

1. Introduction

The order Lepidoptera, which comprises more than 160,000 described species of butterflies and moths, is one of the most speciose branches of the tree of life. Its remarkable diversity is accompanied by tremendous variation in chromosome numbers, ranging from 5 to 223 chromosomes in the haploid karyotype [1,2]. However, this variation is not randomly distributed among genera, as most show the presumed ancestral haploid karyotype of $n=31$, while other genera vary widely ([1], Fig. 1). In several genera, increased diversity in chromosome numbers appears associated with bursts in species numbers, suggesting that chromosomal variation may contribute to speciation [1,3-5]. This view is supported by theory, predicting that chromosomal variation can act as an intrinsic barrier to gene flow, either because hybrids between individuals with different chromosome numbers are at least partially sterile, or because chromosomal rearrangements suppress recombination [6,7]. Nevertheless, empirical evidence for the role of varying chromosome numbers in speciation is mixed, in part contrasting the theoretical predictions. Closely related species with different chromosome numbers can often be crossed [8,9] and hybrid fitness may not necessarily be reduced [10,11]. Moreover, evolutionary modes of diversification within genera in relation to varying chromosome numbers may range from neutral [4,12] to adaptive [5] evolution. However, a comprehensive study across Lepidoptera is lacking. With these inconsistencies at hand, we aim to infer the impact of primarily interspecific chromosomal differentiation on reproductive isolation and rates of speciation across genera. We then discuss different potential underlying mechanisms.

Lepidopteran chromosomes are holocentric, i.e. they lack a central centromeric region that concentrates all kinetochores, which allow attachment of the spindle tubules during mitosis and meiosis. Instead, species with holocentric chromosomes evolved mechanisms that allow kinetochore proteins to bind along the entire chromosome, permitting microtubules to attach broadly [reviewed in 13]. Holocentric chromosomes have evolved from monocentric ancestors at least 13 times in groups as diverse as plants and arthropods [13]. In plants, they have been shown to promote species diversification, for instance in sedges (the genus *Carex*,

1
2
3 57 with about 2'000 species among the largest plant genera), by leading to hybrid dysfunction as
4
5 58 a result of the formation of meiotic multivalents [14]. For species with holocentric
6
7 59 chromosomes, changes in chromosome numbers evolve by either fusing two chromosomes
8
9 60 into a single one, or through fission of a chromosome into two smaller chromosomes. As a
10
11 61 consequence of holocentricity, fragmented chromosomes are initially more likely to be
12
13 62 retained since the fragments maintain kinetochore function, which may make it more likely
14
15 63 for chromosomal variation to evolve in the first place [13]. Additionally, in species with
16
17 64 holocentric chromosomes, hybrid incompatibility between closely related species may be
18
19 65 countered by mechanisms that some of the species have evolved in order to avoid meiotic
20
21 66 mistakes. In the wood white butterfly (*Pieris sinapis*), for instance, the order of meiotic
22
23 67 events is inverted, which is presumed to underlie rescued fitness of chromosomal hybrids [10].
24
25
26 68 Thus, while on the one hand holocentric chromosomes may facilitate karyotype evolution in
27
28 69 some lineages, chromosomal numbers are nevertheless often conserved in other lineages,
29
30 70 suggesting additional genomic control mechanisms that suppress fusion and fission.

31
32
33 71 Despite its evolutionary relevance across the tree of life, the molecular features that
34
35 72 underlie fusion and fission of chromosomes in species with holocentric chromosomes are not
36
37 73 resolved, and likely differ between species [15,16]. Among the potential features are
38
39 74 repetitive sequences such as ribosomal DNA, GC rich DNA segments, and transposable
40
41 75 elements, which have been suggested to facilitate chromosomal fusion and fission by creating
42
43 76 artificial centromere-like regions [17]. However, comparative genomic studies are rare and
44
45 77 based on few species [16,18,19], relying often on short-read sequencing technologies that
46
47 78 limit the study of repetitive parts of the genome. While some of these studies suggested a
48
49 79 higher number of retrotransposons than expected by chance at fusion sites [18] others do not
50
51 80 show such an enrichment [16]. Independent of karyotypic changes, rearranged Lepidoptera
52
53 81 genomes show evidence for conserved syntenic blocks that are maintained across even very
54
55 82 distantly related species [16,20,21].
56
57
58 83

1
2
3 84 Chromosomal speciation implies that chromosomal rearrangements cause
4
5 85 reproductive isolation between populations and, therefore, promote speciation [22,23]. Yet,
6
7 86 causal effects of fusion and fission on the rate of speciation remain contentious [7,15]. Classic
8
9 87 chromosomal speciation models were based on hybrid sterility, i.e. where individuals that are
10
11 88 heterozygous for chromosomal rearrangements are partially or completely sterile [7,22].
12
13 89 Under these scenarios, differentially fixed chromosomal rearrangements between closely
14
15 90 related species may in theory themselves quickly generate strong reproductive isolation and
16
17 91 act as Dobzhansky-Muller incompatibilities (DMIs), potentially reinforced upon secondary
18
19 92 contact, where heterozygotes would suffer from reduced fertility [24]. The problem with these
20
21 93 classic models is that they require chromosomal rearrangements to be fixed in order to be of
22
23 94 major effect, yet the conditions under which fixation of novel chromosomal rearrangements is
24
25 95 likely would result in shallow reproductive barriers. Specifically, newly arising chromosomal
26
27 96 rearrangements would typically be underdominant, i.e., they lead to reduced fitness of hybrid
28
29 97 individuals. While strong underdominance makes it unlikely that they spread to fixation,
30
31 98 weak underdominance may allow for fixation, but would ensure that chromosomal
32
33 99 rearrangements represent only shallow barriers, and are therefore unlikely to cause speciation
34
35 100 [7,25]. Empirical evidence for such chromosomal speciation comes from mammals that have
36
37 101 monocentric chromosomes, including mice [26] and wallabies [27]. Here, monobrachial
38
39 102 homology, i.e., multiple chromosomal fusions with one or more common arms in different
40
41 103 fusion arrangements, causes reproductive isolation. Differences in chromosome numbers have
42
43 104 also been suggested to act as DMIs for plants with holocentric chromosomes [14], however,
44
45 105 to which degree this might apply to other systems, including Lepidoptera, is not known
46
47 106 More recent theoretical approaches have attempted to overcome the underdominance
48
49 107 paradox by focusing on the changes in recombination associated with chromosomal
50
51 108 rearrangements [6,7,25,28]. In essence, under these recent models, rearranged chromosomes
52
53 109 can become fixed by drift or selection when two or more adaptive loci become physically
54
55 110 coupled, enhancing existing reproductive isolation by reducing recombination [6,25]. Such
56
57 111 re-arranged regions of reduced recombination may act as barrier loci and promote further
58
59
60

