats were less reactive (figure 25), even though the small difference may not be physiologically relevant.

Figure 25: Response of PCLS from sensitized and non-sensitized rats to standard EFS conditions.

Rats were actively sensitized to ovalbumin or received saline in the control group as described in chapter 3.12.1. EFS was carried out at $F = 50$ Hz, $B = 1$ ms, $A = 200$ mA and $TW = 2.5$ s. Data are shown as mean + SEM of 47 PCLS from 7 sensitized rats and 43 PCLS from 6 saline control rats; *, $p < 0.05$ in unpaired t-test.

Since there was the probability that not all rats were effectively sensitized the airway response to standard EFS of PCLS from both control and OVA treated group was plotted against their response to allergen provocation. However, Spearman analysis did not result in any correlation (figure 26).

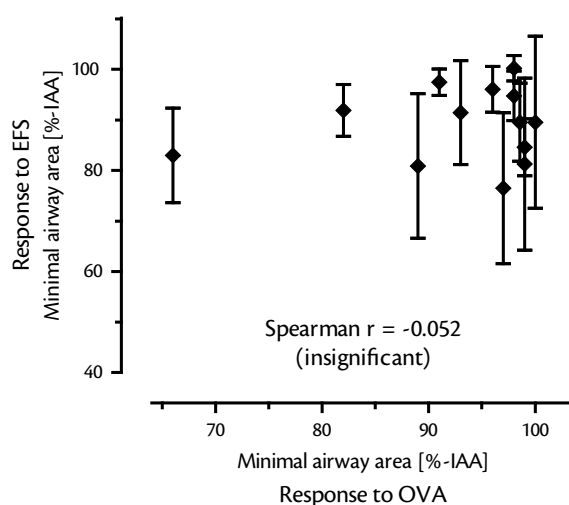

Figure 26: There is no correlation between airway responses to EFS and response to ovalbumin (OVA).

The mean \pm SD response to standard EFS ($F = 50$ Hz, $B = 1$ ms, $A = 200$ mA and $TW = 2.5$ s) of each rat out of the sensitization experiment (chapter 3.12.1), i.e. sensitized and control rats are combined and each data point reflects a single animal, is depicted against the according response to OVA provocation (figure 21). Spearman correlation resulted in $r = -0.052$ pointing to an insignificant correlation.

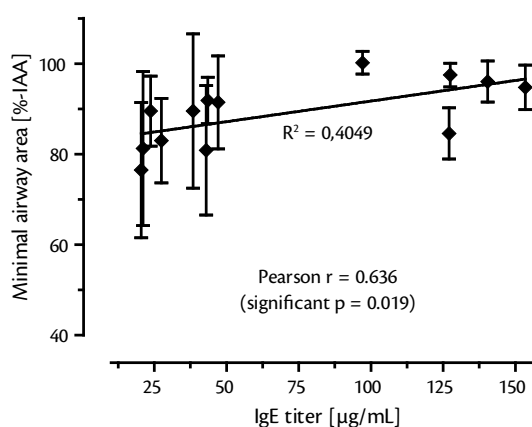

Figure 27: Airway response to EFS is correlated to the IgE titer.

The mean \pm SD response to standard EFS ($F = 50$ Hz, $B = 1$ ms, $A = 200$ mA and $TW = 2.5$ s) of each rat out of the sensitization experiment (chapter 3.12.1), i.e. sensitized and control rats are combined and each data point reflects a single animal, is depicted against the IgE level obtained after 3 weeks of sensitization (figure 23). Pearson correlation resulted in significant correlation ($r = 0.636$, $p = 0.019$), and consequently a linear regression was conducted.

Moreover, as the IgE level is indicative of the immune status of the animal, the airway response to EFS of PCLS from both control and OVA treated rats was correlated to the IgE levels (figure 27). Pearson analysis resulted in a significant dependence ($r = 0.636$, $p = 0.019$). As Pearson correlation assumes a linear dependence, a linear regression was performed showing lesser reactivity with higher IgE titer (figure 27).

4.3 Species comparison

4.3.1 Responses and sensitivity to EFS

PCLS from the various species responded differently to EFS; please note the different scales in

Figure 28: Airway response of PCLS from distinct species to EFS. PCLS from indicated species were stimulated repeatedly at $F = 50$ Hz, $B = 1$ ms, $A = 200$ mA, $TW = 2.5$ s, $TR = 60$ s for 3.3 min, i.e. each PCLS received 4 x EFS. **A.** The time course of airway area in successive EFS trains is depicted as mean – SD for each species. The statistical evaluation based on the minimal (**B**) and maximal airway area (**C**) is shown as Box and Whiskers plots. Groups not indicated by the same letter are significantly different at $p < 0.05$ according to the Steel-Dwass comparison test.

figure 28. Airways from mice did not respond in the range of the EFS conditions studied here even in the presence of neostigmine (Minimal airway area: $(98.2 \pm 0.9)\%$ -IAA (control) vs. $(94.3 \pm 2.2)\%$ -IAA (neostigmine); mean \pm SEM; $n = 4$; $p = 0.1581$ in t -test). However, the application of substantially higher frequencies or pulse durations led to airway contractions also in mouse PCLS, which were blocked by magnesium indicating neural origin (figure 29). PCLS from rats and marmoset contracted reversibly by about 20% (figure 28 A, B). Airways in PCLS from guinea pigs, sheep and human contracted strongest by about 40%-IAA – 60%-IAA and did not revert to the initial area during the one minute interval until the next electric impulse was applied (figure 28 A, B). Marmoset airways showed a unique behaviour in that contraction was followed by relaxation that exceeded the original airway caliber ($(116 \pm 18)\%$ -IAA; figure 28 C).

Figure 29: Electrically activated airway contractions in murine PCLS require higher electric fields and remain neuronally-induced. **A.** Frequency-response curve: The frequency (F) was increased from 1 Hz to 200 Hz, while the other EFS settings were kept constant at $B = 1$ ms/2ms, $A = 200$ mA and $TW = 2.5$ s. **B.** Pulse duration was increased in EFS of murine PCLS from 0.5 ms to 4 ms, while the other parameters were kept constant at $F = 50$ Hz, $A = 200$ mA and $TW = 2.5$ s. **C.** PCLS from mouse were stimulated repeatedly at $F = 50$ Hz, $B = 2$ ms $A = 200$ mA and $TW = 2.5$ s each minute for 3.3 min. Upper panel: Control stimulations, each EFS train was conducted without pharmacological interference. Lower panel: 10 mM magnesium (Mg^{2+}) was added 30 min prior to the second EFS train. Magnesium was able to block airway responses indicating specific neurally-induced bronchoconstriction. Data are shown as mean \pm SD.

Analyzing the frequency-response curves (figure 30) revealed the following order of species sensitivity to EFS: sheep ($EF_{50} = (0.5 \pm 0.2)$ Hz) > guinea pig ($EF_{50} = (7.0 \pm 1.2)$ Hz) = human ($EF_{50} = (8.1 \pm 0.8)$ Hz) > rat ($EF_{50} = (16.5 \pm 0.8)$ Hz). The EF_{50} values for humans and guinea pigs did not differ statistically. The EF_{50} of marmoset was (22.8 ± 7.1) Hz but the frequency-response curve neglects the relaxant response and therefore the EF_{50} appears higher than without relaxation.

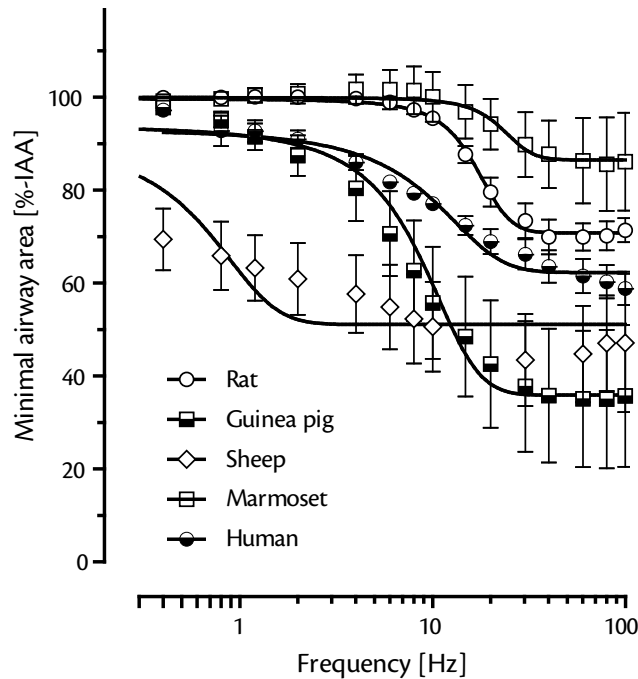

Figure 30: Frequency dependence across species. Frequency-response curves were performed on PCLS from the species indicated. Except for the frequency (F), which was increased from 0.4 Hz to 100 Hz after a single train at the distinct frequency each minute (TR = 60 s), EFS settings were kept constant at B = 1 ms, A = 200 mA and TW = 2.5 s. Sigmoidal curves, in which the top was constrained to 100% of the initial airway area [IAA], were plotted and frequencies for the half-maximal response (EF_{50}) were determined: rat (16.5 ± 0.8) Hz, guinea pig (7.0 ± 1.2) Hz, sheep (0.5 ± 0.2) Hz, marmoset (22.8 ± 7.1) Hz, human (8.1 ± 0.8) Hz. Except for the guinea pig, EF_{50} values from all species were significantly different from the human EF_{50} . Data are shown as mean \pm SEM; n = 6 for rat, n = 5 for guinea pig, n = 4 for sheep, n = 4 for marmoset and n = 4 for human.

