## Summary

The two most prevalent, but phylogenetically distant pathogenic *Candida* species, *C. albicans* and *C. glabrata*, normally exist as harmless commensals on mucosal surfaces of most healthy humans. However, under certain circumstances, these species can become opportunistic pathogens causing superficial or systemic candidiasis, of which the latter is associated with high mortality rates.

During systemic infections, *C. albicans* and *C. glabrata* grow in different morphological forms and follow distinct infection strategies, but also show a common pattern of pathogenicity. Both species are able to colonize multiple organs, though face different humoral and cellular defense activities of the host's immune system. These include internalization by innate immune cells, like macrophages. Inside phagosomes of macrophages, fungal cells face a hostile environment with a low pH, containing high levels of reactive oxygen species and antimicrobial substances, but also low nutrient levels.

*C. albicans* and *C. glabrata* cells are efficiently phagocytosed by macrophages, but have evolved different strategies to survive phagocytosis, proliferate within, and escape from these cells. Besides a comprehensive detoxification system against the antimicrobial activities, *C. albicans* and *C. glabrata* cells adapt to nutrient limitations inside the phagosome by adjusting their central metabolic pathways. The prerequisite for essential micronutrients, however, cannot be bypassed as these are often co-factors of important metabolic enzymes. Micronutrients comprise trace metals but also vitamins, like biotin (vitamin H) – a vitamin for which both *Candida* species are auxotrophic. The main aim of this thesis was to gain new insights into the relevance of biotin acquisition of *C. albicans* and *C. glabrata* on fungal proliferation, survival in specific host niches, such as the phagosome of macrophages, and virulence.

The transcription factor gene *VHR1* and its biotin-related target genes were characterized in *C. albicans* and *C. glabrata*. One major finding of this thesis was the identification of the putative biotin transporter gene *VHT1* in both species. Similar to its ortholog in *S. cerevisiae*, *VHT1* of *C. albicans* and *C. glabrata* contributed to biotin-dependent growth. The expression of *VHT1* in both species was shown to be regulated by biotin availability and was modulated by *Vhr1* in a species-specific manner. Expression analyses further suggested that *VHT1* is regulated by yet unknown additional factors besides *Vhr1* and growth assays hinted at the involvement of *VHR1* in other metabolic processes independent of biotin. *In silico* and growth analyses showed that some, but not all, medically important *Candida* species possess an incomplete biotin biosynthesis gene cluster which allows growth on biotin biosynthesis intermediates. This gene cluster was not required for *C. albicans* during interaction with

## Summary

---

macrophages. Instead, biotin pre-starvation of *C. albicans* and *C. glabrata* or the deletion of *VHR1* diminished survival within macrophages. The importance of Vht1-mediated biotin acquisition for intraphagosomal proliferation together with the increased expression of *VHR1*, *VHT1*, and other biotin-related genes in phagocytosed *C. albicans* and *C. glabrata* cells was a fundamental observation in this study. These data suggest that biotin access is limited in phagosomes containing these *Candida* cells. Finally, the Vht1-mediated biotin acquisition was also crucial for efficient colonization of *C. glabrata* and *C. albicans* in distinct organs and for virulence of *C. albicans* during systemic candidiasis. Overall, these results propose that *C. albicans* and *C. glabrata* experience biotin limitation in certain host niches and that Vht1-dependent biotin import represents a mechanism by which fungi can overcome this limitation.

The evolutionary adaptation of pathogenic *Candida* species may have originated from ancient interactions of these fungi with environmental amoebae. In another project of this thesis it was shown that amoeba predation targets fungal copper and redox homeostasis to incapacitate ingested *C. parapsilosis* cells. A peroxiredoxin-mediated redox homeostasis system depending on the gene *PRX1* was shown to be essential for survival of *C. parapsilosis* in this alternative phagocyte model and to withstand killing by macrophages. Since *PRX1* is conserved among different pathogenic *Candida* species it can be concluded that peroxiredoxins are part of a basic survival package to resist phagocytic attacks.

Taken together, these data showed the importance of micronutrient and redox homeostasis as counterstrategies of different pathogenic *Candida* species to survive phagocytosis and pivotal virulence determinants. Future studies to elucidate fungal pathogenicity mechanisms will benefit from sophisticated gene manipulation approaches in *Candida* species, in particular non-*albicans* species. New gene reintegration, overexpression and complementation, and RNA-mediated gene knock-down protocols established in this thesis will contribute to future analyses of gene functions in *C. glabrata*.

## Zusammenfassung

Die häufigsten, aber phylogenetisch voneinander separaten, *Candida* Spezies *C. albicans* und *C. glabrata* existieren als harmlose Kommensale auf Schleimhäuten von vielen gesunden Menschen. Unter bestimmten Umständen können beide Spezies allerdings opportunistische Infektionen verursachen, die sich entweder oberflächlich oder systemisch manifestieren, wobei letztere durch hohe Mortalitätsraten gekennzeichnet sind. *C. albicans* und *C. glabrata* unterscheiden sich während einer systemischen Blutstrominfektion in ihren morphologischen Wachstumsformen und Infektionsstrategien, folgen aber einem ähnlichen Pathogenitätsmuster. Beide *Candida* Spezies können verschiedene Organe kolonisieren, werden aber mit verschiedenen Verteidigungslinien des humoralen und zellulären Immunsystems konfrontiert. Diese beinhalteten die Aufnahme durch Immunzellen der angeborenen Immunität, wie beispielsweise durch Makrophagen. Pilzzellen finden im Phagosom von Makrophagen eine feindliche Umgebung vor, die durch einen niedrigen pH, hohe Konzentrationen an reaktiven Sauerstoffspezies und antimikrobiellen Substanzen, aber auch durch eine niedrige Nährstoffverfügbarkeit charakterisiert ist.

*C. albicans* und *C. glabrata* Zellen werden erfolgreich durch Makrophagen phagozytiert, haben jedoch Mechanismen entwickelt die Phagozytose zu überleben, intrazellulär zu proliferieren und aus Makrophagen auszubrechen. Neben den ausgeprägten Systemen zur Detoxifizierung der antimikrobiellen Aktivitäten im Phagosom können sich *C. albicans* und *C. glabrata* durch die Umstrukturierung von zentralen metabolischen Strömen an die Nährstofflimitierung in diesem Kompartiment anpassen. Die Anforderung an essentielle Mikronährstoffe kann allerdings nicht umgangen werden, da diese oftmals Kofaktoren von wichtigen metabolischen Enzymen sind. Zur Gruppe der Mikronährstoffe gehören neben Spurenelementen auch Vitamine, wie beispielsweise Biotin (Vitamin H), für das beide *Candida* Spezies auxotroph sind. Der Fokus dieser Arbeit lag darin, neue Erkenntnisse über die Biotinaufnahme von *C. albicans* und *C. glabrata* zu erlangen und dessen Relevanz für das Wachstum, das Überleben in bestimmten Wirtsnischen, wie beispielsweise einem Phagosom von Makrophagen, und die Virulenz zu bestimmen.