1
2
3 112 differentiation, which may eventually lead to postzygotic isolation through the buildup of
4
5 113 genic DMIs [6,7,25]. By suppressing recombination, chromosomal rearrangements could help
6
7 114 to increase reproductive isolation, which may be further enhanced by sexual selection or
8
9 115 reinforcement [29] and may thus promote speciation upon secondary contact. Also, as a
10
11 116 consequence of chromosomal speciation, the effective population size (N_e) may initially
12
13 117 become reduced, which could in turn affect rates of speciation [30] and change the fixation
14
15 118 probabilities of new karyotypes in allopatry. Indeed, for mammals, families with large
16
17 119 geographic distributions but whose species have restricted geographic ranges showed a
18
19 120 greater probability for fixing different karyotypes [31].

21
22 121 To understand the evolution of varying chromosome numbers and their potential
23
24 122 implications on the speciation process, we reviewed the karyotypic literature on Lepidoptera
25
26 123 and compiled the current knowledge on karyotypic diversity, which has doubled since the last
27
28 124 attempt almost half a century ago [1]. We first assessed if published estimates of reproductive
29
30 125 isolation [32] would differ between closely related species pairs with the same, or different
31
32 126 karyotypes. While karyotypic changes in Lepidoptera evolve through fusion and fission
33
34 127 events rather than genome duplications [33], transposable elements that may underlie such
35
36 128 fission sites could perhaps lead to an increase in genome size [34]. Consequently, we also
37
38 129 tested whether chromosome numbers are correlated with genome size. Combining karyotypic
39
40 130 with genetic data, we finally assessed if the rate of chromosome number evolution is
41
42 131 positively associated with the rate of speciation across the best-covered genera. In the light of
43
44 132 the results, we then discuss the different roles of chromosomal variation in Lepidoptera, with
45
46 133 a focus on the best-studied butterfly genera. Chromosomal variation can also include
47
48 134 karyotypic changes through sex chromosome evolution (reviewed in [35]). Albeit information
49
50 135 on sex chromosome evolution is limited to relatively few taxa [36], the current data suggests
51
52 136 that the Z chromosome is highly conserved in Lepidoptera, while the evolution of neo-W
53
54 137 chromosomes through fusion of autosomes may be common [37]. Although sex chromosomes
55
56 138 also promote speciation [38], our study focuses more broadly on karyotype evolution through
57
58 139 fusion and fission processes.
59
60

1
2
3 1404
5 141 **2. Material and Methods**

6
7 142 The previous comprehensive compilation of chromosome numbers in Lepidoptera
8
9 143 was published by Robinson [1] almost fifty years ago, comprising data for 1183 taxa. After
10
11 144 digitizing this list, we used Google Scholar in July 2019 to search for publications containing
12
13 145 chromosome numbers that were not covered by [1]. Search terms were "[*Lepidoptera* OR
14
15 146 *butterfly* OR *moth*] AND *karyotype*", and "[*Lepidoptera* OR *butterfly* OR *moth*] AND
16
17 147 *chromosome number*". Our search yielded another 30 publications (Table ESM1.1), several of
18
19 148 which are themselves compilations of chromosome numbers from multiple studies, e.g. [18].
20
21 149 We subsequently removed duplicate entries and ambiguous cases where taxa were not fully
22
23 150 identified. The 97 cases in which intraspecific chromosomal variation was reported (e.g.
24
25 151 *Pieris sinapis*; n=28-54 [16]) are included in Table ESM1.1 but excluded from subsequent
26
27 152 karyotype specific analyses, because the karyotype of the individuals for which the associated
28
29 153 data was collected is unknown.

30
31
32 154 Genome size estimates for Lepidoptera were taken from the NCBI Genome Database
33
34 155 (<https://www.ncbi.nlm.nih.gov/genome>) on 15th September 2019. From the 66 sequenced
35
36 156 genomes, 64 had chromosome numbers available in our database (Table ESM1.2). Flow
37
38 157 cytometric estimates of genome sizes were available for another 19 species from the Animal
39
40 158 Genome Size Database 2.0 (www.genomesize.com); all also represented in our database.
41
42 159 Flow cytometric estimates were converted to base pair size using the formula from [39]: DNA
43
44 160 content (pg) = genome size (bp) / (0.978 x 10⁹). We then used a phylogenetic linear model in
45
46 161 R 3.5.1 [40] package *phylolm* v.2.6 [41] with genome size as response variable, chromosome
47
48 162 number as fixed factor and accounting for the method of genome size estimate (sequence or
49
50 163 flow cytometry). Non-independence of species data due to shared ancestry was incorporated
51
52 164 by including a phylogenetic tree of the sampled species computed from mitochondrial *COI*
53
54 165 sequences downloaded from GenBank (Table ESM1.3) and reconstructed using RAxML v.8
55
56 166 [42]. To select an appropriate model for the error term, we fitted all implemented
57
58 167 phylogenetic models that allow for measurement error (i.e., Brownian motion, Ornstein-

1
2
3 168 Uhlenbeck with fixed or random root, kappa, delta, and Early-Burst models [41]). Genome
4
5 169 size was normalized by log-transformation and the best-fitting model was determined based
6
7 170 on AIC values.