4.3.2 Evidence for neural activation

Magnesium competes at neural calcium channels (N-type calcium channels) and thus prevents

Table 5: EFS-induced airway contractions are neurally mediated.

Species	EFS		Methacholine	
	Change in airway area [%-IAA] w/o Mg^{2+}	10 mM Mg^{2+}	Minimal airway area [%-IAA] w/o Mg^{2+}	10 mM Mg^{2+}
Rat	19.0 ± 8.8	$1.4 \pm 0.6^{**}$	13.5 ± 15.1	30.0 ± 11.5
Guinea Pig	44.3 ± 37.5	$3.9 \pm 4.1^*$	0.0 ± 0.0	7.3 ± 8.5
Sheep	54.4 ± 22.5	$7.6 \pm 8.3^{##}$	10.1 ± 10.7	18.4 ± 20.0
Marmoset (Con./Rel.)	46.0 ± 20.9 ($28 \pm 27 / 18 \pm 20$)	$13.2 \pm 9.0^{##}$ ($11 \pm 11 / 2 \pm 3$)	39.0 ± 25.3	38.2 ± 16.1
Human	36.8 ± 23.1	$18.9 \pm 19.0^\dagger$	32.2 ± 23.2	35.4 ± 20.2

Magnesium competes with calcium at the terminal synapse and prevents the release of neurotransmitters resulting in a neuromuscular block (40; 53). The muscarinic receptor agonist methacholine was used to confirm that Mg^{2+} did not affect airway smooth muscle directly. Con., contraction; EFS; electric field stimulation; IAA, initial airway area; Mg^{2+} , magnesium; Rel., relaxation; w/o, without; *, $p < 0.05$; **, $p < 0.01$ in Mann-Whitney test; ##, $p < 0.01$ in t-test; †, $p < 0.05$ in paired t-test.

neural responses, but not those acting directly on smooth muscle cells (40; 53). EFS performed in the presence of 10 mM magnesium inhibited airway reactions in all species, but did not alter responses to exogenously added methacholine (table 5) demonstrating that the EFS-induced responses depended on neural transmission in all species.

4.3.3 Cholinergic antagonism

The muscarinic antagonist atropine significantly reduced airway contraction in repeated EFS of rat, sheep, marmoset and human PCLS (figure 31). Of note, in the case of rat PCLS the acetylcholine esterase inhibitor neostigmine was used to augment the response. In guinea pigs, PCLS had to be pre-incubated with atropine before the first stimulation in order to demonstrate cholinergic airway innervation (figure 33 C, D).

Figure 31: Cholinergic responses in EFS-triggered airway contraction. PCLS from either rats (A), sheep (B), marmosets (C) or human (D) were stimulated repeatedly at F = 50 Hz, B = 1 ms, A = 200 mA, TW = 2.5 s, TR = 60 s for 3.3 min, i.e. 4 x EFS. As control, the first stimulation (1st EFS) was always carried out without any cholinergic interference. In subsequent EFS separated by at least 15 min to the preceding stimulation, neostigmine and/or atropine were added to augment or inhibit, respectively, cholinergic airway contraction. *, p < 0.05 and **, p < 0.01 for atropine vs. no atropine (paired t-test). The guinea pig data are shown in figure 33.

4.3.4 Activation by capsaicin

Neurally triggered airway contraction may not be restricted to cholinergic innervation but can also be due to eNANC innervation. Therefore, the effect of capsaicin was studied.

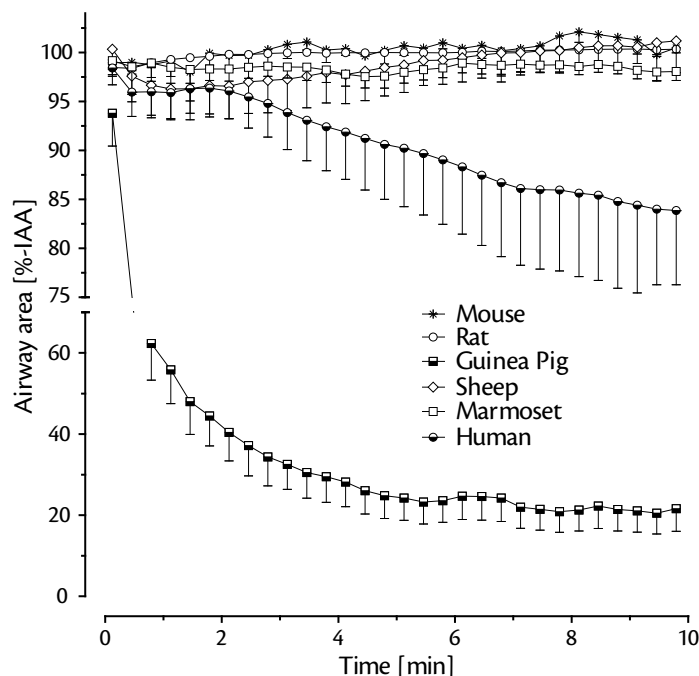

Figure 32: Effect of capsaicin on airway contraction in PCLS. Capsaicin was applied to PCLS from the species indicated at a concentration of $10 \mu\text{M}$ and airway contraction was monitored. Data are shown as mean \pm SEM; $n = 3$ for mouse, $n = 10$ for rat, $n = 9$ for guinea pig, $n = 4$ for sheep, $n = 3$ for marmoset and $n = 5$ for human.

Capsaicin induced strong airway contractions in PCLS from guinea pigs and moderate contractions in human PCLS (figure 32); of note, two out of five human lungs did not respond to capsaicin. In mouse, rat, sheep and marmoset capsaicin did not affect airway tone (figure 32).

4.3.5 Role of TRP-channels in neurally evoked bronchoconstriction

To further characterize the strong response to capsaicin in guinea pigs, PCLS were incubated with the unspecific TRP-channel blockers SKF96365 or Ruthenium red before stimulation by capsaicin. Both inhibitors significantly reduced the response to capsaicin (figure 33). Since in guinea pigs airways did not relax back to the initial airway area after an EFS (figure 28), even if recovery periods were prolonged, a non-cholinergic mechanism appeared likely. This was studied by the application of Ruthenium red and SKF96365 during EFS of guinea pig PCLS. As PCLS could not be stimulated repeatedly due to the lack of relaxation, PCLS were grouped and incubated with the inhibitors prior to the first stimulation. Atropine, Ruthenium red and SKF96365 were all effective in blocking the response compared to the control group, although they failed to abolish the response completely (figure 33).

Figure 33: Characterization of peripheral airway innervation in guinea pigs. **A.** Capsaicin was added to precision-cut lung slices (PCLS) at a concentration of 10 μ M, either after 15 min pre-incubation with an unspecific transient receptor potential (TRP) channel blocker (Ruthenium red, SKF96365) or without pre-incubation (control). Data are shown as mean \pm SEM; $n = 5$. 100% of the initial airway area (IAA) was considered as baseline and the area above the curve (AAC), i.e., the area enclosed by the baseline and the curve, is depicted as shading. **B.** Statistical analysis was performed on the AAC calculated from panel A. Data are shown as mean \pm SEM; $n = 5$; *, $p < 0.05$ in linear mixed model analysis followed by the Tukey test. **C.** Electric field stimulation (EFS; $F = 50$ Hz, $B = 1$ ms, $A = 200$ mA, $SD = 2.5$ s) was carried out on PCLS either after pre-incubation with TRP channel blockers, the muscarinic inhibitor atropine or without pre-treatment (control) and the airway responses are depicted as mean \pm SEM; $n = 5 - 6$. **D.** The minimal airway area obtained in the EFS of PCLS was used in statistical analysis showing an effect for all antagonists. Data are shown as mean \pm SEM; $n = 5 - 6$; *, $p < 0.05$ and **, $p < 0.01$ for the comparison to the control group in the Tukey multiple comparison test.