Das Gen des Transkriptionsfaktors *VHR1* sowie dessen Biotin-assoziierten Zielgene wurden in *C. albicans* und *C. glabrata* charakterisiert. Ein wichtiger Fund dieser Arbeit war die Identifizierung des putativen Biotintransportergens *VHT1* in beiden *Candida* Spezies. *VHT1* von *C. albicans* und *C. glabrata* förderte das Biotin-abhängigen Wachstum, vergleichbar mit der Funktion des Orthologs in *S. cerevisiae*. Es konnte verdeutlicht werden, dass die Expression von *VHT1* durch die Verfügbarkeit von Biotin reguliert und durch *Vhr1* Spezies-spezifisch moduliert wird. Expressions- und

## Zusammenfassung

---

Wachstumsanalysen legten zusätzlich nahe, dass *VHT1* außer durch *Vhr1* von anderen bis jetzt unbekanntem Faktoren reguliert wird. Darüber hinaus scheint *Vhr1* an anderen Biotin-unabhängigen Stoffwechselprozessen beteiligt zu sein. Das Vorhandensein von unvollständigen Biotinsynthese Genclustern konnte über *in silico* und Wachstumsanalysen in einigen medizinisch-relevanten *Candida* Spezies gezeigt werden. Ein solches Gencluster ermöglicht das Wachstum mit Biotinvorstufen, war jedoch nicht relevant für die Interaktion von *C. albicans* mit Makrophagen. Stattdessen verminderte das Aushungern von *C. albicans* und *C. glabrata* für Biotin oder die Inaktivierung von *VHR1* das Überleben in Makrophagen. Eine wesentliche Beobachtung in dieser Arbeit war die Bedeutsamkeit der *Vht1*-vermittelten Biotinaufnahme auf die intraphagosomale Proliferation sowie die erhöhte Expression von *VHR1*, *VHT1* und anderen Biotin-assoziierten Genen in *C. glabrata* und *C. albicans* Zellen nach dessen Phagozytose. Diese Daten suggerieren eine verminderte Biotinverfügbarkeit in Phagosomen, welche *Candida* Zellen enthalten. Schließlich war der *Vht1*-vermittelte Biotintransport auch essentiell für die erfolgreiche Kolonisierung von bestimmten Organen in Mäusen durch *C. glabrata* und *C. albicans* sowie die Virulenz von *C. albicans* bei systemischen Mausinfektionen. Insgesamt deuten die Ergebnisse darauf hin, dass *C. albicans* und *C. glabrata* in bestimmten Wirtsnischen Biotinmangel ausgesetzt sind, welcher durch die *Vht1*-abhängige Biotinaufnahme überwunden werden kann.

Die evolutionäre Anpassung von pathogenen *Candida* Spezies könnte ihren Ursprung in einer Interaktion zwischen Pilzen und in der Umwelt vorkommenden Amöben haben. In einem weiteren Projekt dieser Arbeit konnte gezeigt werden, dass die Kupfer- und Redoxhomöostase von Pilzzellen durch die Prädation von Amöben angegriffen wird, um aufgenommene *C. parapsilosis* Zellen abzutöten. Das Peroxidoxin-vermittelte System der Redoxhomöostase ist abhängig von dem *PRX1* Gen und notwendig für das Überleben von *C. parapsilosis* in diesem alternativen Phagozytenmodell, sowie in Makrophagen. Da *PRX1* in verschiedenen *Candida* Spezies konserviert ist, kann geschlossen werden, dass Peroxiredoxine ein Teil eines grundlegenden Überlebensprogramms gegenüber Angriffen durch Phagozyten sind.

Zusammenfassend konnten die Daten dieser Arbeit die Bedeutung der Mikronährstoff- und Redoxhomöostase als Gegenstrategie von pathogenen *Candida* Spezies zum Überleben in Phagozyten, sowie als wichtige Virulenzdeterminanten zeigen. Zukünftige Studien zur Aufklärung von pilzlichen Pathogenitätsmechanismen werden von weiter entwickelten Genmanipulationsansätzen in *Candida* Spezies und insbesondere in nicht-*albicans* Spezies profitieren. Die in dieser Arbeit neu entwickelten Methoden zur Genintegration, -Überexpression und -Komplementierung, sowie zu einem RNA-

vermittelten Gen-Knockdown Protokoll, werden zu zukünftigen funktionalen Genanalysen in *C. glabrata* beitragen.

# 1 Introduction

## 1.1 *Candida* spp. infections

*Candida* species are the second most common agents causing invasive fungal infections worldwide and belong to the fourth leading cause of nosocomial infections [1]. In contrast to most other fungal pathogens, *Candida* species exist as human commensals and belong to the normal microbiota of 30-70% of the human population [2], while they are rarely found in soil, insects, and on fruits or plants [3]. Under certain circumstances, some *Candida* species can become opportunistic pathogens causing candidiasis. This encompasses superficial infections, either of the skin (cutaneous candidiasis) or mucosal surfaces (oropharyngeal, esophageal, vulvovaginal candidiasis) and systemic bloodstream infections leading to invasive candidiasis (IC) of internal organs. The latter are associated with high mortality rates ranging from 15 to 75% dependent on different patient groups and *Candida* species [1, 4-6], and each episode of IC costs approximately \$ 40,000 per patient [7, 8]. The highest mortality rates among the most common four *Candida* species are documented for infection with *C. albicans*, *C. tropicalis*, and *C. glabrata* and the lowest mortality rates are caused by *C. parapsilosis* [9-11].

Predisposing risk factors leading to mucosal or systemic candidiasis vary significantly. The development of disseminated candidiasis occurs under common iatrogenic and/or nosocomial conditions, prolonged hospitalization, parenteral nutrition, breakdown of anatomical barriers by surgery, vascular catheter insertion, anticancer chemotherapy, and broad-spectrum antibacterial therapies and require the colonization with *Candida* cells [12-14]. Other risk factors that predominantly predispose to mucosal candidiasis are an immunosuppressive status, for example caused by chemotherapy (neutropenia, corticosteroids), infection with HIV, metabolic dysfunction (diabetes), impaired salivary gland function, dentures or pregnancy [15, 16]. An early diagnosis of invasive *Candida* infections is essential for a timely initiation of antifungal therapy [17]. Unfortunately, the lack of highly sensitive and specific diagnosis tools and the limited number of available antifungal agents (which cause few side effects) contribute to the high mortality rates of systemic candidiasis [18]. The understanding of pathogenicity mechanisms is therefore critical as a basis for the development of new diagnosis tools or antifungal therapies [19].

### 1.2 *Candida* genetics, phylogeny and pathogenicity mechanisms

The genus *Candida* is member of the subphylum Saccharomycotina (phylum ascomycota) [20] and currently consists of about 150 species [21, 22]. However, only fifteen species were so far isolated from patients and the majority of *Candida* infections (> 90%) are caused by *C. albicans*, *C. glabrata*, *C. tropicalis*, *C. parapsilosis* and a few other species [4, 23] (**Table 1**). Medically important *Candida* species are different in their frequency of isolation, the morphology and the ploidy (**Table 1**).

**Table 1: Characteristics of clinically important *Candida* species** (adapted from [24]).

species	frequency range	morphologies	ploidy
<i>C. albicans</i>	49 – 68%	yeast, pseudohyphae, hyphae	diploid
<i>C. glabrata</i>	7 – 21%	yeast, pseudohyphae <sup>1</sup>	haploid
<i>C. tropicalis</i>	5 – 13%	yeast, pseudohyphae, hyphae	diploid
<i>C. parapsilosis</i>	4 – 14%	yeast, pseudohyphae	diploid
<i>C. krusei</i>	1 – 4%	yeast, pseudohyphae	diploid
<i>C. guilliermondii</i>	0.1 – 2%	yeast, pseudohyphae	haploid
<i>C. lusitaniae</i>	0.5 – 0.6%	yeast, pseudohyphae	haploid
<i>C. dubliniensis</i>	0.1 – 0.2%	yeast, pseudohyphae, hyphae	diploid
<i>C. auris</i>	few outbreaks reported [25]	yeast, pseudohyphae <sup>2</sup>	haploid

<sup>1</sup> pseudohyphae rarely described [26]

<sup>2</sup> pseudohyphae found in some isolates and under certain conditions [27]

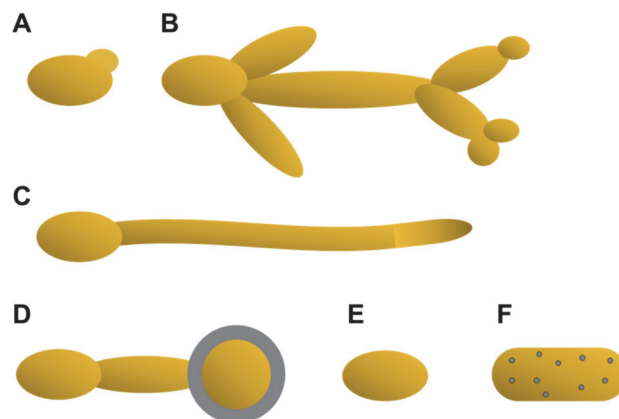

**Figure 1: Phylogeny of *Candida* species.** Important pathogenic *Candida* species belong to either the Saccharomycetaceae or the CUG clade. A common ancestor of *C. glabrata* and the baker's yeast *S. cerevisiae* underwent the whole genome duplication (WGD). The figure is adapted from [24].