9 171 We next tested if published estimates of reproductive isolation [32] differ between
10
11 172 closely related species that share the same number of chromosomes (N=49) or not (N=19;
12
13 173 Table ESM1.4). We used two linear mixed effect models with reproductive isolation (Total
14
15 174 Isolation Index in [32]) as a response variable and the genus as random effect. In one model,
16
17 175 we used as fixed factor a categorical variable, i.e. if chromosome numbers differed or not, and
18
19 176 in the other the actual difference in chromosome numbers. It was not possible to more fully
20
21 177 account for the phylogenetic error structure, because such an analysis requires the inclusion of
22
23 178 a phylogeny with the most recent common ancestor of each species pair. We could not
24
25 179 construct such a phylogeny due to the lack of phylogenetic data for, or resolution among,
26
27 180 many of these closely related species, e.g. [5]. For the same reason, it was not possible to
28
29 181 account for the age (divergence times) of each species pair.

30
31
32 182 To test if varying chromosome numbers have an effect on species diversification rates,
33
34 183 we selected all genera that had enough karyotype data, DNA sequence data, and species
35
36 184 representation to warrant phylogenetic investigation. Because missing species can critically
37
38 185 affect diversification rate analyses [43] and estimated rates of trait evolution [44], we only
39
40 186 included the 16 genera for which we had both karyotype information and DNA sequence data
41
42 187 for more than 25% of the genus (Table ESM1.5), and no generic para- or polyphyly was
43
44 188 indicated (thus genera correspond to clades). This large sampling (representing ca. 1055
45
46 189 species – 371 of which had karyotypes) will thus likely provide insights about the association
47
48 190 of chromosome number evolution and species diversification across Lepidoptera.

49
50
51 191 For each genus, we reconstructed a phylogenetic hypothesis with branch lengths
52
53 192 proportional to divergence times, to be able to compare genera on the same measurement
54
55 193 scale. We employed a Bayesian approach, to take full account of uncertainty in phylogeny
56
57 194 reconstruction and propagate it in downstream analyses. First, we used the pipeline
58
59 195 OneTwoTree [45] to obtain DNA sequence data. This pipeline downloads all sequence data

1
2
3 196 on NCBI GenBank (<https://www.ncbi.nlm.nih.gov/genbank/>) for a set of input taxon names,
4
5 197 clusters the sequences based on OrthoMCL [46] to define groups of homologous sequences,
6
7 198 and aligns these using MAFFT [47]. Thus, the approach guides marker selection objectively,
8
9 199 based on sequence information rather than sequence headers. To run OneTwoTree, we
10
11 200 provided the name of each genus, plus one outgroup taxon based on the global Lepidoptera
12
13 201 phylogeny of [48]. Genbank IDs and details on taxon sampling are provided in Table
14
15 202 ESM1.6. We then groomed alignments after manual inspection by removing loci available for
16
17 203 fewer than 10% of the species, and eliminated sites with > 90% missing data using PhyUtility
18
19 204 [49].

205 Phylogenetic inference was based on a MrBayes v. 3.2.7a [50] analysis for each genus.
206 We employed GTR substitution models and Gamma-distributed rate variation among sites,
207 performing two runs of four metropolis-coupled Markov chains per analysis, using default
208 proposal mechanisms and temperatures. We made sure that runs converged to the target
209 distribution based on the potential scale reduction factors (approaching 1 for all parameters),
210 average standard deviations of split frequencies (being well below 0.1), effective sample sizes
211 (>>200 for each parameter), and by inspecting the traces. The number of MCMC generations
212 required for convergence differed between genera, from 1 to 10 million (Table ESM1.5). We
213 then combined trees from both runs after excluding 25% as burnin, and thinned it uniformly
214 to a sample from the posterior distribution of 100 trees (hereafter, "posterior") per genus using
215 BurnTrees v.0.3.0 (<https://github.com/nylander/Burntrees>). We rooted each tree with the
216 outgroup, and performed divergence time estimation using a relaxed, correlated molecular
217 clock fitted based on penalized likelihood [51], implemented in the *ape* package in R [52].
218 The split between in- and outgroup was dated based on the median ages reported in [48].
219 Subsequently, the outgroup and stem lineage were pruned, yielding a posterior sample of 100
220 dated trees per genus.

221 To test for an association of chromosomal evolution and species diversification rates,
222 we used a Bayesian approach to fit a phylogenetic model (*ChromoSSE*) tailored for
223 chromosome evolution [53], implemented in the statistical software *RevBayes* [54], to each

1
2
3 224 genus. This model jointly describes the evolution of chromosome numbers through fusion and
4
5 225 fission (i.e., a change in chromosome number by -1 or +1, respectively), and the origination
6
7 226 and extinction of phylogenetic lineages (hereafter, species). Chromosome numbers are thus
8
9 227 allowed to evolve along branches (i.e., anagenetic change) or at speciation events (i.e.,
10
11 228 cladogenetic change). Specifically, we fitted three speciation rate parameters: fission-
12
13 229 associated speciation, fusion-associated speciation, and speciation without chromosomal
14
15 230 change; and two parameters for anagenetic chromosomal change: one for fission and one for
16
17 231 fusion. We estimated a single species turnover rate per genus. As such, we did not allow for
18
19 232 dysploidy and polyploidy, because these processes are not documented in Lepidoptera [1,2].
20
21 233 We fitted the model sequentially to each of the 100 trees in the posterior, feeding the final
22
23 234 MCMC sample of one tree as the starting values for the next. After computing a generous
24
25 235 burnin of 300 generations on the first tree, we computed 20 generations per tree. We then
26
27 236 combined MCMC samples across trees, evaluated MCMC performance using Tracer
28
29 237 v.1.7.1[55], and thinned it uniformly to 100 samples per genus. It was computationally not
30
31 238 feasible to fit the *ChromoSSE* model to the data of *Polyommatus*, probably because of its very
32
33 239 large range of chromosome numbers (range 10-223, Fig. 1) that made exponentiation of the
34
35 240 instantaneous rate matrix computationally prohibitive. Therefore, we also employed a
36
37 241 computationally simpler approach where we computed for each genus a single speciation rate
38
39 242 using a Yule model of lineage diversification and a single rate of chromosomal evolution
40
41 243 based on Brownian motion, using the R-packages *diversitree* v.0.9-11 [56] and *phytools*
42
43 244 v.0.6-99 [57], respectively. Even though, at least in principle, chromosome number evolution
44
45 245 is poorly described by a random drift process, the results were overall fully congruent with
46
47 246 the *ChromoSSE* model, irrespective of assumptions on extinction rates, divergence time
48
49 247 uncertainty and error structures. These results are detailed in ESM3.
50
51
52
53