4.3.6 Effect of propranolol and L-NAME in EFS of PCLS from marmoset

As noted above, in marmosets the airway caliber enlarged following electric stimulation suggesting adrenergic or iNANC responses. To examine their contributions, EFS was performed subsequently to a control train in the presence of the β -blocker propranolol, the NO synthase inhibitor L-NAME or both together. Each antagonist alone was unable to significantly reduce the relaxant response, but the combination of both was effective (figure 34). Figure 34 suggests that propranolol alone might also have been effective; however the statistical power was probably not sufficient; a statistical

Figure 34: Airway relaxation in marmosets is due to adrenergic and inhibitory nonadrenergic noncholinergic (iNANC) innervation. The same PCLS was stimulated repeatedly ($F = 50$ Hz, $B = 1$ ms, $A = 200$ mA, $TW = 2.5$ s, $TR = 60$ s): the entire time course for a single experiment with one PCLS is shown on the abscissa. The time course of airway area in successive EFS trains (4 x EFS in 3.3 min) is depicted on the left and the statistical evaluation based on the difference between the maximal and minimal airway area (Δ -airway area) during the respective train is shown as bar graphs on the right. **A.** The results of EFS without any addition to the incubation medium. **B.** The results from EFS experiments in the presence of the adrenergic β -blocker propranolol. **C.** The results from EFS experiments in the presence of the NO synthase inhibitor L-NAME. **D.** The results from EFS experiments in the presence of the combination of propranolol and L-NAME. Data are shown as mean - SD (left) or mean + SD (right); *, $p < 0.05$ in one-tailed paired t -test.

power analysis suggested that 9 independent experiments might be required to achieve statistical significance. However, as marmosets are non-human primates and in order to save animals, we refrained from further experiments to clarify this issue. Regarding L-NAME it is remarkable, that in its presence airway recovery to baseline values was prevented (figure 34 C, 2nd train), suggesting a role of NO in this process.

5 Discussion

Application of an electric field to PCLS resulted in airway contractions that were inhibited by magnesium. Therefore, in PCLS bronchoconstriction triggered by EFS is neurally induced implying that nerve endings remain intact in PCLS. In rats, neural responses are mainly cholinergic and decrease with decreasing airway size. PCLS from allergic rats were neither hyperresponsive to EFS nor to methacholine indicating that increased release of acetylcholine from postganglionic parasympathetic nerves does not occur and that acetylcholine receptors and the postreceptor transduction mechanisms are not affected by allergen exposure in rat. Finally, the EFS was adopted for PCLS from mice, guinea pigs, sheep, marmosets and humans. Cholinergic airway responses were found for guinea pigs, sheep, marmosets and humans. Furthermore, guinea pig and human PCLS were activated by capsaicin showing eNANC responses. The EFS-induced airway dilation in PCLS from marmosets was blocked by propranolol and L-NAME pointing to iNANC nerves in this species.

5.1 Design and development of EFS-setup on the basis of rat PCLS

Viable PCLS have been established as a useful tool to study airway tone, pulmonary vascular responses, ciliary beating as well as immunological and toxicological properties of the lung (34; 68; 111; 112; 188; 189). This study established neural stimulation of PCLS. EFS-induced bronchoconstriction is consistent, reproducible, sensitive to anticholinergics and enhanced by an acetylcholine esterase inhibitor in rats. Ipratropium was more potent to block EFS-induced cholinergic airway contraction than atropine or 4-DAMP. The effect of the EFS was strongest in the larger airways and appeared to be mediated by synaptic release of acetylcholine. This model will be useful to further study mechanisms of neural airway control and cholinergic AHR in rats and other species.

5.1.1 General EFS-setup in PCLS

The extent of the EFS-induced contractions of 15%-IAA in large airways roughly corresponds to contractions elicited by 330 nM of the metabolically stable acetylcholine derivative methacholine (figure 8 B in (111)), suggesting that this may be the effective acetylcholine-concentration in the synaptic cleft following presynaptic discharge. These findings indicate that neurally-induced bronchoconstriction can regulate airway tone, but is unlikely to lead to complete airway closure as shown for instance for allergen provocation (189). Comparing the present findings to other studies it should be noted that the data were not normalized to contractions induced for example by KCl, a procedure which may overstate the real magnitude of the effects. Normalization to receptor agonists (e.g. methacholine) was omitted throughout the study as it has been previously shown that responsiveness of small airways is stronger to methacholine and other stimuli (111; 112; 188;

189). In such a situation, normalization would distort the results. The EFS-induced contraction by approximately 15%-IAA was strongly potentiated by inhibition of the acetylcholine esterase (figure 12). These findings indicate that in PCLS cholinergic synapses remain intact, as they respond to electrical currents, possess active acetylcholine esterase (see experiments with neostigmine) and acetylcholine-receptors (see experiments with atropine) and recycle acetylcholine in a normal fashion (otherwise repetitive stimulations would not have been possible).

EFS was applied to stimulate neuronal cells, but, depending on the frequency and duration of the electric stimulus, direct contraction of smooth muscle cells may also occur (45). To exclude such an unspecific direct stimulation of voltage-gated channels on ASM, the effect of magnesium was examined. At high concentrations, magnesium prevents voltage-induced calcium entry and thereby the release of neurotransmitters from nerve terminals (40; 53). Since magnesium completely prevented the bronchoconstriction induced by EFS, but not by methacholine, it is concluded that in the present setup the EFS acts only on nerve endings and not on ASM (figure 15).

5.1.2 Relevance of the basic EFS conditions

For organ bath experiments, Wang and colleagues (183) systematically studied the influence of pulse duration (0.5 - 3 ms), muscle preload (2 - 20 g), voltage (5 - 20 V) and frequency (0.5 - 16 Hz) on the release of acetylcholine from equine airway cholinergic nerves, in order to provide guidelines for selecting EFS parameters in future studies. As they observed an increasing acetylcholine release from $2.1 - 18.6 \text{ pmol/g}_{\text{tissue-wet-weight}}/\text{min}$ with increasing frequencies (2 - 16 Hz), frequencies were analyzed in the present study by steadily increasing them while the other stimulation parameters were kept constant. This resulted in a sigmoidal frequency-response curve for the airway area change (figure 11 A) plateauing at $F = 50 \text{ Hz}$, somewhat above the frequency observed by Wang and colleagues (183) ($> 8 \text{ Hz}$). The most likely explanation for these differences is interspecies variability, as PCLS from other species (e.g. sheep) responded already at lower frequencies (figure 30) and our EF_{50} of $(16.7 \pm 4.9) \text{ Hz}$ is almost identical to the $(19.3 \pm 4.3) \text{ Hz}$ reported by Gonzalez and Santana (61) on isometric tension studies of rat tracheal smooth muscle. In addition they also found a plateau phase above 40 Hz (61), whereas the EF_{50} of 4.4 Hz in Wang's and colleagues' (183) study of horse airways was markedly lower. To put these figures into proportion, the maximal frequency that allows motoneurons to depolarize during repetitive stimulation is 500 - 1000 Hz (84). It should also be noted that Mitchell and colleagues (119) showed relatively high frequencies of action potentials (peak frequency of 10 - 13 Hz) for feline tracheal parasympathetic ganglion cells during normal breathing. Also other factors such as electrode geometry and the ionic strength of our cell culture medium have to be taken into account, as the inner electric field strength depends on the conductivity of the medium and on the current density, which in turn depends on a shape factor, the frequency and the external electric field strength. Taken together, the frequencies that were applied in rat PCLS appear reasonable.

With respect to pulse duration it was found, similar to Wang and colleagues (183), that durations of $B \geq 1$ ms were needed to reach a plateau response. In all the experiments (except figures 11 and 24) a current density of $A = 200$ mA was used, which was the only current that gave a reproducible contraction; since 200 mA is the maximum current output of the HSE-stimulator II, higher currents could not be studied. Another important factor influencing ASM contraction is train width: in the present study maximal contraction was achieved at $TW \geq 10$ s (figure 11), similar to Bosse and colleagues (25; 26), who used a maximum airway contraction at $TW = 9$ s when examining the influence of increased tone (by acetylcholine) on the mechanical properties of ASM. However, at $TW = 10$ s airway contractions took longer to reverse and, more importantly, could not be blocked completely by magnesium, indicating that the electrical stimulation was more unspecific at this train width and activated both nerve endings and ASM. In order to avoid direct activation of ASM $TW = 2.5$ s was used, but a $TW = 5$ s would also seem appropriate. Since a frequency of $F = 50$ Hz was used, a train width of $TW = 2.5$ s implies a series of 125 single pulses that were separated by a recovery phase of about one minute (exactly 57.5 s). The duration of this phase allowed recovery under normal conditions (figure 10 and figure 12 upper panel), but was too short when neostigmine was present. However, as the maximum contraction was always reproducible, it is concluded that the lack of complete recovery in figures 12, 15 and 17 is not a major limitation. It is important though to note that the different stimulation trains were separated by at least 15 min to assure full recovery of the ASM to its physiological ground state before the next experimental setting was examined. In addition this period was used to equilibrate the slices with the pharmacological agents to be studied next.

5.1.3 Cholinergic neuronal response in PCLS

Acetylcholine release from parasympathetic nerve terminals regulates the airway tone in various species including human (14; 32; 61). The enhanced airway contraction after addition of neostigmine, an acetylcholine esterase inhibitor (figure 12), indicates locally increased concentrations of acetylcholine at the neuroeffector junction (104; 114). Atropine, an unspecific inhibitor of muscarinic receptors, almost completely inhibited the neuronal cholinergic contraction in PCLS, even in the presence of neostigmine (figure 12). Atropine most probably prevents ASM contraction by blockade of the M_3 (and M_2) receptors on the postsynaptic membrane, such that the M_3 receptors cannot initiate the contraction via the IP_3 pathway (14; 21; 115; 141). The small residual bronchoconstriction in the presence of $10 \mu\text{M}$ atropine may be explained by the blockade of presynaptic muscarinic receptors by atropine, preventing the autoinhibitory effect of acetylcholine release (14; 21). Furthermore, the release of SP might potentiate the release of acetylcholine from cholinergic nerves (14) and trigger the release of bronchoconstrictive tachykinins from excitatory NANC (49).