*Candida* species belong to different clades. The CUG clade contains organisms that translate the triplet codon CUG as serine instead of leucine, including *C. albicans* and *C. parapsilosis* [28]. A second major clade (Saccharomycetaceae) contains species whose genomes have undergone whole genome duplication (WGD) and in which the CUG codon encodes leucine (**Figure 1**) [29], including *C. glabrata*. Furthermore, *Candida* species differ in their ploidy (**Table 1**), independent from the CUG and WGD clades, and the ploidy can be different in different clinical isolates [30].

### 1.2.1 *Candida albicans*

*C. albicans* has a diploid genome with 6198 ORFs (haploid total) [31] and is the most prevalent (**Table 1**) and best-investigated *Candida* species. The transition between yeast and hypha (**Figure 2**) in response to changing environmental conditions represent an important virulence factor of *C. albicans* [32], and mutant strains of *C. albicans*, either locked in the yeast or hypha morphology, are attenuated in virulence [33]. Moreover, other morphologies, including pseudohyphae [34] and chlamydo spores [35] contribute to a high morphological flexibility of *C. albicans*. Furthermore, *C. albicans* can undergo phenotypic switching (white-to-opaque switching with is associated with different characteristic [36]) and mating [37].

**Figure 2: Common morphotypes of *Candida albicans*.** During certain environmental circumstances *C. albicans* can grow as (A) yeast, (B) pseudohypha (elongated non-separated yeast cells) or (C) true hypha (divided by septa), and can develop (D) chlamydo spores, characterized by a thick cell wall (gray) [38]. *C. albicans* can undergo the transition into an (D) white or (E) opaque phenotype.

The hyphal form of *C. albicans* has increased adhesion, invasion, and host tissue damage potential during interaction with epithelial cells due to the expression of hypha-associated factors like adhesins (Hwp1 [39] and Als3 [40]), invasins (Als3 [40, 41] and Ssa1 [42]), the peptide toxin candidalysin [43], and secretory aspartic proteases (Saps) [44]. The yeast form is believed to be important for spreading and disseminating during

## Introduction

---

systemic infection [45] and promoting colonization and persistence on mucosal surfaces [46, 47]. Interestingly, commensal and infecting *C. albicans* are genetically similar or identical [48, 49] and it is believed that the gut represents a main reservoir of systemic *C. albicans* infections [50, 51].

### **1.2.2 Non-*albicans* *Candida* species**

The prevalence of infections with non-*albicans* *Candida* species (NAC) species increased in the last decades, and NAC account now for 35-65% of all systemic candidiasis cases with geographic and patient group variations [9, 22, 52, 53]. *C. glabrata* represents the most common NAC species in many studies (**Table 1**) and is frequently isolated in North America, whereas *C. tropicalis* is more frequently found in Asia-Pacific and *C. parapsilosis* is three times more often found in America than in Europe [52]. Recently, *C. auris* emerged in different countries all over the world, a species that can cause severe illness of hospitalized patients [54, 55] and is often multidrug-resistant [56].

#### **1.2.2.1 *Candida glabrata***

*C. glabrata* has a haploid genome with 5293 ORFs and was described as strict asexual yeast [31]. It is mainly found in the yeast form, does not form true hyphae and only infrequently forms pseudohyphae [26]. This yeast is phylogenetically more related to the baker's yeast *Saccharomyces cerevisiae* than to other *Candida* species (**Figure 1**) [57]. Surprisingly, not only the genetic machinery for phenotypic switching [58], but also the potential for sexual recombination has been identified [59]. Therefore, it seems that *C. glabrata* can potentially mate [60], and it has been suggested that mating probably occurs at sites of infection [61]. *C. glabrata* is found as a commensal among the microbiota of warm-blooded animals and frequently colonizes the oral cavity, with increased colonization rates in elderly individuals and diabetic patients [62, 63]. Possibly because of that, systemic *C. glabrata* infections are commonly found in these individuals [64, 65].

*C. glabrata* is, compared to *C. albicans*, less virulent in mouse models of systemic candidiasis without causing mortality in immunocompetent mice [66-68]. However, *C. glabrata* can adhere to human epithelial cells dependent on fungal GPI-anchored cell wall adhesins (Epa, epithelial adhesin), mainly Epa1, Epa6, and Epa7 [69, 70]. *C. glabrata* lacks any secreted proteolytic activity [71], but the genome contains eleven genes encoding for extracellular GPI-anchored aspartic proteases (*CgYPS1-11*) [72], regulating cell wall remodeling, biofilm formation, and cellular homeostasis, which in turn can influence the interaction with host cells [72-75]. *C. glabrata* possesses a

relative high level of intrinsic fluconazole resistance and rapidly develops further resistance potential after fluconazole prophylaxis by different mechanisms, which likely contributes significantly to the high frequency of *C. glabrata* infections [76-78]. *C. glabrata* is, in contrast to other pathogenic *Candida* species, auxotrophic for niacin, pyridoxine, thiamine and cannot catabolize galactose and allantoin [79, 80].

#### **1.2.2.2 *Candida parapsilosis***

*C. parapsilosis* has a diploid genome with 5837 ORFs (haploid total) [31] and grows as yeast or pseudohyphae, but in contrast to *C. albicans*, it cannot form true hyphae [81, 82]. *C. parapsilosis* is part of the healthy microbiota of skin and nails [83], however, the yeast is also found in diverse environmental sources and insects [82, 84-86]. The presence of *C. parapsilosis* on the skin of health care personnel and the frequent isolation from medical devices (catheters and surfaces) are potential iatrogenic factors leading to nosocomial infection with this fungus. Therefore, it is not surprising that *C. parapsilosis* is an emerging pathogen of invasive infections in neonates, which are caused by direct transmission through health care workers, catheterization or inoculation [87-89]. Contrary to *C. albicans*-caused disseminated infections, the majority of *C. parapsilosis* infections are due to exogenous sources [90, 91]. *C. parapsilosis* displays, compared to *C. albicans*, a lower virulence, probably due to the lack of true hypha formation [21], and is less virulent in mouse models [92]. The adhesion to medial plastic devices and catheters, and the subsequent formation of a tenacious and carbohydrate-rich biofilm is an important virulence factor of *C. parapsilosis* [93, 94]. In addition to that, secreted aspartic proteases and lipases contribute to its virulence [95-98].

### **1.3 Genetic tools to investigate pathogenicity mechanisms of *Candida* spp.**

The genomes of all medically important *Candida* species are now sequenced and publically available *via* the *Candida* Genome Database (CGD) [31]. Over the last three decades, researchers developed several genetic manipulation techniques to elucidate the function of *C. albicans* genes, especially of those required for pathogenicity of *C. albicans* (summarized in [99]). The most frequently used strategy is the classical gene disruption method, using different nutritional or drug-resistant selection marker genes [100-102] and based on homologous recombination. Other techniques were developed to study the role of essential genes by using conditional knock-outs [103] or to epitope-tag proteins [104]. These new techniques permit a more dynamic view about the importance and function of certain genes (during infection). Pleiotropic effects of

## Introduction

---

ectopically expressed selection marker genes can have an impact on the pathogenicity and virulence potential of *C. albicans* [105-107]. Therefore, researchers are encouraged to reintroduce the gene into the mutated organism (which lack this gene), fulfilling molecular Koch's postulates [108]. The *SAT1* flipper and Clp10-based protocols were established to recycle drug-resistant marker genes in clinical isolates, and to standardize the localization of genomic reintegration, respectively [109, 110]. Some of these techniques were also transferable to other *Candida* species, like the replacement of genes by nutritional and drug-resistant marker genes. However, noncanonical translation of CUG codons of classically used markers [111], the decreased homologous recombination efficiency [112-114], and the haploid genome architecture in *C. glabrata* reduced the transferability.