54 248 To attempt to reject the hypothesis that the rate of speciation is not related to the rate of
55
56 249 chromosome number evolution, we performed a phylogenetic linear regression analysis using
57
58 250 the R package *phylolm* [41]. The rate of species diversification was the response variable and
59
60 251 defined as the sum of all estimated speciation rate parameters, while the rate of chromosome

252 evolution was the predictor and constructed as the sum of all fusion and fission rate
253 parameters. After computing species-means, checking assumptions and performing the
254 relevant log-transformations, we determined the best evolutionary model for the error term by
255 fitting all implemented models that account for measurement error (i.e., Brownian motion,
256 Ornstein-Uhlenbeck with fixed or random root, kappa, delta, and Early-Burst models [41])
257 and selected the model with the lowest (best) AIC score. This analysis accounts for the non-
258 independence among observations (i.e., genera) by including the phylogeny of [48] pruned to
259 just represent the phylogenetic relations among the included genera. To also account for
260 phylogenetic uncertainty, we repeated the analysis 100 times by randomly sampling values
261 for each genus from their respective posterior distributions, and checking significance and
262 slope.

264 3. Results

265 Our literature survey identified 2399 lepidopteran taxa for which a chromosome
266 number was reported (Table ESM1.1), about double from the previous comprehensive survey.
267 However, chromosome numbers were only available for 41 of the 124 Lepidoptera families
268 [58] with a strong bias to some groups of butterflies (e.g. almost half of the observations came
269 from two families: *Nymphalidae*, N=869; *Lycaenidae*, N=239). Only 610 (25.4%) taxa with
270 chromosome numbers were moths. The median chromosome number was n=29 (range 5-223)
271 and the most common karyotype was the putatively ancestral chromosome number of n=31
272 (N=630; Fig. 1). The effect of chromosome number on genome size was best described using
273 a OU-model for the error term (AIC = 56.2, irrespective of root assumptions; AIC for other
274 models ranged 59.3 - 61.3), and included a weak ($r^2 = 0.01$) yet significant, positive effect of
275 chromosome number ($t = 3.53$, $p = 0.0006$, Fig. 2), also when including method (sequence or
276 flow cytometry) as an additional factor ($t = 2.91$, $p = 0.045$). In particular species with few
277 chromosomes had smaller genomes. However, the available data covered only a small range
278 of known chromosomal variation (sampled range 12-60, median: 29.5; known range 5-223;
279 Table ESM1.2).

1
2
3 280 In our species-pairs analysis, we could not detect a significant effect of presence of
4
5 281 chromosome number difference on reproductive isolation (Fig. 3). This was independent of
6
7 282 whether the difference was coded as a categorical variable ($\chi^2_1 = 1.05, p = 0.305$), or the
8
9 283 actual differences in chromosome numbers were used ($\chi^2_1 = 0.04, p = 0.836$).

11 284 The groomed sequence matrices contained on average 50 taxa per genus, representing
12
13 285 70% of the species (range 11 to 166 taxa, representing 59% and 90% of the species
14
15 286 respectively) with an average of 8095 bps of sequence data (range 3790-23905 bps; Table
16
17 287 ESM1.5). Dated phylogenies with tip states are provided in ESM2.

20 288 Analyses based on *ChromoSSE* models strongly supported the hypothesis that rates of
21
22 289 speciation and chromosome evolution are related. All rate parameters differed strongly across
23
24 290 the 15 genera for which we could fit the *ChromoSSE* model (Fig. ESM4.1). The posterior
25
26 291 mean net diversification rate (i.e. the difference between speciation and extinction rates) per
27
28 292 genus ranged from 0.047 (*Lycaena*) to 0.305 (*Lysandra*) species per species per million years,
29
30 293 with the species turnover fractions ranging 0.13 (*Erebia*) to 0.98 (*Lysandra*; Fig. ESM4.1).
31
32 294 The relation between total speciation rates and total chromosome evolution rates across
33
34 295 posterior-mean values was strongly positive (Fig. 4; effect size 0.630 ± 0.193 in log-log space,
35
36 296 $t = 3.26, p = 0.006$, using a BM-model for the error term, AIC = 53.5; AIC for other models
37
38 297 ranged 55.3 - 55.5). To further confirm this result, we replaced each species-mean value by a
39
40 298 random draw from the respective posterior distribution and checked significance of the
41
42 299 relation. Repeating this process 100 times yielded a significant, positive relationship in each.