Having proven the cholinergic mechanism in EFS of PCLS from rat, the method was tested against distinct M receptor antagonists at different concentrations to evaluate its potential for pharmacological discrimination of drugs. Atropine, ipratropium and 4-DAMP were used as representative substances - the first two being unspecific M receptor antagonists and the latter a selective M₃ receptor antagonist (168). Since repeated stimulations were reproducible (figure 13 A) an increase of the inhibitor concentration in consecutive EFS trains is feasible and a diminished response can be attributed to the effect of the antagonist and not to fatigue of the ASM. Consistently, increasing concentrations of atropine, ipratropium or 4-DAMP inhibited EFS-induced airway contractions. Calculated log IC₅₀ values (figure 14), revealed ipratropium (-10.0 ± 0.4) being more potent to inhibit EFS evoked airway responses than atropine (-8.8 ± 0.4) or 4-DAMP (-8.4 ± 0.3). So far only one other study compared the effect of atropine, ipratropium and 4-DAMP in parallel in the same EFS setup, but on twitch responses of guinea pig tracheal ring preparations (168). However, equal log IC₅₀ of -8.63 ± 0.04, -8.64 ± 0.04 and -8.61 ± 0.05 were found for atropine, ipratropium and 4-DAMP, respectively, which except for ipratropium were similar to those determined for rats in this study. Species differences and differences in setup may account for the discrepancy. Therefore, the obtained log IC₅₀ values herein seem reasonable and the EFS of PCLS is a valuable tool to characterize and discriminate potential anticholinergic drugs.

5.1.4 Reactivity of different airway generations

PCLS have previously been used to study airway responses along the bronchial tree. Smaller airways are more responsive to methacholine, serotonin, the TP receptor agonist U46619 and allergens in lungs of different species (112; 188; 189). Endothelin-1 contracted airways independent of their size (112), indicating that smaller airways are not more sensitive in principle. In the present work it was shown that smaller airways are less sensitive to EFS (figure 16). This observation can be explained most likely by the decreasing innervation of the bronchial tree towards the peripheral regions (14). Thus, parasympathetic bronchoconstriction in the airways appears to be balanced by inversely arranged innervation and acetylcholine-responsiveness: rich innervations with low acetylcholine-responsiveness in large airways opposed to more sparse innervations with high sensitivity in smaller airways.

5.1.5 Role of the TP receptor in neuronal activation

Subthreshold doses of TP receptor agonists (e.g. U46619), i.e. doses which do not evoke airway contraction via the TP receptor themselves, have been shown to increase parasympathetic cholinergic bronchoconstriction in mice (as measured by *lung resistance*) (7), guinea pig (*lung resistance*) (176) and dogs (*isometric tension*) (4; 167). Interestingly, in the study of Takata and colleagues (167) the effect was only found for bronchial smooth muscle, whereas tracheal smooth muscle was unaffected. This suggests regional differences in airway responsiveness, with smaller

airways being more susceptible to TXA. Additionally, Saroea and colleagues (150) suggested U46619-induced bronchoconstriction via acetylcholine release in asthmatic subjects. Moreover, rat tracheal prostanoid synthesis can be stimulated by activation of M receptor-linked calcium mobilization (78). These observations suggested a possible influence of endogenously released TXA on EFS in the present model. However, the TP receptor antagonist SQ29548 had no effect (figure 17), indicating that EFS-induced airway contractions in the rat are not influenced by TXA. This is confirmed by the observation that even a pre-contracting concentration of U46619 did not alter the response to EFS (figure 18). These observations are in line with other *in vitro* studies. For instance, Aizawa and Hirose (3) measured airway contraction of canine tracheal strips in response to acetylcholine or EFS either in presence or absence of $\text{PGF}_{2\alpha}$ or stable TXA_2 and found no difference. They therefore suggested that the interaction of TXA and cholinergic pathways depends on stimulation of vagal sensory endings and activation of the reflex pathway *in vivo*. This conclusion is supported by studies from Underwood and colleagues (176), who discriminated strictly between *in vitro* and *in vivo* responses to PGD_2 and $9\alpha,11\beta\text{PGF}_2$. *In vivo*, atropine antagonized PG increased airway resistance similar to the TP receptor antagonist SK&F 88046, whereas *in vitro* (tracheal strip) only TP receptor antagonists were effective. Thus, our findings suggest that the reflex arc is not complete in PCLS.

An interaction of TP and M receptor pathways may not be limited to prejunctional nerves, but may also occur at the ASM itself. Therefore, cumulative concentration-response curves were conducted with U46619 in presence or absence of atropine and no difference was found (figure 19). This finding is in accordance with *in vitro* contraction of tracheal strips from guinea pigs, where comparable concentration-response curves for TP receptor agonists (U44069, PGD_2 , and $9\alpha,11\beta\text{PGF}_2$) in the presence or absence of atropine were obtained (176). In contrast, Allen and colleagues (7) observed a notable reduction in U46619- (50 - 500 nM) evoked murine tracheal ring constriction at 1 μM atropine. They explain their findings by an increased sensitivity of the ASM M_3 receptor to its cognate physiological ligand acetylcholine after stimulation of the ASM TP receptor by TXA. However, their model presupposes the existence of an ASM basal tone and constitutive release of acetylcholine in the unprovoked airways. Therefore, their data are not conflicting to the results herein, as it is assumed that there is no or negligible basal release of acetylcholine in the present system, since neostigmine had no effect in un-stimulated PCLS (figure 12). Nonetheless, possible species differences can easily be studied with the help of PCLS (34; 111; 145; 188; 189).

5.1.6 Comparison to other *in vitro* models

Previously, EFS has been almost exclusively studied in the organ bath using trachea, bronchi and parenchymal strips. In comparison, PCLS have both advantages and disadvantages. First, organ bath studies are limited to the trachea or upper bronchi or to the very distal part of the lungs as in parenchymal strips. PCLS from rat lungs allow to study nearly all generations along the bronchial

tree. On the other side PCLS are very thin and therefore the percentage of neurons and especially ganglia will be lower than in tracheal and bronchial preparations. Second, airway contractions in the organ bath are either isotonic or isometric, whereas they are more auxotonic (like *in vivo*) in PCLS. The airways remain embedded in the parenchyma that exhibits tethering forces on the airways increasing with contraction. These tethering forces became visible when using a Teflon ring that weighs on the outer parts of the slice, so that the tethering forces increase during airway contractions. In the absence of the Teflon ring the whole slice contracted and no relaxation occurred, implying the lack of sufficient tethering forces (figure 10). So presumably, the Teflon ring acts like the attachment of the lung tissue to larger vessels and airways. Third, the PCLS setup requires only small buffer volumes of 1 mL and volume could be further decreased to 0.4 mL, which is advantageous when expensive substances will be tested. Fourth, PCLS allow to analyze airway responses throughout the bronchial tree, allowing to analyze airways down to a diameter of 50 μm (111; 188; 189). Thus, the present method will help to further elucidate the role and the mechanisms of small airway innervation. In contrast to classic parenchymal preparations for the study of peripheral lungs, in which force generation from different sources (ASM, vasculature) cannot be distinguished, the present model can specifically attribute contractions to airways or vessels along the entire tracheobronchial tree. And finally, the technique of PCLS can be easily transferred to other species, including human.

5.2 Active sensitization of rats

In the present study, only healthy animals were examined in EFS of PCLS and their peripheral airway innervation could be characterized. In the following section rats were sensitized with OVA as a representative experimental animal model of asthma and alterations in neural responses were studied. Haemorrhages in the lung and airway contractions in response to allergen pointed to an ongoing inflammatory process and an acute allergic response, but responses to methacholine and EFS were the same in control and OVA treated animals excluding a hyperresponsive state. IgE levels were determined to prove the immune status of the animals. While OVA alone did not raise IgE levels, inactivated *Bordetella pertussis* organisms, given as adjuvants, were effective in increasing the IgE levels more than threefold.

5.2.1 Sensitization scheme

The Brown Norway rat strain was chosen for sensitization, because it presents a more pronounced IgE and inflammatory response to allergen challenges than other rat strains (87). The common features of Brown Norway rats and human asthma include high IgE levels, EAR, LAR, eosinophilia and TH₂ cytokine production (87). The sensitization scheme of Brown Norway rats was based on the protocol from Glaab and colleagues (60). This group could prove an EAR and LAR in response to OVA *in vivo* after sensitization by two modes of measurement: noninvasive head-out body

plethysmography and invasive determination of pulmonary conductance. Moreover, enhanced IgE levels and pronounced inflammation were detected by Glaab and colleagues (60). Therefore, the sensitization scheme promised to obtain a suitable rat model imitating acute allergic asthma.