### **1.4 Immunology of *Candida* spp. infections**

Mammals are equipped with a complex innate and adaptive immune system consisting of humoral and cellular components to fight against invading microbes [115]. The innate immune system is an ancient part of the host defense mechanism and responds very fast and efficient [116]. If natural barriers are surmounted by *Candida* cells and these cells reach the bloodstream, they can colonize multiple organs. The complement cascade represents the first line of innate immune response to coordinate further cellular responses of the innate and adaptive immune system [117]. *C. albicans* induces the complement system followed by a pro-inflammatory response [118-120], which decreases the susceptibility for systemic candidiasis [121, 122]. As a part of an invading *C. albicans* population survives within a complement-competent host, it is not surprising that this fungus evolved specific mechanisms to evade the complement system by direct binding of inhibitory proteins, proteolytic degradation or invasion into host cells [123, 124]. A second wave of host activities towards invading *Candida* cells is facilitated by the innate immune cell population involved in phagocytosis, fungal killing and induction of pro-inflammatory responses, mainly encompassing macrophages, neutrophils, and monocytes (only in the blood) [125, 126]. An activated innate immune response is important for coping with invading *Candida* cells, but is also required for subsequent stimulation of the cellular adaptive immune response, needed to sufficiently eradicate the fungus [127]. Especially, a protective T-cell response (Th1 and Th17), mediated by dendritic cells (DCs)[128], decreases the susceptibility to systemic candidiasis [129].

The outer structure of the fungal cell, the cell wall, exposes different pathogen-associated molecular patterns (PAMPs) - absent in mammalian cells - which can be recognized by the host innate immune system [130, 131]. The cell wall consists of an

outer O- and N-linked mannose polymer (mannan layer), followed by an inner three-dimensional network of microfibrils consisting of covalently bound  $\beta$ -glucan and chitin [132]. Host immune cells detect fungal PAMPs by pattern recognition receptors (PRRs), consisting of Toll-like receptors (TLRs), C-type lectins (CLRs), Nucleotide-binding oligomerization domain (NOD)-like receptors (NLRs), and retinoic-acid-inducible gene I (RIGI)-like receptors (RLRs) [133, 134]. These receptor families are differently expressed in innate immune cells and recognize different fungal PAMPs, either extracellularly on the plasma membrane or intracellularly in endosomes or the cytoplasm [126, 134]. Each fungal pathogen possesses species-specific differences in their recognition and cytokine response, probably due to slightly different cell wall structures [131].

The process of phagocytosis by specialized cells, called phagocytes, was discovered by Ilya Mechnikov and awarded with the Nobel prize in 1908 [135]. He observed that leucocytes can migrate towards infectious agents, can take them up and digest them intracellularly [136]. Today, we know that phagocytes can migrate towards the pathogen and use the dynamic and proceeded receptor-mediated process, named phagocytosis to engulf the pathogen in membrane-enclosed compartments, termed phagosomes [137, 138]. Subsequently, the phagosome matures by different fusion events with other intracellular compartments (endosomes and lysosomes), creating a hostile environment for microbes. Their highly microbicidal activity is attributed to the acidification of the phagosomal lumen, the production of reactive oxygen (ROS) and nitrogen species (RNS) and the release of antimicrobial peptides (mostly cationic antimicrobial peptides) and lysosomal acidic hydrolases (summarized in [139, 140]).

#### **1.4.1 Surveillance by neutrophilic granulocytes**

Neutrophilic granulocytes (short: neutrophils or polymorphonuclear leukocytes (PMNs)) are important innate immune cells and play a pivotal role in elimination of invading pathogens [141]. They are produced in the bone marrow and are released into the bloodstream for constant patrolling [142].

Neutropenia is a major risk factor for systemic candidiasis, associated with a poor prognosis [143-145]. Neutrophils are essential to control *C. albicans* cells infecting the liver, spleen and kidney during invasive candidiasis [143, 146, 147], as well as mucosal tissues [148, 149], and are the most potent leukocytes that can inhibit the yeast to hypha transition [150]. The fast neutrophil recruitment into *C. albicans*-infected organs such as the liver and the spleen lead to fungal clearance, whereas the late neutrophil infiltration in kidneys is linked to immunopathology [147]. Neutrophils use phagocytosis, degranulation and NETosis (Neutrophil extracellular traps) as main killing strategies

## Introduction

---

[151, 152]. Further on, the NADPH-oxidase and myeloperoxidase (MPO)-dependent killing is essential for fungal control [153-156] and the inhibition of NADPH-oxidase decreases the fungicidal activity against *C. albicans* [157, 158]. *Candida* cells, phagocytosed by neutrophils, react towards these oxidative stresses with a transcriptional activation of stress-responsive genes [159-161].

### **1.4.2 Surveillance by mononuclear phagocytes**

Mononuclear phagocytes are a heterogeneous subset of leukocytes that mature in the bone marrow and comprise monocytes, monocyte-derived macrophages (MDMs), tissue-resident macrophages, and DCs with cell type-specific characteristics [162-164]. Circulating monocytes represent 2% to 8% of the whole blood count (WBC) count in humans and app. 1% to 2% in mice [165]. They can differentiate into MDMs and DCs, determined by the inflammatory milieu and location, to contribute directly to immune defense against microbial pathogens, inflammation, and adaptive immune response [163, 164, 166, 167]. Tissue-resident macrophages are essential for maintaining homeostasis in all organs by clearance of apoptotic cells. They differ from monocyte-derived phagocytes as they are still able in self-renewing [163, 168], except macrophages of the intestine, dermis, pancreas and heart [167].

The role of mononuclear phagocytes during disseminated candidiasis is, compared to neutrophils, less investigated and originated mostly from *in vivo* studies. First studies revealed a controversial role of mononuclear phagocytes during systemic candidiasis. While splenic macrophage elimination *in vivo* decreased clearance of *C. albicans* from the bloodstream and increased mortality [169], monocytopenia alone did not increase the susceptibility to systemic candidiasis [170]. Recent studies, however, showed an expansion of inflammatory monocytes in the blood and all organs, and the disrupted trafficking of these cells into the kidneys worsened fungal clearance and survival outcome [147, 171]. Recently, it was shown that the protective effect of inflammatory monocytes is dependent on phagocytosis of *C. albicans* and further activation of other immune cells [172, 173]. Also, macrophages accumulate during systemic candidiasis in spleen and liver [147] and tissue-resident macrophages in the liver, called Kupffer cells, are involved in limiting fungal dissemination [174].

In addition to studies based on animal models, isolated immune cells and environmental phagocytic organisms (like amoebae) are used to investigate the interaction with *Candida* cells. These *in vitro* models help to identify host factors which mediate fungal killing, and fungal factors which promote resistance against antimicrobial activities. Therefore, different host cell models, like immortalized cell lines

[33, 175, 176] or primary monocytes and macrophages [177, 178] as well as predatory amoebae [179, 180] have been used.

## **1.5 Survival and immune evasion strategies of *Candida* cells towards mononuclear phagocytes**

The resistance against the host immune system is a striking feature of pathogens, that can help establishing and maintaining infections in a susceptible host. Cells of all *Candida* species are efficiently phagocytosed by macrophages, exemplary shown for *Candida* species of the CUG clade [181], but have evolved different strategies to prevent detection or prohibit intracellular killing by these phagocytes.