45 300 Comparing the fits of the *ChromoSSE* models across genera yielded further insights
46
47 301 into the role of chromosome evolution in species diversification. Foremost, the overall
48
49 302 importance of chromosomal speciation was underlined by the finding that speciation rates
50
51 303 with chromosomal change exceeded speciation without chromosomal change in 12 of 15
52
53 304 genera (the exceptions being *Colias*, *Heliconius*, and *Papilio*; Fig. ESM4.2). In most genera,
54
55 305 chromosomal change was more frequently anagenetic (along a branch) than cladogenetic (at
56
57 306 speciation; Fig. 4B; ESM4.3). Although the three exceptions *Lysandra*, *Oleria* and
58
59 307 *Pteronymia* (Fig. ESM4.3) were those with also the highest rates of chromosomal change,

1
2
3 308 there was no general association between the absolute rate of chromosomal evolution and the
4
5 309 importance of its cladogenetic component (Fig. 4B). Overall, the absolute importance of the
6
7 310 cladogenetic component of chromosomal change ranged from 3.6% in *Lycaena* to 98% in
8
9 311 *Lysandra*.

11 312 The *ChromoSSE* models also allowed us to infer whether fission or fusion events are
12
13 313 more common and more commonly implicated in speciation. Overall, fission events occurred
14
15 314 at higher rates than fusion events in all but two genera (*Papilio* and *Memphis*; Fig. ESM4.4).
16
17 315 However, the cladogenetic component did not consistently differ between fission and fusion
18
19 316 events, where it was significantly higher for three and seven genera for fission and fusion
20
21 317 events, respectively (Fig. ESM4.5).

22
23
24 318 Our complementary approach, based on Brownian motion for chromosomal evolution
25
26 319 rates and Yule diversification rates allowed to include the chromosomally most diverse genus
27
28 320 *Polyommatus* and yielded fully congruent results, irrespective of how we accounted for
29
30 321 extinction and dating uncertainty (ESM3).

31
32
33 322

34 323 **4. Discussion**

35
36 324 The karyological variation in Lepidoptera has attracted much interest over the past
37
38 325 decades, yet many aspects underlying its incredible diversity remain enigmatic. Lepidoptera
39
40 326 show the highest known range in chromosome numbers among non-polyploid eukaryotes [2].
41
42 327 Among hexapods only hemipterans, that also have holocentric chromosomes, are known to
43
44 328 have up to a hundred chromosomes [59]. In plants, polyploidization often generates
45
46 329 tremendous variation in chromosome numbers [60], but the highest known range that is not
47
48 330 attributed to polyploidization occurs in genera with holocentric chromosomes such as *Carex*
49
50 331 ($n=6-62$, [61]). Performing the most comprehensive literature survey on chromosome
51
52 332 numbers to date, we found that most Lepidoperan species show the putative ancestral
53
54 333 chromosome number of $n=31$, or a number close to this (Fig. 1). This is consistent with the
55
56 334 previous systematic review [1] that covered half as many taxa. However, variation in
57
58 335 chromosome numbers differs strikingly among genera (Fig. 1). Interestingly, while our
59
60

1
2
3 336 analyses based on the *ChromoSSE* model suggests that rates of chromosomal fission are
4
5 337 generally higher than those of chromosomal fusions (Fig. 4C), a reduction in chromosome
6
7 338 numbers from the ancestral number seems to be more common among the extant species (Fig.
8
9 339 1). This could be because fission events are predicted to be more likely to result in deleterious
10
11 340 meiotic products, and may therefore more often be selected against, though this effect is
12
13 341 debated in Lepidoptera [62].

14
15 342 While karyotypic variation has been extensively studied in some Lepidoptera genera
16
17 343 (e.g. [1,3,16]), the macroevolutionary impact of varying chromosome numbers on the
18
19 344 dynamics of clade diversification had not been assessed. By employing a phylogenetic
20
21 345 diversification rate analysis for the best-covered genera, we show that, overall, increased rates
22
23 346 of chromosomal evolution are associated with increased rates of speciation (Fig. 4A). Similar
24
25 347 positive relationships between rates of speciation and karyotypic variation were reported for
26
27 348 *Sceloporus* lizards [63], some plant genera, including *Carex* and *Helianthus* (reviewed in
28
29 349 [64]), and mammals [65].

30
31 350 In principle, it is possible that factors covarying with chromosome number exert
32
33 351 effects on speciation, rather than chromosomal evolution *per se*. Changes in genome size
34
35 352 have been suggested to affect rates of speciation themselves [66], and indeed, we observed
36
37 353 that genome size significantly increases with the number of chromosomes (Fig. 2). It is,
38
39 354 however, unlikely that the effects we ascribe to karyotypic variation (Fig. 4) are primarily
40
41 355 due to genome size differences. This is because the effect of genome size differs among
42
43 356 taxonomic groups, where increased genome size correlates positively with speciation rates in
44
45 357 mammals, the opposite is true for insects including Lepidoptera [66]. For plants the rate of
46
47 358 genome size evolution rather than genome size itself is positively correlated with speciation
48
49 359 [67]. Also, chromosome number is only loosely associated with genome size ($r^2=0.01$; Fig.
50
51 360 2), while the association of chromosome number with speciation rates was tight (Fig. 4). The
52
53 361 paucity of broadly sampled species level phylogenies with associated genome size estimates
54
55 362 for Lepidoptera (Table ESM1.2) precludes testing for associations between genome size and
56
57 363 speciation directly. However, we cannot rule out other unaccounted factors. For example,

364 genetic diversity was previously found to be positively correlated with chromosome numbers
365 rather than genome size in Lepidoptera [68], though this association has to be considered with
366 care, given the small sample size (N=34) and the limited range of chromosome numbers
367 covered (range n: 13-34). Among the factors that could explain some of the variation in
368 genome size that we observed are the genetic features suggested to underlie fusion and fission
369 sites. These include transposable elements and may lead to increased genome size, as has
370 been found in *Pieris* [34]. However, the currently available taxonomic breadth and sample
371 sizes are limited (Table ESM1.2) and comparative studies of the presence and abundance of
372 transposable elements are missing.