The macroscopic observation of increased haemorrhage in sensitized animals versus the control animals (figure 20) points to an acute inflammatory process - in which vascular leakage appeared - and gives evidence for an immunogenic response to OVA. Confirming this and according to Glaab's and colleagues' (60) findings, airways contracted in response to OVA in PCLS from sensitized rats, whereas no contraction was found in control animals. However, the observed contractions of $(12 \pm 11)\%$ were weak. In contrast, Glaab and colleagues (60) found a pronounced EAR to OVA in sensitized animals as both the midexpiratory flow and the pulmonary conductance dropped about more than 70% from baseline values. However, those physiological parameters may not directly correlate with the decrease in airway caliber in PCLS. Hence, a comparison with an allergic response in PCLS itself maybe more appropriate. So far, there is no data published on OVA provocation of PCLS from actively sensitized rat, which describe the extent of airway contraction exactly. However, in an abstract, Martin and colleagues (109) report of strong and sustained airway contractions to allergen *in vivo* and in PCLS. Surrogate quantitative data may be considered from passively sensitized PCLS, i.e. PCLS that were incubated overnight with sera from actively sensitized animals. Two studies describe the response of passively sensitized PCLS from rat to OVA (107; 189). Wohlsen and colleagues (189), for instance, found an airway contraction of approximately 90% after allergen provocation suggesting that a nearly complete airway closure should also be possible in PCLS from actively sensitized animals. In principal, the rat is a weak allergic bronchoconstrictor and more agonist is necessary to produce airway contractions compared to doses used in guinea pigs (87).

Furthermore, the weak contraction found in the present study suggests only a low number of mast cells bearing OVA specific IgE and therefore only low mast cell degranulation. This correlates well with the unaffected IgE titers during sensitization to OVA (figure 23). IgE titers were only affected if in addition heat inactivated *Bordetella pertussis* organisms were used as adjuvants to induce T_H2 -lymphocyte immune reaction, i.e. T_H2 -lymphocytes release IL-4, which stimulates B-lymphocytes to produce IgE (30). Although IgE titers were elevated by the *Bordetella pertussis* adjuvants, doses of the adjuvants may be critical for a successful allergen sensitization, since the activity of the *Bordetella pertussis* preparation may vary and since other protocols use higher doses per animal (e.g. Kucharewicz et al. (88) 10^{10} organisms, Misawa et Chiba (118) 2×10^{10} organisms) than in the present protocol (6×10^9 organisms), which was in accordance to Glaab and colleagues (60). A more sophisticated approach could therefore comprise a titration of the adjuvants to achieve IgE increases depending on the sensitization with allergen. Since the IgE ELISA determined total IgE and not OVA specific IgE and as both sensitized animals and control animals showed equal levels of IgE, a quantitative statement on OVA directed immune response cannot be

made. However, total IgE levels were quite high even in non-sensitized animals, since they exceeded the levels found by Palmans' group (136) (1.66 ± 0.80) $\mu\text{g/mL}$ in saline treated rats vs. (15.87 ± 1.4) $\mu\text{g/mL}$ in OVA sensitized rats) and Glaab's group (60) (0.49 ± 0.06) $\mu\text{g/mL}$ in saline treated rats vs. (1.61 ± 0.59) $\mu\text{g/mL}$ in OVA sensitized rats) by one and two orders in magnitude, respectively.

Since basic IgE levels were still high one may speculate that pre-sensitization of the animals could have occurred, in which case an increase due to OVA sensitization would hardly be visible. Pre-sensitization is conceivable, since in Brown-Norway rats pulmonary inflammation has been observed under normal animal room environment due to ambient particles ($0.3 - 1 \mu\text{m}$ in diameter) and the number of those particles correlated strongly with the number of eosinophils in the bronchoalveolar lavage fluid (133). However, in the present study lung tissue was reserved for PCLS preparation, which excluded the determination of eosinophils.

5.2.2 Airway hyperresponsiveness

AHR - an exaggerated airway response to an unspecific stimulus - is a common feature of human bronchial asthma. To test whether sensitized rats exhibit an AHR, concentration-response curves were performed for methacholine on PCLS from OVA or saline challenged rats (figure 22). However, the concentration-response curves were the same in both groups indicating that there was no hyperresponsiveness to methacholine after three weeks of sensitization. This was unexpected as AHR was reported to occur in rats (89; 136), but in these studies AHR was measured *in vivo*, whereas PCLS are an *in vitro* method. The lack of an AHR to methacholine might be explained by that fact. However, this is questionable because Martin and colleagues (109) performed a comparative study on asthmatic airway responses in rats *in vivo* and *in vitro* and found AHR to acetylcholine and adenosine. The AHR to acetylcholine *in vitro* only occurred if an EAR was experienced one day before *in vivo*. Although the rats were challenged by OVA one day before PCLS preparation, it cannot be guaranteed that an EAR took place and may therefore explain the lack of AHR in the present study. Moreover, the time schedule of sensitization could have an important impact on the occurrence of an AHR. For instance, Palmans and colleagues (136) found an increase in airway responsiveness to carbachol as measured by airway resistance if rats were challenged for two weeks by OVA in comparison to PBS-exposed animals, but not if challenge lasted 4 or 12 weeks. This concerned the concentration to produce 50% increase in baseline lung resistance. In addition to this, a left ward shift in dose response curves of carbachol was observed for animals treated two weeks with OVA compared to animals treated for 4 or rather 12 weeks with OVA (136). Since in the present study animals were exposed to OVA for three weeks, this may be a critical timeframe for whether an AHR is observable or not. The time is especially crucial with respect to airway remodelling, i.e. structural changes observed in asthmatics, and Palmans and colleagues (136) ascribe their observed difference to different states in airway remodelling. Firstly, the inner airway

wall became thicker with two weeks of OVA challenge, which then gradually declined until the 12th week and secondly, collagen deposition increased with prolonged OVA exposure (136). The increased thickness of the inner airway wall enhances the effect of a given ASM contraction (as elicited by a bronchoconstrictor, e.g. carbachol and methacholine) following Poiseuille's law for laminar flow (in other words: with thicker airway wall the inner airway diameter is more reduced by the same extent of ASM contraction) and thus contributes to increased airway sensitivity, i.e. AHR (120; 136). In contrast, increased collagen deposition increases airway wall stiffness opposing airway contraction (90; 136) and increased collagen associated with the ASM layer itself also limits airway narrowing (29; 136).

5.2.3 EFS of PCLS from actively sensitized animals

During asthma AHR attributed to nerves can be due to enhanced reflex activity, increased mediator release, altered signal transmission, increased receptor-density on neurons and quantitative changes in sensory and/or motor neurons (65; 143). Moreover, the ASM may exhibit an enhanced sensitivity to neuropeptides and tachykinins or also display an increased receptor expression (143) (chapter 1.9). To test whether nerve function is altered after three weeks of sensitization and if this is measurable *in vitro*, PCLS from OVA-sensitized rats were subjected to EFS and the airway response was compared to saline treated animals. However, there was no difference in the sensitivity to the four basic EFS parameters except for the current (figure 24). A shared frequency-response curve was found for sensitized and control animals. For the other parameters the curves of OVA exposed rats run above the curves of the saline group indicating weaker airway contraction. Hence, there is no AHR to EFS found in PCLS, but rather hyporesponsiveness, which is further confirmed by a significant reduction in bronchoconstriction to standard EFS (F = 50 Hz, B = 1ms, A = 200 mA, TW = 2.5 s) of sensitized rats compared to control rats (figure 25). In consequence of the uncertain susceptibility of rat to sensitization and therefore heterogeneous immune state, the airway responses of all PCLS - both of sensitized and control rats - were correlated to IgE levels and confirmed lesser reactivity with higher IgE (figure 27), i.e. higher immunogenicity. In contrast, the airway response to EFS was uncorrelated to the response to allergen suggesting that sensitization of rat has no effect on neurally evoked bronchoconstriction (figure 26).

Overall, the findings contradict the expectation of an AHR, which is in contrast to literature. For instance, Braun and colleagues (30; 31) found in two EFS studies on mouse trachea a drop in the EF_{50} from 4 Hz in PBS challenged mice to 2 Hz in OVA challenged mice. However, those studies were performed in another species and species differences may account for the discrepancy. Notably, a Pubmed search on the keywords: rat, airway hyperresponsiveness and electric field stimulation was performed and revealed only three results of which one deals with AHR to OVA sensitization (50). In that study, confirming the findings herein, there was no AHR to EFS developed after both acute and chronic sensitization to OVA and AHR was also not found for acetylcholine.

It was concluded, which may also be the case here, that increased release of acetylcholine from postganglionic parasympathetic nerves does not occur and that acetylcholine receptor and the postreceptor transduction mechanisms are not affected by allergen exposure.

The observed hyporesponsiveness within the present model may result from a fibrotic remodelling of the airways resulting in an increased airway wall stiffness or affecting the ASM itself as discussed above (chapter 5.2.2) (29; 90; 136). The airways of sensitized animals have possibly been precontracted due to inflammatory mediators – thus limiting the extent of EFS-inducible airway contraction, but this issue has to be elucidated by the application of ASM relaxant agonists.