### **1.5.1 Evading immune recognition**

The recognition of invading pathogens is essential for generating a protective antimicrobial response. Fungal pathogens have evolved sophisticated strategies to avoid the recognition of highly immunogenic cell wall components like  $\beta$ -glucan by the host immune system [182]. For example, shielding of  $\beta$ -1,3-glucan on the cell wall surface of *Candida* spp. by highly mannosylated glycoproteins promotes escape from immune cell recognition [131, 183, 184]. Several environmental and host-derived signals or drug treatment can dynamically influence the exposure of  $\beta$ -1,3-glucan and, indeed, a differential exposure modulates immune recognition and pro-inflammatory response [185-190]. Besides shielding PAMPs, hiding in non-immune cells can serve as an immune evasion strategy. *C. parapsilosis* can be internalized by and replicate within endothelial cells thereby preventing killing by immune cells [191].

### **1.5.2 Modulating immune cell function**

The recognition of fungal cell wall components is associated with immune cell activation coupled to downstream processes like phagocytosis and cytokine response [192]. Not surprisingly, alterations in fungal recognition or masking of immunogenic components and *Candida* species-specific surface properties influence these immune cell functions. Furthermore, *Candida* cells can interfere with immune cells causing dampening of their antifungal activities or the modulating of one immune cell type, which then diminished the antifungal response of a second immune cell [182]. One interesting example is *C. glabrata*, which hardly elicits any pro-inflammatory responses in macrophages [178, 193]. *Ex vivo* whole blood models and isolated immune cells studies showed that *C. glabrata* attracts monocytes or associates more with these cells compared to other medically relevant *Candida* spp. and that *C. glabrata* increases phagocytosis by monocytes to prevent engulfment by neutrophils [Kaemmer *et al.*,

## Introduction

---

unpublished data]. Additionally, *C. glabrata* activates neutrophils differently compared to *C. albicans*, and *C. glabrata*-infected neutrophils secrete less chemokines and cytokines, which are known to recruit further PMNs [194]. These *ex vivo* studies confirmed the situation observed during systemic infection and *vice versa*. *In vivo*, *C. glabrata* cells are mostly associated with mononuclear cells in murine organs and cause almost no infiltration of neutrophils [68]. In stark contrast, a predominant association with neutrophils in a whole blood model and a massive neutrophil infiltration during systemic infections are characteristic for *C. albicans* [147, 195, 196], which is mostly caused by candidalysin [197].

Pathogenic *Candida* species are also able to modulate immune cell function directly. Increased chitin exposure of *C. albicans* induces the expression of the host arginase and modulates macrophage polarization with impact on fungal killing [198]. Prostaglandin production of *C. parapsilosis* increases the fungal survival and diminishes pro-inflammatory cytokine secretion influencing fungal persistence *in vivo* [199, 200]. Interestingly, *C. albicans* is also known as producer of immunomodulatory prostaglandins in presence of arachidonic acid [201].

### 1.5.3 Escaping from or persisting in the phagosome

Successful pathogens either escape early from hostile phagosomes or stay in and adapt to the phagosomal niche and may escape later. Microbial escape strategies are myriad and widely described for bacterial intracellular pathogens [202-204]. Sooner or later, all facultative intracellular microbes have to exit from the phagosome to disseminate or transmit in the host. Fungal pathogens have evolved different strategies to escape from the phagosome. A non-lytic expulsion from macrophages, as described for *Cryptococcus (Cr.) neoformans* [205, 206], is rarely observed in *C. albicans* [207] and *C. parapsilosis* [208]. *C. glabrata* can replicate or persist in macrophages, probably due the protective shielding from detection, missing filamentation, immune cell activation, and elimination [68, 75, 178, 209]. An increase in fungal biomass by intracellular proliferation of *C. glabrata* yeast cells and of *C. parapsilosis* pseudohyphal cells can finally lead to bursting of the infected macrophage and the release of fungal cells [178, 208].

*C. albicans* proliferates inside phagosomes as well, but does so in the hyphal growth form, which is induced early after phagocytosis [33, 210]. Within hours, *C. albicans* escapes from macrophages by intraphagosomal hypha formation *in vitro* [211, 212], and mutants with defects in filamentation are typically more sensitive to phagocytosis-mediated killing [176]. Another early escape mechanism, the triggering of host cell pyroptosis and/or damage, is used by *C. albicans* [213, 214] and requires cell wall

remodeling [215, 216], hypha formation [211, 213, 214, 217], and the fungal peptide toxin candidalysin [218]. Expanding filaments generate discontinuities in the phagosomal membrane integrity and luminal alkalinization, which probably allows the fungus to have access to the nutrient-rich cytosol [219].

#### **1.5.4 Coping with the intraphagosomal environment**

Phagocytes destruct invading microorganisms by engulfment into phagosomes to bundle their antimicrobial activities and prevent damage of surrounding host cells. Some *Candida* species, however, found ways to create their own less-hostile intracellular environment.

##### ***Modulating intracellular trafficking***

Many intracellular pathogens modulate the maturation of phagosomes by interfering with intracellular signaling cascades to prevent the formation of an antimicrobial and hostile compartment [139]. Viable *C. glabrata* cells block phagosome acidification and remain in a late endosomal compartment [178, 220]. *C. albicans* delays phagolysosome maturation dependent on cell wall composition and morphogenesis [221, 222] until the phagosomal membrane is ruptured by hyphal expansion [219].

##### ***Withstanding phagocyte-induced stress and nutrient limitation***

Phagocytosis by macrophages induces DNA damage repair mechanisms, detoxification systems and significant reorganization of metabolic processes in *C. albicans* [175] and *C. glabrata* [72, 178]. Phagocytosed fungal cells also have to cope with ROS and RNS inside the phagosome. The rapid induction of genes encoding proteins with antioxidant properties, like fungal catalases, glutathione peroxidases, thioredoxins, and superoxide dismutases are important to detoxify and withstand the oxidative burst of phagocytes [160, 223-227]. While both, *C. albicans* and *C. glabrata*, have nearly the same enzymatic systems for oxidative stress responses, these two species react differentially to this stress [228]. *C. albicans* suppresses the production of nitric oxide and ROS in macrophages in a dose-dependent manner [229], while *C. glabrata* possesses a high intrinsic oxidative stress resistance partially due to a highly active and phagocytosis-induced catalase Cta1 [230, 231].

Phagocytes use the intoxication with trace metals inside phagosomes, mainly by copper and zinc to kill engulfed microbes due to redox cycling, mismetallation and further excessive oxidative and nitrosative stress due to the generation of free radicals [232-234]. In line with this, an efficient copper detoxification system is essential for survival of *C. albicans* during copper stress within phagosomes [235-237] and zinc

## Introduction

---

intoxication by macrophages is used as fungicidal response to phagocytosed *C. glabrata* cells [238].

Phagocytosed *Candida* cells are not only bombarded with toxic compounds. The limitation of preferred macronutrients and essential micronutrients in the phagosome, as indicated by transcriptional data [72, 175], represents a major stress factor fungal cells have to deal with. *C. albicans* and *C. glabrata* have evolved strategies to counteract the severe deprivation of favorable nutrients [72, 175, 224, 239], by constantly sensing carbon- and nitrogen sources and changing its metabolism. Different nutritional sensors [240, 241] and signaling pathways [242-245] are closely intertwined for adaptation to nutritional conditions on transcriptional, translational and posttranslational levels.