373 The reliability of our results also critically depends on the robustness of our analytical
374 approach. The *ChromoSSE* model belongs to a family of state-dependent speciation and
375 extinction models (*SSE*; [69]) that evaluate the effect of a focal character state on the rate of
376 lineage origination and loss. Though widely used, their statistical performance remains
377 debated, and much potentially undesired behaviour has been evaluated, including unbalanced
378 prevalence of the focal character [70], assumptions about its root state [71], and effects of
379 covarying, unevaluated characters [72,73]. The effects of these issues are mixed, i.e. they can
380 lead to inflated Type I [74] or Type II error [70] rates, and partly addressed in more recent
381 implementations (e.g., [73]) and alternatives approaches (e.g. [75]), that themselves have also
382 received criticism. Overall, *SSE* models require careful interpretation and adequate
383 accounting for relevant sources of error [76]. The recently developed *ChromoSSE* has been
384 evaluated under a wide range of simulated conditions [53], that demonstrate its reliability for
385 our study: Although parameter estimates were typically accurate and precise, cladogenetic
386 components of chromosomal change tended to be underestimated relative to anagenetic
387 change [53], making the approach in our context rather conservative. Most importantly, even
388 when as little as 10% of extant species are sampled, the accuracy of *ChromoSSE* model
389 estimates was only marginally compromised [53]. Given that we accounted for various
390 sources of error in a Bayesian framework and only included the most densely-sampled
391 genera, these findings suggest that our estimated parameters are robust. Our implementation

1
2
3 392 of the phylogenetic linear model analysis [41] further accounted for inaccuracy of parameter
4
5 393 estimates for individual clade. Importantly, our result was also robust regarding phylogenetic
6
7 394 uncertainty and different analytical approaches, as the analyses based on the *ChromoSSE*
8
9 395 model (Fig. 4) yielded results fully congruent with those based on Brownian motion, while
10
11 396 accounting for extinction rates and dating uncertainty (ESM3). Our statistically significant
12
13 397 results are therefore unlikely to be artefactual.

14
15
16 398 The contribution of chromosomal speciation to all cladogenetic events differed
17
18 399 among genera (Fig 4B), where the rate of anagenetic chromosomal change, i.e. along
19
20 400 branches, exceeded that of cladogenetic chromosomal changes in nine genera (Fig.
21
22 401 ESM4.3). This suggests that only some fusion and fission events may directly lead to
23
24 402 speciation and that the probability of chromosomal speciation differs considerably among.
25
26 403 The difference between anagenetic and cladogenetic changes could furthermore suggest that
27
28 404 the evolutionary mechanisms underlying the role of chromosomal change in speciation may
29
30 405 differ among genera: For genera where cladogenetic changes predominate, chromosomal
31
32 406 changes may act as Dobzhansky-Muller incompatibilities (DMIs) as has been found in plants
33
34 407 with holocentric chromosomes [14]. Conversely, when chromosomal changes are
35
36 408 predominantly anagenetic, novel chromosomes may suppress recombination, leading
37
38 409 eventually to the buildup of genic DMIs, suggesting indirect, gradual effects of anagenetic
39
40 410 chromosomal change on speciation. These are hypotheses and need thorough investigation
41
42 411 (see section 5).

43
44
45 412 Interestingly, species turnover, measured as the ratio of extinction over speciation
46
47 413 rates, was highest in the genera *Lysandra*, *Oleria*, and *Pteronymia*, (Fig. 4B) that also had
48
49 414 highest rates of chromosomal change, suggesting that new species form frequently through
50
51 415 chromosomal change but may not persist [77]. If selection against new karyotypes is weak,
52
53 416 novel karyotypes may form new species and proliferate before going extinct also reducing
54
55 417 effective population sizes, with suspected effects promoting extinction rate [78]. Conversely,
56
57 418 if selection is stronger, new karyotypes may be selected against immediately without ever
58
59 419 giving rise to new species. While the former scenario is congruent with the pattern in the

1
2
3 420 aforementioned three genera, the latter scenario would result in an apparent
4
5 421 macroevolutionary stasis as seen in the genera with lowest rates of chromosomal change (Fig.
6
7 422 4; see ESM2 for the phylogenetic distribution of chromosome numbers per genus).
8
9 423 Understanding *why* the effect of chromosomal change differs among genera might thus be
10
11 424 achieved by comparing the potentially different selective forces acting on newly arising
12
13 425 karyotypes.

14
15
16 426 Whereas our phylogenetic analyses suggest that increased chromosomal variation is
17
18 427 associated with increased rates of speciation, we did not detect a significant effect of
19
20 428 difference in chromosome number on reproductive isolation between closely related species
21
22 429 pairs (Fig. 3). This observation could reflect that prezygotic barriers may be more likely to
23
24 430 drive reproductive isolation in some genera [3,79]. However, we note that the available
25
26 431 number of estimates for reproductive isolation was limited and that the data were strongly
27
28 432 phylogenetically structured, yet the lack of relevant phylogenetic information precluded a
29
30 433 formal phylogenetic analysis (Table ESM1.4). As a consequence, we could also not account
31
32 434 for differences in reproductive isolation due to different evolutionary ages. In the following,
33
34 435 we discuss the evidence for chromosomal variation driving diversification among the best-
35
36 436 studied genera of Lepidoptera.