5.3 Comparison of different species in EFS of PCLS

In the present study an electric field was applied to PCLS from different mammals allowing the species comparison of neuronally triggered airway responses under identical conditions. Species were heterogeneous in their response (table 6): In rats, sheep, guinea pigs, marmosets and humans, bronchoconstriction was caused by cholinergic innervation. Moreover, in guinea pig and human PCLS also activation of eNANC nerves led to airway contractions. The blockade of airway relaxation in marmosets by the inhibition of β -receptors and NO synthase points towards adrenergic and iNANC innervation in this species.

5.3.1 General considerations on EFS of PCLS

In the preceding part rat EFS was introduced as a means to study neural responses in PCLS and the following EFS settings were found to be effective (152): $F = 50$ Hz, $B = 1$ ms, $A = 200$ mA and $TW = 2.5$ s. The same parameters were also used to stimulate PCLS from mice, guinea pigs, sheep, marmosets and humans and evoked characteristic airway contractions in each species (figure 28), except for the mouse. The neural mediation of these responses was proven by the inhibitory effect of magnesium concentrations (10 mM) high enough to prevent voltage-induced calcium entry and the release of neurotransmitters at the nerve terminals (40; 53) (table 5). The contractions to exogenous methacholine were not affected by magnesium, excluding the possibility that the high magnesium concentrations altered ASM physiology itself. These findings show that the EFS, like in rats, acts also in the other species on neurons and not directly on ASM.

Differences in stimulation conditions compared to other *ex vivo* EFS studies on lung tissue (183) can be due to species or tissue variability, different electrode geometry, and different ionic strength of the cell culture medium, which all influence the electric field. In the present study, different species were compared in an identical setup, including nearly identical tissue preparation. These identical conditions are the basis for the conclusion about the differences between species with respect to neurally mediated bronchoconstriction.

Under the standard conditions ($F = 50\text{Hz}$, $B = 1\text{ ms}$, $A = 200\text{ mA}$, $TW = 2.5\text{ s}$) mice showed no significant response. However, EFS elicited contractions in murine tracheal preparations in previous studies (11; 12; 93) and in line with that neurally-evoked bronchoconstriction was observed in murine PCLS at higher electric fields (figure 29). Higher electric fields were also required in studies by Braun and colleagues (31) as well as Larsen and colleagues (93), who used pulse durations of 2 ms when stimulating murine tracheal smooth muscle segments. In contrast, Bachar and colleagues (11; 12) only used pulse durations of 0.8 ms, but train widths lasted 60 s and were therefore much longer than the 2.5 s within this study. Hence, the observations made here are reasonable concluding that murine preparations are less susceptible to EFS and require harsher EFS conditions. Nonetheless, those harsher conditions seem still to neurons specifically, since magnesium blocked the EFS-induced airway response (figure 29 C). In ovine PCLS, on the other hand, airways were highly excitable (figures 28 and 30) and nerve activation was observed already at low frequencies or even after one single electrical stimulus (0.4 Hz at train width 2.5 s). Overall, the EF_{50} values observed in the present study are in line with the literature. The EF_{50} of $(0.5 \pm 0.2)\text{ Hz}$ is in the range of that for ovine bronchial rings and tracheal segments of about 0.2 Hz (156). The rat EF_{50} of $(16.5 \pm 0.8)\text{ Hz}$ was equal to that of $(16.7 \pm 4.9)\text{ Hz}$ in the previous part of the study and comparable to $(19.3 \pm 4.3)\text{ Hz}$ from isometric tension studies of rat tracheal smooth muscle (61). The guinea pig EF_{50} of $(7.0 \pm 1.2)\text{ Hz}$ is close to the 5.3 Hz and 3.7 Hz observed by Altieri and colleagues (8) when studying cholinergic responses in the trachea and tachykinergic responses in the bronchus, respectively. For human airways, the EF_{50} of $(8.1 \pm 0.8)\text{ Hz}$ herein is close to $(8.9 \pm 0.4)\text{ Hz}$ that was obtained in human bronchi before (47). Among all species studied here, the EF_{50} values of guinea pigs $((7.0 \pm 1.2)\text{ Hz})$ are closest to that of humans $((8.1 \pm 0.8)\text{ Hz})$, providing another argument for the conclusion that guinea pig airways are a reasonable proxy for human airways.

The differences between the species within this study are not explained by differences in ASM cells, because the responses to methacholine are very similar in all species (68; 111; 145; 151; 155; 188) and the experiments with magnesium also exclude direct electric activation of ASM. Possible explanations are differences in neurotransmitter release or neurotransmitter degrading enzymes such as the acetylcholine esterase that may vary in amount or activity (86; 113; 148). However, one may speculate that the type of innervation, i.e., cholinergic, adrenergic, eNANC or iNANC, is the most relevant reason for the differences between species. For instance the repetitive reversible contraction in rat is cholinergic (152), whereas the steady contraction without relaxation in guinea pigs (figure 28) suggests a mechanism other than a cholinergic one, in which the neurotransmitter is not metabolized.

5.3.2 Pharmacological characterization of distal airway innervation

The type of innervation was addressed by pharmacological agents: the muscarinic antagonist atropine (141) was used to show involvement of parasympathetic cholinergic nerves, whereas the TRPV1 channel activator capsaicin (126) or the unspecific TRP channel blockers SKF96365 and Ruthenium red (140) were used to demonstrate eNANC nerves. Relaxant nerve responses were addressed by the sympathetic adrenergic antagonist propranolol (82) or by the NO synthase inhibitor L-NAME to prevent NO release from iNANC nerves (95).

Atropine blocked the EFS-induced bronchoconstriction in PCLS from rats, guinea pigs, sheep, marmosets and humans (figures 31 and 33), indicating that these species receive cholinergic innervation in the distal part of their lungs. These findings extend former studies on larger airways (8; 14; 54; 61; 70; 158) and they are important, because innervation is unevenly distributed along the tracheobronchial tree (8). This is also true for tachykinergic innervation in guinea pigs that so far was thought to supply predominantly the large airways (8). In this species distal airways seem to be supplied by both cholinergic and tachykinergic nerves, as shown by the effects of atropine and the TRP channel antagonists (figure 33). In contrast to the rats, in which cholinergic responses are weaker in smaller airways (152), distal airways from sheep or human were quite susceptible to EFS-induced cholinergic bronchoconstriction (figure 31), indicating relatively strong innervation of peripheral airways in these species. The residual airway contractions in the presence of atropine may be due to eNANC activation, or blockade of presynaptic muscarinic receptors by atropine, preventing the autoinhibitory effect of acetylcholine release (14; 21) or due to release of SP that might potentiate the release of acetylcholine from cholinergic nerves (14).

Various types of TRP channels are expressed in the mammalian lung and are involved in the regulation of airway functions, in which particularly TRPV1 and TRPV4 play an important role. TRPV1 channels are generally expressed in non-myelinated C-fiber afferents, which innervate the airways and contain sensory neuropeptides (79). Activation of TRPV1 channels on nerves induces calcium influx into neurons, membrane depolarization and action potentials. Such excited chemosensitive nerves correspond to eNANC nerves, which induce bronchoconstriction by the release of SP or a related tachykinin (9). Therefore, the effects of capsaicin, a potent TRPV1 agonist (79; 126), were studied to estimate the role of eNANC innervation in the various species. Notably, only airways of guinea pigs and humans responded to capsaicin providing further evidence for the presence of tachykinergic nerves in the distal lung of these species (figure 32). Undem and coworkers (175) reported contractions of $(66 \pm 10)\%$ in guinea pig bronchi towards capsaicin and Spina with colleagues (158) made similar observations in human airways, albeit the effects were smaller here ($1\mu\text{M}$: $(2 \pm 3)\%$, $10\mu\text{M}$: $(14 \pm 13)\%$ and with $100\mu\text{M}$ capsaicin $(44 \pm 40)\%$ of the maximal contraction by 10^{-4} M methacholine). Also, findings by Lundberg and colleagues (100) support the notion that human airways are less responsive to capsaicin than those from guinea

pigs, by showing that guinea pig tracheas are 1000-fold more sensitive to SP and 100-fold more sensitive to capsaicin than human bronchi. Further on, Lundberg's and colleagues' (100) study also supports the observation made in the present work that not all human airways are capsaicin sensitive. From studies with transmural EFS of human segmental bronchi, they report two different scenarios: one where contractions were abolished by atropine and another one where only tetrodotoxin (specific antagonist of voltage-gated sodium channels on nerve cells), but not atropine was effective. These findings suggest the existence of two types of human airways: either solely innervated by cholinergic nerves or innervated by both cholinergic and eNANC nerves.

That capsaicin failed to evoke clear bronchoconstriction in PCLS from marmosets is in line with data presented for marmoset trachea and bronchus, which weakly contracted by $(2.3 \pm 2.8)\%$ and $(8.0 \pm 6.6)\%$ of maximal contraction by 10^{-4} M methacholine, respectively, after application of $100 \mu\text{M}$ capsaicin (158). In conflict to capsaicin responses in ovine PCLS, sheep lambs exerted a reduction in tidal volume from 91 mL to 36 mL when capsaicin ($5 \mu\text{g}/\text{kg}$) was injected intravenously (10). This opposing finding may be explained either by regional differences along the tracheobronchial tree (trachea/bronchus vs. peripheral airways in PCLS) (8) or by reflex arcs *in vivo* (79), which are destroyed in the PCLS preparation. In rat and mouse bronchi, but probably also in marmoset and sheep airways, capsaicin may play a more prominent role in the activation of sensory nerves of the inhibitory system than in the excitatory system (105; 164).