Intracellular *C. albicans* and *C. glabrata* cells induce the expression of genes involved in alternative carbon source utilization (glyoxylate cycle,  $\beta$ -oxidation of fatty acids, gluconeogenesis, methyl citrate cycle) [72, 175]. Moreover, these cells activate their proteolytic machinery, possibly to degrade phagosomal proteins or to recycle own proteins, and simultaneously induce genes associated with the uptake and assimilation of amino acids and ammonium [72, 175]. Interestingly, arginine biosynthesis pathway is upregulated in both *Candida* species [72, 175]. At the same time phagocytosed cells represses the energy consuming protein synthesis to save energy [72, 175]. The starvation mode of phagocytosed *C. glabrata* cells is underlined by the fact that phagocytosed fungal cells activate autophagy (protein degradation process) and pexophagy, a process to degrade damaged peroxisomes [231, 246]. Not surprisingly, defects in alternative carbon utilization pathways worsen survival within phagocytes, immune evasion, and fungal virulence [247-258].

### **1.6 Nutrition during infection**

The efficient utilization of nutrients and especially the adaptation to changes in nutritional composition or nutritionally restrictive environments represents an important pathogenicity mechanism as it is essential for pathogens to drive nutritional homeostasis and establish an acute infection [239, 259, 260].

When nutrients are getting limited inside phagocytes, *Candida* cells have to use alternative strategies to overcome the lack of nutrients essential for cellular homeostasis of metabolic pathways, development, production of energy, and biomass – all processes that are needed to colonize and survive in different host niches [261]. During colonization of different mucosal surfaces in the commensal state, *Candida* cells have access to several favorable nutrients despite their competition with the bacterial microbiota, which often restrict nutrient availability and fungal overgrowth

[262]. This is especially true for the orogastrintestinal tract, a nutrient-rich environment due to regular food uptake of the host [263]. However, the host and the host's immune system has developed mechanisms to actively restrict the accessibility of nutrients, thereby limiting microbial growth, a phenomenon called 'nutritional immunity' [264-266]. This process is best investigated for trace metals like iron, zinc and manganese. Phagocytes sequester these trace metals from the phagosome using the cation transporter NRAMP1 [267] or iron exporter Fpn1 [268, 269]. *Candida* species have evolved the reductive pathway, the receptor-mediated uptake, and siderophore-mediated iron acquisition as high affinity systems to cope with iron limitation [270]. A siderophore (Sit1)-mediated iron uptake system and iron homeostasis in general are essential for *C. glabrata* to survive macrophage killing [271, 272].

The preferred carbon source glucose of many microbes [273] including *C. albicans* and *C. glabrata* is present in the blood but often scarce in other host niches [274]. Instead, other carbon sources like lactate and acetate are potentially available in the gut, in the kidney tissue or within phagocytes [72, 175, 259, 275-277]. The sensing and metabolism of glucose trigger the resistance against oxidative stress and antifungal agents as well as cell wall remodeling [278-282] reflecting that carbon source availability within different host niches have a strong impact on fungal virulence [259]. On the other hand, amino acid sensing and metabolism trigger important virulence features of *C. albicans* like morphogenesis [283-285] and biofilm formation [286].

### **1.7 Vitamin acquisition during host-pathogen interaction**

As described above, intracellular *Candida* cells face a phagosomal environment that lacks certain nutrients. So far, it is unknown whether vitamins are present in the phagosome, but it is likely that vitamins are not present in excess. The uptake or synthesis of essential vitamins by *Candida* cells could therefore be crucial for survival and fitness during an intracellular lifestyle. Vitamins, belonging to micronutrients, are required in very small quantities for any organism [287]. Vitamins are chemically diverse, involved in different cellular functions and the uptake from the environment is essential in case an organism is not able to synthesize the corresponding vitamin *de novo* [287-289]. Depending on their abilities to synthesize or take up certain vitamins, different successful pathogens have their own vitamin requirements when growing in the host [290]. Vitamin auxotrophies increase the dependency of pathogens on external supply by the host or the microbial community in certain micro-niches [291]. The biosynthesis and uptake of vitamins is particularly well characterized in bacteria. For example, *Mycobacterium tuberculosis* depends on its own synthesis of riboflavin, biotin, pyridoxine and pantothenic acid synthesis [292-295]. Contrary, some other

## Introduction

---

bacterial pathogens lack the biosynthetic pathway and need riboflavin transporter systems, probably for their survival in host niches [296, 297]. For example, the uptake of riboflavin modulates important virulence traits of *Listeria monocytogenes* [298]. Vitamin biosynthesis pathways of pathogens, that lack vitamin uptake machineries and which dependent on endogenous vitamin biosynthesis, have been considered as potential drug targets [293, 299-302].

**Table 2: Currently described vitamins impairing pathobiology of fungal pathogens.**

vitamin	essential for	reference
riboflavin (B <sub>2</sub> )	<i>Aspergillus</i> spp.	[303]
		[304]
	<i>H. capsulatum</i>	[305]
	<i>C. albicans</i>	[306]
pantothenic acid (B <sub>5</sub> )	<i>A. fumigatus</i>	[303]
	<i>H. capsulatum</i>	[305]
pyridoxine (B <sub>6</sub> )	<i>Aspergillus</i> spp.	[303]
		[304]
folate (B <sub>9</sub> )	<i>Aspergillus</i> spp.	[307, 308]

The role of vitamin biosynthesis for fungal pathogens during the interaction with their host is less investigated and only a few examples are described by now (**Table 2**). As described for bacterial pathogens, not only the biosynthesis, but also the uptake from the host may be essential during infection in case the pathogen is auxotrophic for that vitamin. *C. glabrata* possesses more vitamin auxotrophies than *C. albicans*. It possesses an intrinsic auxotrophy for niacin, pyridoxine and thiamine, whereas *S. cerevisiae* and *C. albicans* are prototrophic for these vitamins [79, 80, 309]. All medically relevant *Candida* species are biotin auxotrophic, and some isolates are also thiamine auxotrophic [310, 311], suggesting that an transport system for these vitamins might be essential for viability, the survival in specific host niches, and probably virulence.

## 1.8 Aim of this study

*Candida* species are common colonizers of mucosal surfaces, but can also cause superficial and life-threatening systemic infections under predisposing conditions [2]. Infections are characterized by recruitment of innate immune cells which limit fungal proliferation and spreading [147-149]. However, pathogenic *Candida* species have evolved mechanisms to survive phagocytosis, proliferate within and escape from innate immune cells [312].

This study aimed to convey a better understanding on how *Candida* species cope with nutrient limitation within the phagosome of macrophages, representing an important phagocytic immune cell during candidiasis [147, 313]. **Manuscript I** of this thesis was written in order to compare nutrient acquisition and adaptation strategies of different bacterial and fungal pathogens with a facultative intracellular lifestyle within macrophages (**manuscript I**).

Since *Candida* species are naturally dependent on biotin, and the putative regulator of biotin-related processes Vhr1 was shown to promote survival within macrophages and virulence of *C. glabrata* [314, 315], the focus was set on this essential vitamin. Hence, this study aimed to characterize *VHR1* and its downstream target genes to unveil new insights into the regulation and maintenance of biotin homeostasis in *C. glabrata*, but also in the phylogenetically distant pathogenic *Candida* species, *C. albicans*, using transcriptional analysis, mutagenesis of biotin-metabolic genes, biotin-dependent growth analyses, as well as macrophage infection experiments and a systemic murine infection model (**manuscript II**).

As further improvement of genetic and molecular tools for assaying *C. glabrata*-host interaction, a RNA-mediated gene knock-down, a gene complementation strategy in *C. glabrata* and a flow cytometry-based method for determination of intraphagosomal replication rates were established and described in further manuscripts (**manuscript II, III & V**).

Finally, predatory amoebae are often used to understand how fungal pathogens evolved resistance strategies against mammalian phagocytes [316] and why species-specific differences occur in fungal immune evasion mechanisms [180]. Therefore, transcriptional analyses and mutagenesis approaches were used to gain new insights into the interaction of *C. parapsilosis* with amoeba and to compare these to the established macrophage model (**manuscript IV**).

*Int J Med Microbiol.* 2018 Jan;308(1):215-227.

doi: 10.1016/j.ijmm.2017.11.001. Epub 2017 Nov 7.