37
38
39 437 With a range of 10 to 223 chromosomes in the haploid karyotype, *Polyommatus* is
40
41 438 karyotypically the most diverse known Lepidoptera genus (Fig. 1; [2,3]). Together with its
42
43 439 sister genus *Lysandra*, *Polyommatus* showed the highest speciation rates in our analyses
44
45 440 based on Brownian motion (1.80 sp⁻¹my; ESM3), which is consistent with former genus-
46
47 441 specific inferences [4,80,81]. Species of both genera occur across the Palearctic region and
48
49 442 have diversified recently, i.e. over the last 1-3 million years [4,12,80]. Comparative
50
51 443 phylogenetic analyses suggested that chromosomal variation may gradually accumulate in a
52
53 444 random walk manner, consistent with neutral evolution [12], where the fixation of a particular
54
55 445 karyotype has been suggested to occur through bottleneck events [4]. While hybrids between
56
57 446 *Polyommatus* species with distinct karyotypes can suffer from reduced fertility due to
58
59 447 segregation problems during meiotic division, promoting reproductive barriers [3,81], in

1
2
3 448 some cases hybridization can lead to homoploid hybrid speciation [82], further boosting
4
5 449 species diversification. Karyotypic changes in *Polyommatus* are thought to primarily
6
7 450 accumulate in allopatry and speciation to become complete through reinforcement upon
8
9 451 secondary contact [3]. Closely related *Polyommatus* species indeed exhibit a higher
10
11 452 karyotypic difference in sympatry than closely related allopatric populations where
12
13 453 reinforcement leads to increased phenotypic differentiation in zones of secondary contact
14
15 454 [3,81]. The genomic features underlying fusion and fission sites in both *Polyommatus* and
16
17 455 *Lysandra* are not resolved and genomic data is lacking. Jointly, these data suggest that
18
19 456 chromosomal change likely has an important role in driving speciation in these genera
20
21 457 potentially as intrinsic post-zygotic barrier, however, causality remains to be shown.

22
23
24 458 In contrast to *Polyommatus*, species of the family *Pieridae* often show the putatively
25
26 459 ancestral karyotype of $n = 31$, with comparatively little interspecific karyotypic variation
27
28 460 (Table ESM1.1). Consistent with this observation, we documented both low rates of
29
30 461 chromosomal evolution and low rates of species diversification for the genera *Colias*, *Eurema*
31
32 462 and *Pieris* (Fig. 4). This result is in line with the idea that genera that remained close to the
33
34 463 ancestral chromosome number of 31 diversify at lower rates than those in which
35
36 464 chromosomal change has been substantial. However, while in *Pieridae* karyotypes rarely
37
38 465 differ between species, intraspecific and even intra-population chromosomal variation can
39
40 466 occur, e.g. in wood whites – *Leptidea* [10,83]. *L. sinapis* shows the highest non-ployploid
41
42 467 intraspecific chromosomal variation documented to date in Lepidoptera ($n = 28-54$) [10]. The
43
44 468 polymorphic *Leptidea* karyotypes are thought to result from rapid accumulation of fusion and
45
46 469 fission events, as well as other complex rearrangements, followed by extinction of
47
48 470 intermediate forms [83]. Notably, heterozygotes between chromosomal races of *Leptidea* are
49
50 471 abundant and do not appear to be selected against. The lack of fitness disadvantages of such
51
52 472 chromosomal hybrids may be a result of inverted meiosis, in which the order of the meiotic
53
54 473 steps is switched in order to facilitate the proper segregation of chromosomes [10]. Despite
55
56 474 the lack of hybrid dysfunction, chromosomal rearrangements are still expected to promote the
57
58 475 evolution of reproductive isolation by reducing gene flow and recombination among
59
60

1
2
3 476 chromosomal races of *Leptidea* [84] or through the evolution of novel sex chromosomes [83].
4
5 477 Smaller chromosomal rearrangements may furthermore be abundant within genera that show
6
7 478 little karyotypic variation. For example, in a recent comparative study on *Pieris napi* and *P.*
8
9 479 *rapae*, the genomes of both species were shown to be reorganized into collinear blocks
10
11 480 mainly through translocations, with a minor role for fusion and fission. The rearranged
12
13 481 genomic sections were locally enriched with functional gene clusters, highlighting the
14
15 482 potential selective advantage of chromosomal rearrangements [16]. In the case of *Pieris*,
16
17 483 diversification is mainly driven by an arms race with their *Brassicaceae* host plants, though
18
19 484 the potential role of chromosomal rearrangements for speciation has not been assessed [85].
20
21 485 Our results suggest these effects are rather weak in this genus (Fig. 4).
22
23

24 486 The well-studied radiation of *Heliconius* butterflies has emerged over the last 10-13
25
26 487 million years in the Neotropics, where speciation has been shown to be predominantly driven
27
28 488 by strong natural selection on wing patterns, resulting in different mimicry rings. Interspecific
29
30 489 gene flow and adaptive introgression occurs among distantly related species that have the
31
32 490 same karyotype [20,86], where different co-adapted loci are in some cases maintained by
33
34 491 small-scale chromosomal rearrangements such as inversions [87]. While most *Heliconius*
35
36 492 species have only 21 chromosomes, higher chromosome numbers have evolved at least twice,
37
38 493 i.e. in the *doris* group and more recently in the *sapho* group (Table ESM1.1, [88]). In contrast
39
40 494 to the rest of the radiation, very little is known about these species and none of their genomes
41
42 495 have so far been sequenced (Table ESM1.2). If differences in chromosome numbers restrict
43
44 496 interspecific gene flow, the otherwise abundant adaptive introgression is expected to be
45
46 497 significantly reduced or absent and may thus limit the evolutionary potential in these groups.
47
48 498 While mimicry is similarly prevalent in many other Neotropical butterfly groups, these often
49
50 499 also show karyotypic variation that is thought to have evolved through non-adaptive
51
52 500 processes such as drift or genetic bottlenecks, and which may further reinforce speciation
53
54 501 [89].
55
56

57
58 502 Taken together, the evolution of chromosomal variation may be a significant factor
59
60 503 for speciation, but its effect and magnitude seems to differ among (Fig. 4) and potentially

1
2
3 504 within genera. The latter is indicated by the observation that the strength of reproductive
4
5 505 isolation caused by differences in chromosome numbers can be limited when species have
6
7 506 only recently diverged [10,11]. While some large-scale chromosomal rearrangements may act
8
9 507 as DMIs, suggested by our inferred cases of cladogenetic chromosomal change (ESM 4.3),
10
11 508 changes are more often anagenetic and may suggest that chromosomal rearrangements could,
12
13 509 if at all, promote speciation by suppressing recombination in genomic regions underlying
14
15 510 adaptation [6,7]. Combined with other evolutionary forces such as reinforcement or sexual
16
17 511 selection, they may then lead towards complete reproductive isolation and overall accelerate
18
19 512 speciation as is indicated by our macroevolutionary inferences.
20
21
22
23