Nervous stimulation can also cause bronchorelaxation via either sympathetic or iNANC nerves (32; 143). In the present study, dilation of airways appeared only in PCLS from marmoset after multiple EFS (figures 28 and 34). The effects of propranolol and L-NAME demonstrate that this relaxant response was due to both sympathetic and iNANC innervation, because only the combination of the two inhibitors was effective in blocking the relaxant response. Although power analysis revealed the possibility of sympathetic contribution, iNANC contributions seem also to be involved for two reasons: Firstly, L-NAME prevented the return to baseline levels during EFS (figure 34 C, 2nd train) and secondly Spina and colleagues (158) reported relaxations in marmoset tracheae and bronchi at capsaicin concentrations as high as $100 \mu\text{M}$ after the tissue was precontracted with methacholine. The marmoset maybe a useful model to study relaxant innervation of the lung, as interferences with precontracting agents can be excluded. Whether the peripheral airways of the other species are innervated by relaxant nerves still has to be elucidated, because usually relaxation becomes apparent only in precontracted airways (43; 146).

In summary cholinergic innervations were found to contract airways of rats, guinea pigs, sheep, marmosets and humans. In addition eNANC nerves contracted guinea pig and human airways. Furthermore, the dilation of airways in marmoset PCLS was attributed to sympathetic and iNANC responses (table 6).

Table 6: Peripheral airway innervation of distinct mammals as verified in the current examination

Species	Cholinergic	Adrenergic	eNANC	iNANC
Mouse			-	
Rat	+		-	
Guinea Pig	+		+	
Sheep	+		-	
Marmoset	+	+	-	+
Human	+		+	

eNANC, excitatory nonadrenergic noncholinergic; iNANC, inhibitory nonadrenergic noncholinergic; +, proven; -, insignificant.

5.3.3 Phylogenetic considerations

Airway pharmacology varies strikingly between species, not only with respect to neural transmission, but also with respect to various mediators and transmitters. For instance, airways from rodents, marmosets or rhesus monkeys do respond weakly or not at all to LTs (67; 155), that readily contract airways in humans (37), cynomolgus, baboons (155) and guinea pigs (46; 66). All these studies suggest that, regarding airway pharmacology, guinea pigs resemble humans more closely than mice or rats do (121; 161).

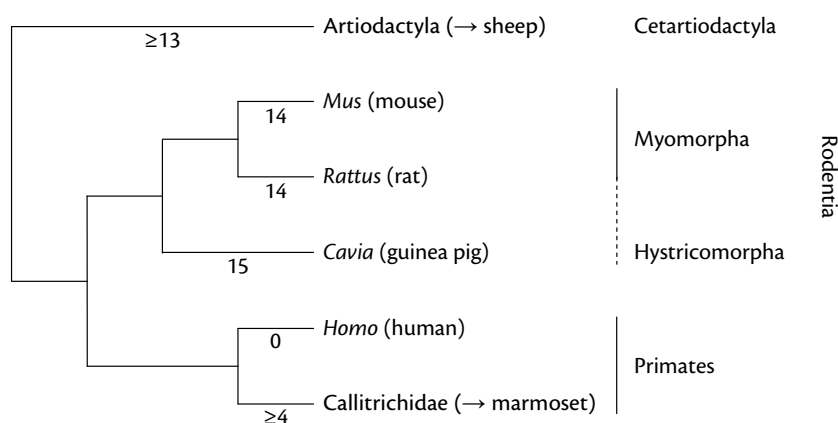

Figure 35: Phylogenetic relationships among the examined species. Relationships are deduced from Murphy and colleagues (122), who analysed 9779 base pairs from 15 nuclear and three mitochondrial DNA genes among 64 placental mammals and two marsupials. Except for the sheep all animal belong to one clade, the Neotropical order of Xenarthra. There is current debate on rodent monophyly or polyphyly and whether the guinea pig is a rodent or not (36). However, in line with D'Erchia's and colleagues' (36) phylogenetic study on the whole mitochondrial genome, the *Cavia* separates earlier than Myomorpha and is traditionally classified as Hystricomorpha. The marmoset is considered as a non-human primate and belongs to the family of Callitrichidae, for which Murphy and colleagues (122) refer to the *Callimico*. Direct data for sheep also lacked and therefore the sheep was categorized to Artiodactyla. Numbers indicate the total count of branches beginning from human up to the examined species as suggested by Murphy and colleagues (122) for the interrelationship of their 66 studied Amniota, in which the minimum evolution topology was estimated by neighbour joining using maximum likelihood distances.

The physiological observations might suggest a close phylogenetic relationship between guinea pigs and humans. Therefore, a phylogenetic tree based on Murphy's and colleagues' examinations (122) was drawn for all species within in this study (figure 35). Interestingly, however, this mapping does not indicate an exceptional close relationship between guinea pigs and humans, although this may be due to the selection of genes that were not specific for the lungs.

5.4 Conclusion

PCLS are widely used in airway pharmacology. In the present study EFS of PCLS was introduced as a novel way to study neural airway responses. The finding that in PCLS airways contract in response to electrical fields and that this response is sensitive to magnesium indicates that terminal nerves remain intact in this preparation and can be activated specifically. PCLS were prepared from different species including humans and peripheral neural airway responses were characterized. The present findings suggest that airways of rats, guinea pigs, sheep, marmosets and human do all receive cholinergic innervations. Moreover, distal airways from guinea pigs and humans also receive eNANC innervations, whereas marmoset airways display relaxations by sympathetic and iNANC nerves.

In the allergic rat model no AHR was observed, indicating that increased release of acetylcholine from postganglionic parasympathetic nerves does not occur and that acetylcholine receptors and the postreceptor transduction mechanisms are not affected by allergen exposure in rat.

Since the cholinergic response can be influenced pharmacologically in EFS of PCLS and log IC_{50} for antagonists can be determined, this new method allows the screening of drugs affecting neurally evoked bronchoconstriction. As the guinea pig resembled the human response profile best, this species is particularly suitable for studies on the role of peripheral airway innervations and their involvement in human lung diseases.

6 Summary

Chronic airway diseases, such as bronchial asthma and chronic obstructive pulmonary disease (COPD), are the fourth-leading cause of death in developed countries and have a high personal, societal, and economical impact. Recurring inflammation is one characteristic of those diseases leading to airway remodelling and modulating the function of nerves resulting in excessive bronchoconstriction. The precision-cut lung slice (PCLS) technique is widely used in pulmonary pharmacology, but neurally-induced bronchoconstriction has not been studied yet. Hence, the aim of this study was to develop a system, which specifically activates nerves within PCLS of different species, allowing the investigation of neural function and its pharmacological interference throughout the whole lung - also in an allergic animal model.

Electric field stimulation (EFS) is considered to activate nerve endings in tissue preparations. Therefore, a device was constructed in which the PCLS were faced by two platinum electrodes and which delivered serial rectangular electric stimuli. EFS-induced bronchoconstriction in PCLS was monitored by videomicroscopy.

EFS of PCLS was first established for the rat. EFS conditions were systematically studied and stable repeated airway contractions were obtained at a frequency of 50 Hz, pulse duration of 1 ms, current of 200 mA and train width of 2.5 s. Magnesium antagonized airway contractions induced by EFS, but not by methacholine, indicating that they are neurally evoked. The EFS-triggered contractions were increased by the acetylcholine esterase inhibitor neostigmine and were highly reproducible, which allowed the study of muscarinic antagonists in consecutive EFS-trains. The decadic logarithmic inhibitory concentration of half-maximal effect ($\log IC_{50}$ M) of antagonists was determined in EFS of PCLS and revealed ipratropium (-10.0 ± 0.4) being more potent than atropine (-8.8 ± 0.4) and 4-DAMP (-8.4 ± 0.3). Furthermore, it was tested if thromboxane facilitates cholinergic bronchoconstriction by using the thromboxane prostanoid receptor antagonist SQ29548, but no effect was observed. In EFS of PCLS on different airway sizes, larger airways showed stronger response than smaller ones.

In a model of allergic asthma, Brown-Norway rats were sensitized against ovalbumin (OVA). Besides haemorrhages in the lung also airway contractions in PCLS after OVA-provocation were found, pointing to a persisting inflammation and an acute allergic response, respectively. However, in PCLS from these rats no airway hyperresponsiveness was found in response to methacholine or EFS.