#### Summary

Successful intracellular pathogens evolved strategies to withstand antimicrobial activities within macrophages and resist destruction by these immune cells. Nutrient limitation within the phagosomal compartment represents one important mechanism to restrict microbial growth and further spreading in the host. This review focusses on adaptation mechanisms of selected bacterial and fungal pathogens to metabolic conditions of the phagosomal compartment as well as the cytosolic environment, with a focus on species-specific requirements.

## ABSTRACT

The mature phagosome of macrophages is a hostile environment for the vast majority of phagocytosed microbes. In addition to active destruction of the engulfed microbes by antimicrobial compounds, restriction of essential nutrients in the phagosomal compartment contributes to microbial growth inhibition and killing. However, some pathogenic microorganisms have not only developed various strategies to efficiently withstand or counteract antimicrobial activities, but also to acquire nutrients within macrophages for intracellular replication. Successful intracellular pathogens are able to utilize host-derived amino acids, carbohydrates and lipids as well as trace metals and vitamins during intracellular growth. This requires sophisticated strategies such as phagosomal modification or escape, efficient nutrient transporters and metabolic adaptation. In this review, we discuss the metabolic adaptation of facultative intracellular bacteria and fungi to the intracellular lifestyle inside macrophages.

## 1. Antimicrobial mechanisms of macrophages

Macrophages are phagocytic cells of the innate immune system patrolling in nearly all human tissues and on mucosal surfaces and thus contributing to the first line of defence against invading microbes (Pollard, 2009). Defined microbe-associated molecular patterns (MAMPs) of invading microorganisms are recognized by vesicular or cytosolic pattern recognition receptors (PRRs) of macrophages (reviewed by (Ewig and Gow, 2016; Ren et al., 2017; Weiss and Schaible, 2015)) leading to host signalling cascades, which regulate downstream processes such as immune cell activation, changes in host cell metabolism, inflammation and phagocytosis (Ren et al., 2017; Weiss and Schaible, 2015). Phagocytosis represents a cellular uptake machinery required for efficient destruction of invading microbes (reviewed in (Mao and Finnemann, 2015)). Following phagocytosis, ingested microbes are localized within defined membrane-enclosed phagosomal compartments, which mature to phagolysosomes via a tightly regulated series of fusion events with the endocytic machinery (Jeschke and Haas, 2016; Mao and Finnemann, 2015; Pauwels et al., 2017; Stein et al., 2012). In the matured phago(lyso)some, microbes are exposed to an

acidic hostile environment with antimicrobial activities due to lysosomal proteases, reactive oxygen species and antimicrobial peptides (Flannagan et al., 2015). Nevertheless, an astonishing number of microbes have developed strategies to survive within this intracellular compartment.

Intracellular survival strategies are manifold and extensively reviewed elsewhere (Awuh and Flo, 2017; Gilbert et al., 2014; Ramond et al., 2012; Sarantis and Grinstein, 2012). Some microbes adapt to antimicrobial activities within the phagosome, while others either actively modify the phagosome, inhibit phagosomal maturation (thereby generating a less hostile replicative environment), or escape from the phagosomal compartment into the cytoplasm.

In addition to the above-mentioned direct antimicrobial mechanisms, phagocytosed pathogens also face an environment with a reduced supply of nutrients as compared to the extracellular milieu. For example, essential trace metals like iron or manganese and other nutrients are scarce due to host induced sequestration activities (Appelberg, 2006; Flannagan et al., 2015). Thus, microbial growth inhibition or killing within phagocytes may not only be based on the toxic environment in the phagosome, but may also result from the scarcity of

nutrients. Consequently, successful facultative intracellular pathogens must not only be equipped with strategies that ensure avoidance of or resistance to toxic mechanisms of macrophages, but also be able to adapt to the special nutritional conditions inside macrophages.

In this review, we focus on the impact of nutrients within macrophages for intracellular pathogens, as well as on the adaptation of pathogens to these nutritional conditions. We discuss strategies of selected examples of bacterial and fungal pathogens with diverse infection cycles including stages of intracellular proliferation within macrophages. In addition to macrophages, we discuss intracellular survival within amoebae (e.g. *Acanthamoeba castellanii*). Amoebae show macrophage-like behaviour and microbicidal activity (Guimaraes et al., 2016), and successful environmental mammalian pathogens, such as *Legionella pneumophila* or *Cryptococcus neoformans*, are known to have the potential to resist antimicrobial activities and to replicate intracellularly in environmental amoebae (Guimaraes et al., 2016). Selected exemplary bacterial and fungal pathogenic species discussed in this review are briefly introduced in the following paragraphs.

*Mycobacterium tuberculosis*, a Gram-positive bacterium with an exceptional hydrophobic cell wall, is the causative agent of tuberculosis and has evolved strategies to use macrophages as a replicative niche, thus evading host immune responses and allowing it to persist and/or spread in the host (Awuh and Flo, 2017). *M. tuberculosis* prevents phagosome-lysosome fusions and efficiently manipulates host macrophages to obtain sufficient host-derived nutrients to ensure survival, replication and intracellular persistence (Neyrolles et al., 2015).

The Gram-negative bacterium *Legionella pneumophila*, etiological agent of severe pneumonia (Legionnaire's disease), replicates in environmental amoebae, accidentally infects humans and resists human alveolar macrophages after phagocytosis (Khodr et al., 2016). Inside macrophages, *L. pneumophila* induces the formation of a replicative non-endosomal vacuole, where the pathogen is able to acquire nutrients, replicate and further differentiate into a flagellated form, which mediates escape from the phagosome into the cytoplasm and finally from the macrophage into the extracellular space (Eisenreich and Heuner, 2016; Robertson et al., 2014).

*Francisella tularensis* is a Gram-negative, highly virulent, zoonotic bacterium, which can infect a broad range of mammalian species and cause tularemia (Meibom and Charbit, 2010). During infection, this facultative intracellular bacterium primarily infects macrophages and enters the phagosomal compartment, but to survive and replicate within infected macrophages, *F. tularensis* needs to escape from the phagosome into the cytosol (Ramond et al., 2012).

*Listeria monocytogenes* is a facultative intracellular Gram-positive bacterium that causes the fatal foodborne disease listeriosis (Vazquez-Boland et al., 2001). After phagocytosis by macrophages, *L. monocytogenes* prevents the maturation of the phagosome, escapes to and replicates within the cytosol (Ireton et al., 2014).

*Salmonella enterica* is a facultative intracellular Gram-negative pathogen that causes a range of diseases in humans. *S. enterica* serovars such as Typhimurium or Enteritidis are frequently transmitted from reservoirs in livestock and cause gastroenteritis, a self-limiting infection of the small intestine with local inflammation. High human-adapted serovars Typhi and Paratyphi A are transmitted from infected humans and cause a systemic, often fatal disease termed typhoid fever. The ability of certain *Salmonella* spp. to survive and replicate within phagocytic cells is generally considered as requirement to cause systemic diseases (Fields et al., 1986). However, this notion is mainly based on experimental studies in a systemic infection model with *S. Typhimurium* in susceptible mouse strains.

*Candida albicans* and *C. glabrata* are commensal yeasts of warm-blooded animals and humans as well as opportunistic fungal pathogens that provoke superficial mucosal infections, but also life-threatening systemic candidiasis (Odds, 1988). Both *Candida* species can resist elimination by macrophages and have evolved strategies to proliferate within phagocytes (Erwig and Gow, 2016; Gilbert et al., 2014; Kasper

et al., 2015). Phagocytosis of *C. albicans* by macrophages induces intracellular filamentation, which mediates damage of the host cell and escape, whereas *C. glabrata* is not able to form hypha and grows in the phagosome as yeast cells until the host macrophages burst (Miramon et al., 2013; Seider et al., 2010).