24 514 5. Knowledge gaps and future directions

25
26 515 The evolutionary mechanisms that may lead toward the completion of speciation are
27
28 516 still not fully understood [90]. Chromosomal rearrangements resulting in karyotypic variation
29
30 517 have been suggested to promote reproductive isolation, either by promoting hybrid sterility
31
32 518 [7,22,24] or by suppressing recombination promoting the accumulation of reproductive
33
34 519 isolation over time [6,7,25]. Importantly, the theory underlying the aforementioned
35
36 520 predictions was developed for species with monocentric chromosomes. To which degree they
37
38 521 also apply for species with holocentric chromosomes needs further investigation. By
39
40 522 executing 16 parallel case studies of the karyologically best-covered genera, our analyses
41
42 523 suggest that chromosomal variability in Lepidoptera is overall associated with increased rates
43
44 524 of speciation (Fig. 4). The underlying evolutionary mechanisms seem to differ with the timing
45
46 525 of chromosomal change relative to speciation: while they are primarily cladogenetic in some,
47
48 526 they are anagenetic in most genera (Figure ESM 4.3). Further in-depth studies are thus needed
49
50 527 to understand if cladogenetic events represent cases where karyological differences result in
51
52 528 DMIs or if speciation is rapidly completed by other factors such as sexual selection or
53
54 529 reinforcement, with a minor role of chromosomal change. Similarly, genomic investigations
55
56 530 are needed to assess if and to which degree novel chromosomes may suppress recombination
57
58 531 particularly in clades that show primarily anagenetic speciation events such as *Erebia*. Given
59
60

1
2
3 532 that karyotypes were only available for a third of all Lepidoptera families (Table ESM1.1),
4
5 533 further investigations comprising genera from many more families are needed to assess the
6
7 534 generality of our observed pattern across the order of Lepidoptera, ideally including a very
8
9 535 high fraction of extant species sampled for more speciose genera, which would also allow for
10
11 536 accurate extinction rate estimates.

12
13
14 537 As for the evolutionary processes, our understanding of the genomic architecture of
15
16 538 fusion and fission sites is limited. Only few genomes are currently sequenced, with a bias
17
18 539 towards a few model species such as the genus *Heliconius* (Table ESM1.2), where we
19
20 540 document exceptionally low chromosome-associated speciation (Fig. 4). The sequenced
21
22 541 species primarily cover taxonomic groups that show little karyotypic variation, and have
23
24 542 karyotypes that evolved mainly through chromosomal fusions from the putative ancestral
25
26 543 karyotype. The few genomic studies suggest genus-specific mechanisms and genomic
27
28 544 features that could underlie chromosomal rearrangements [16,18,91]. However, the genomic
29
30 545 features underlying increased rates of chromosomal fission, as e.g. seen in *Lysandra* and
31
32 546 *Polyommatus*, are unresolved. Also, it remains unknown whether fusion and fission processes
33
34 547 always involve the same chromosomes, and whether species groups that show conservatism
35
36 548 in terms of chromosome numbers may have degenerated fusion and fission sites, and are thus
37
38 549 genetically constrained [15]. Given that similar genomic architectures are likely to be at play
39
40 550 across very distinct taxonomic groups [14,15,17], resolving the aforementioned issues – by
41
42 551 using e.g. novel long-read sequencing methodologies and a broader taxonomic scope – will
43
44 552 help to resolve the evolution of one of the most speciose taxonomic orders and provide
45
46 553 insights for evolution in species with holocentric chromosomes in general.

3 802 Fig. 1: Distribution of chromosome numbers in *Lepidoptera* based on 2399 taxa (Table
4
5 803 ESM1.1) with boxplots summarizing chromosome numbers for the 16 genera used for the
6
7 804 phylogenetic analysis. The number under each boxplot indicates the available number of taxa
8
9 805 with chromosome counts.

10
11 806
12
13 807 Fig. 2: Weakly positive relationship between genome size and chromosome numbers
14
15 808 (phylogenetic linear model, $t = 3.53$, $p = 0.0006$, $r^2 = 0.01$). Data on genome size is either
16
17 809 based on genome sequences (open circles) or estimates from flow cytometry (filled circles).

18
19
20 810
21
22 811 Fig. 3: Estimates of reproductive isolation (Total Isolation Index from [32]) between closely
23
24 812 related species pairs that either differ in their karyotype or not.

25
26
27 813
28
29 814 Fig. 4. Joint phylogenetic analyses of chromosomal evolution and speciation rates based on
30
31 815 the *ChromoSSE* model across 15 *Lepidoptera* genera. Panel (A): total speciation (the sum of
32
33 816 all speciation rate parameters) is positively associated with total chromosomal variation (the
34
35 817 sum of all chromosomal change parameters - phylogenetic linear model, $t = 3.26$, $p = 0.006$,
36
37 818 black line). Dots indicate posterior mean rates estimated for each genus, with error bars,
38
39 819 extending one standard deviation in either direction. Names of genera for each observation
40
41 820 are indicated. Panel (B): the cladogenetic component of chromosomal change (in % of total
42
43 821 chromosomal evolution) differs strongly among genera, but is not significantly associated
44
45 822 with total chromosomal evolution (phylogenetic linear model, logit-transformation, $t = 1.52$ p
46
47 823 $= 0.150$). Annotation as in (A). Panel (C): Rates of fission exceed rates of fusion (summing
48
49 824 cladogenetic and anagenetic components) in most genera, indicated by their position above
50
51 825 the dashed line that indicates $y=x$. Annotation as in (A).