Since airway responses are known to exhibit considerable species differences, the neural responses of PCLS prepared from mice, guinea pigs, sheep, marmosets and humans were examined. Peripheral neurons were activated either by EFS or additionally, in order to probe excitatory nonadrenergic

noncholinergic (NANC) nerves, by capsaicin. Bronchoconstriction in response to EFS varied between species in magnitude ($(2 \pm 2)\%$ in mouse to $(61 \pm 26)\%$ in guinea pig) and sensitivity (half-maximal response in frequency-response curves: (0.5 ± 0.2) Hz in sheep to (23 ± 7) Hz in marmoset). As in rats, atropine antagonized the EFS-induced bronchoconstriction in PCLS from guinea pigs, sheep, marmosets and humans. Capsaicin caused bronchoconstriction only in human and guinea pig lungs. Transient receptor potential channel antagonists (SKF96365/Ruthenium red) inhibited airway contractions after EFS or capsaicin addition in guinea pigs. Only marmoset airways showed airway dilation after multiple EFS and this was blocked by propranolol and L-NAME.

In conclusion, the findings within this study show that nerve endings remain intact in PCLS. The present method is useful to study neurogenic responses in airways of different size and pharmacological interventions are possible. In rat PCLS, lesser sensitivity to EFS with smaller airways is in contrast to the response of exogenously applied methacholine, which suggests that parasympathetic bronchoconstriction in the airways seems to be balanced by inversely arranged innervation and acetylcholine-responsiveness: rich innervations with low acetylcholine-responsiveness in large airways opposed to more sparse innervations with high sensitivity in smaller airways. In the rat model of allergic asthma, increased release of acetylcholine from postganglionic parasympathetic nerves does not take place and acetylcholine receptors and the postreceptor transduction mechanisms are not affected after allergen sensitization. As in rats, airways of guinea pigs, sheep, marmosets and humans do all receive cholinergic innervations. Moreover, distal guinea pig and human airways also receive excitatory NANC innervations. Marmoset airways even display relaxations by sympathetic and inhibitory NANC nerves. As guinea pig resembled the human response profile best, this model may be particularly suited for studies on the role of peripheral airway innervation and its involvement in human lung diseases.

7 Deutsche Zusammenfassung

Chronische Atemwegserkrankungen, wie Asthma bronchiale und die chronisch obstruktive Lungenerkrankung (COPD), sind die vierthäufigste Todesursache in Industrieländern und haben einen bedeutenden persönlichen, sozialen und ökonomischen Einfluss. Diesen Erkrankungen liegt eine chronische Entzündung zugrunde, die zum Umbau der Atemwege führt und die Nervenfunktion moduliert, so dass eine exzessive Bronchokonstriktion auftritt. Lebende Lungenschnitte (PCLS) werden in der Lungenpharmakologie zu unterschiedlichen Zwecken genutzt, aber neuronale Fragestellungen wurden in PCLS noch nicht untersucht. Das Ziel dieser Arbeit war es daher, ein System zu entwickeln, das spezifisch die Nerven in PCLS verschiedener Spezies aktiviert, um so die neuronale Funktion und ihre pharmakologische Beeinflussung in Atemwegen zu studieren. Ein Tiermodell des allergischen Asthmas sollte Aufschluss über eine etwaige Veränderung der Nervenfunktion in der Krankheit geben.

Elektrische Feldstimulation (EFS) wird genutzt, um Nervenendigungen in Gewebepreparationen zu aktivieren. In dieser Arbeit wurde die EFS an PCLS bewerkstelligt, indem PCLS zwischen zwei Platinelektroden platziert wurden und seriell elektrische Rechteckimpulse angelegt wurden. Die Bronchokonstriktion nach EFS wurde mit Hilfe der Videomikroskopie verfolgt.

Das Modell der EFS wurde zuerst an PCLS der Ratte entwickelt. Die das elektrische Feld bestimmenden Bedingungen wurden systematisch untersucht und reproduzierbare Atemwegskontraktionen wurden bei einer Frequenz von 50 Hz, einer Reizbreite von 1 ms, einem Strom von 200 mA und einer Seriedauer von 2,5 s gefunden. Die EFS-induzierte Bronchokonstriktion ist neuronal bedingt, da Magnesium die Bronchokonstriktion in der EFS antagonisierte, aber nicht die durch Methacholin hervorgerufene Kontraktion der glatten Muskulatur der Atemwege. Die durch EFS ausgelösten Kontraktionen wurden durch den Acetylcholinesteraseinhibitor Neostigmin verstärkt und waren höchst reproduzierbar, sodass muskarinische Rezeptorantagonisten in aufeinanderfolgenden EFS-Serien untersucht werden konnten. Darin wurde die logarithmische inhibitorische Konzentration des halbmaximalen Effekts ($\log IC_{50}$ M) ermittelt und es zeigte sich, dass Ipratropium (-10.0 ± 0.4) potenter als Atropin (-8.8 ± 0.4) und 4-DAMP (-8.4 ± 0.3) wirkte. In einem anderen Ansatz wurde geprüft, ob Thromboxan die parasymphatisch-cholinerge Bronchokonstriktion begünstigt, indem SQ29548 als Thromboxanprostanoid-Rezeptor-Antagonist eingesetzt wurde. Hierbei konnte jedoch kein Effekt festgestellt werden. In der EFS an PCLS mit unterschiedlicher Atemwegsgröße zeigte sich, dass größere Atemwege reaktiver waren als kleinere.

Als Tiermodell des allergischen Asthmas dienten gegen Ovalbumin sensibilisierte Brown-Norway Ratten. Hämorrhagien in der Lunge und Atemwegskontraktion in PCLS nach Allergenprovokation deuteten auf eine bestehende Entzündung und eine akute allergische Reaktion hin. Allerdings trat Atemwegshyperreaktion weder nach Methacholinzugabe noch nach EFS auf.

Neben der Ratte wurde die neuronale Reaktion in PCLS von Maus, Meerschwein, Schaf, Marmoset und Mensch untersucht, da die Innervation der Atemwegsmuskulatur in verschiedenen Spezies sehr unterschiedlich ausfällt. Periphere Neuronen wurden per EFS oder zusätzlich durch Capsaicin als Stimulanz exzitatorischer nicht-adrenerger nicht-cholinerger (NANC) Nerven aktiviert. Die durch EFS hervorgerufene Bronchokonstriktion variierte zwischen den Spezies im Ausmaß ($(2 \pm 2)\%$ in der Maus bis $(61 \pm 26)\%$ im Meerschwein) und in der Sensitivität (halbmaximale Antwort in der Frequenz-Wirkungskurve: $(0,5 \pm 0,2)$ Hz im Schaf bis (23 ± 7) Hz im Marmoset). Wie bei der Ratte antagonisierte Atropin die EFS induzierte Bronchokonstriktion in PCLS des Meerschweins, Schafs, Marmosets und Menschen. Capsaicin bewirkte eine Bronchokonstriktion nur in humanen PCLS sowie in denen des Meerschweins. Ruthenium Red und SKF96365 sind Inhibitoren an TRP-Kanälen (engl. transient receptor potential channels) und antagonisierten die Atemwegskontraktion im Meerschwein sowohl nach EFS als auch nach Zugabe von Capsaicin. Lediglich Marmoset-Atemwege zeigten eine Relaxation in der EFS an PCLS, die sensitiv gegenüber Propranolol und L-NAME war.

Zusammenfassend konnte gezeigt werden, dass Nervenendigungen in PCLS intakt bleiben. Die entwickelte Methode eignet sich dazu neurogene Mechanismen in Abhängigkeit der Atemwegsgröße zu untersuchen und pharmakologische Beeinflussungen der EFS-induzierten Antwort sind möglich. Die geringere Antwort mit kleineren Atemwegen in der EFS widerspricht der höheren Anfälligkeit kleiner Atemwege nach äußerer Zugabe von Methacholin. Dies deutet jedoch auf eine geschickte Regulation der parasymphatischen Bronchokonstriktion hin: Größere Atemwege scheinen stärker innerviert als Kleine, sind aber dafür weniger anfällig gegenüber Acetylcholin als die Kleinen. Im Rattenmodell des allergischen Asthmas konnte gezeigt werden, dass die cholinerge Antwort unverändert ist. Entsprechend der Ratte weisen die Spezies Meerschwein, Schaf, Marmoset und Mensch alle cholinerge Innervierung auf. Zudem sind distale Atemwege des Meerschweins und Menschen noch exzitatorisch NANC innerviert, wohingegen die Dilation der Atemwege des Marmosets durch adrenerge und inhibitorische NANC Nerven bestimmt ist. Meerschwein PCLS wiesen die größten Gemeinsamkeiten mit humanen PCLS auf, und dürften sich deshalb in Zukunft besonders für klinisch relevante Untersuchungen neuronaler Atemwegsreaktionen eignen.

Lebenslauf

Persönliche Daten

Name: Schlepütz
Vorname: Marco
Geburtstag: 20. Januar 1982
Geburtsort: Simmerath
Staatsangehörigkeit: Deutsch

Qualifikationen

2001 Abitur am Burgau Gymnasium, Stadt Düren
2002 - 2005 Bachelorstudium Biotechnologie / molekulare Biotechnologie an der RWTH Aachen University
2005 – 2007 Masterstudium Biotechnologie / molekulare Biotechnologie an der RWTH Aachen University
Seit 2007 Promotion am Institut für Pharmakologie und Toxikologie des Universitätsklinikums Aachen der RWTH Aachen University