The encapsulated and opportunistic fungus *Cryptococcus neoformans* is able to cause life-threatening respiratory and systemic infections (cryptococcosis) in immunocompromised individuals (Johnston and May, 2013). Inhaled airborne yeast cells, or sexually produced basidiospores, of environmental *Cr. neoformans* switch to capsulated yeast morphology (Kwon-Chung et al., 2014). Although capsules inhibit phagocytosis by alveolar macrophages, *Cr. neoformans* is known to persist and proliferate within a mature phagolysosome once phagocytosed (Gilbert et al., 2014; Johnston and May, 2013; Leopold Wager et al., 2016).

The environmental fungal pathogen *Histoplasma capsulatum*, causing most endemic respiratory mycoses in the USA, is able to infect macrophages, resist the antimicrobial activities and proliferates intracellularly (Garfoot and Rappleye, 2016; Horwath et al., 2015). Engulfed by macrophages, *H. capsulatum* enters the phagosomal compartment, blocks acidification and avoids killing e.g. due to detoxification of reactive oxygen radicals (Gilbert et al., 2014).

## 2. Nutrient limitation as an antimicrobial strategy

Phagocytosis by macrophages is thought to generate an environment with restricted nutrient availability as compared to the extracellular milieu, and there is evidence that macrophages actively deprive pathogens of accessible nutrients (Appelberg, 2006). However, intracellular pathogens have developed specific virulence mechanisms that target host biosynthetic and degradation pathways or nutrient-rich sources to enhance supplies of limiting nutrients, a paradigm termed as 'nutritional virulence' (Abu Kwaik and Bumann, 2013). However, the defined characterization of the biochemical composition of pathogen-containing compartments in macrophages has been challenging, and knowledge about nutrient composition has mostly been derived indirectly from microbial responses to conditions in their intracellular niche (Appelberg, 2006; Weiss and Schaible, 2015). For example, it has been assumed from transcriptional profiling approaches and metabolic flux analysis that intraphagosomal pathogens encounter glucose and trace metal limitation and rely on alternative C<sub>2</sub> and C<sub>3</sub> carbon sources like amino acids or lipid degradation products. Examples for such proposed nutritional conditions come from studies dealing with intracellular bacterial (*M. tuberculosis*) and fungal pathogens (*C. albicans*) (Lorenz et al., 2004; Lorenz and Fink, 2002; McKinney et al., 2000). However, it is unlikely that these observations can be generalized for an intracellular life style *per se*, as the replicative niche used inside macrophages differs among pathogens. For example, the cytosol, used by several intracellular bacteria, is thought to be less nutrient-deprived as compared to membrane-enclosed compartments (Appelberg, 2006). Further, the fact that *L. pneumophila* uses amino acids, glucose and glycerol as major nutrients during intra-vacuolar growth (in contrast to *M. tuberculosis* and *C. albicans*) (Eisenreich and Heuner, 2016), points to a defined nutrient composition depending on the pathogen-associated membrane-enclosed compartment. In line with this, the active manipulation of the host endocytic pathways by intracellular pathogens results in not only a less hostile niche, but in a distinct replication-permissive pathogen vacuole with rather favourable conditions including sufficient access to nutrients (e.g. *Salmonella*, *Legionella*) (Hilbi and Haas, 2012).

Due to incomplete amino acid biosynthesis clusters, pathogens like *F. tularensis* require host-derived amino acids within the intracellular milieu of macrophages (Meibom and Charbit, 2010). Interestingly, some of these amino acids, for example cysteine, are strongly limited within host cells (Meibom and Charbit, 2010). Therefore, intracellular growth of some intracellular pathogens maybe suppressed by limiting

certain amino acids, which has been termed a ‘nutritional rheostat’ (Abu Kwaik and Bumann, 2013). A similar defence strategy of macrophages to limit intracellular microbial growth is amino acid deprivation by activation of degradation pathways (Weiss and Schaible, 2015).

Engulfment of pathogens induces not only host signalling cascades that activate antimicrobial responses, but also a change in metabolism, which is associated with macrophage polarization. In fact, clear metabolic differences exist between M1 and M2 macrophages (Galvan-Pena and O’Neill, 2014). Classically activated M1 macrophages exhibit high glucose and glutamine turnover, supporting the synthesis of NADPH, which is essential for the generation of ROS within the phagosome (reviewed in (Ganeshan and Chawla, 2014)). In contrast, alternatively activated M2 macrophages change their metabolism to oxidative phosphorylation and  $\beta$ -oxidation (Ganeshan and Chawla, 2014). Many pathogens have evolved strategies to interfere with macrophage polarization, taking advantage of the various (immune) functions of the different macrophage phenotypes (Ren et al., 2017). It is tempting to speculate that interference with macrophage polarization may also be a strategy to generate an optimal metabolic niche for the pathogen.

Host strategies used to limit the access of essential trace metals for invading microorganisms are well-investigated and extensively reviewed elsewhere (Caza and Kronstad, 2013; Cerasi et al., 2013; Juttukonda and Skaar, 2015; Nairz et al., 2015b)). The host transporter NRAMP1 (SLC11A1), for example, removes divalent cations (manganese, iron and cobalt) from the phagosomal compartment to starve intracellular pathogens and limit intracellular fitness (Forbes and Gros, 2003; Jabado et al., 2000; Juttukonda and Skaar, 2015; Nairz et al., 2009). Also, iron-binding proteins like transferrin, ferritin and the manganese, calcium and zinc binding protein calprotectin are important to sequester metal ions to prevent microbial growth (Hood and Skaar, 2012; Zaackular et al., 2015). In contrast, intoxication with high levels of zinc and copper are used as antimicrobial mechanisms. These host strategies of trace metal withholding, but also intoxication are summarized as ‘nutritional immunity’ (Hood and Skaar, 2012).

### 3. The intracellular lifestyle—nutrients as a limiting factor within macrophages

Microbial replication requires large amounts of energy, as well as macro- and micronutrients to maintain metabolic and cellular processes. This is driven by the degradation of macromolecules, such as carbohydrates, lipids and proteins (macronutrients), and consumption of their degradation products (e.g. amino acids). Further, trace metals or vitamins (micronutrients) are needed, e.g. as cofactors of essential metabolic enzymes. Thus, intracellular pathogens have to acquire macro- and micronutrients from the host.

Pathogens prefer to metabolize certain nutrients and strictly control their nutrient assimilation pathways on transcriptional and post-transcriptional levels (Lorenz, 2013). For example, glucose is an essential and preferred nutrient for many microbes to generate energy and to synthesize cellular components (Towle, 2005). However, glucose is often restricted in biological systems. Therefore, pathogens compete with their hosts and have evolved strategies to efficiently sense, acquire and metabolize this nutrient (Sabina and Brown, 2009). Furthermore, since glucose is not readily available within macrophages, alternative carbon and energy resources for an intracellular lifestyle are crucial to permit survival and replication in this niche. Therefore, intracellular pathogens have developed several different strategies to efficiently acquire nutrients during intracellular growth as summarized in Table 1.

Many pathogens are well adapted to the nutrient-restrictive situation of their intracellular environments and rely on efficient acquisition systems or utilize various alternative nutrient sources during intracellular stages (Table 1). For example, many pathogens express distinct transporters for the respective nutrients. *M. tuberculosis* is able to utilize extracellular amino acids, glycolytic C<sub>3</sub>-sources, C<sub>2</sub>-sources (acetyl-CoA), host lipids and even CO<sub>2</sub> (Beste et al., 2013; Pandey and

Sassetti, 2008). Similarly, *F. tularensis* possesses high affinity transporters for different amino acids that facilitate efficient escape from the phagosome and multiplication within the cytosol (Ziveri et al., 2017). Other pathogens have evolved mechanisms to successfully manipulate the host cell to import or degrade host-derived nutrients, which are then used to survive and replicate within macrophages. For example, *L. pneumophila* and *F. tularensis* manipulate the host amino acid pool by inducing the expression of the host amino acid transporter gene SLC1A5 to create a more favourable microenvironment (Barel et al., 2012; Wieland et al., 2005).

The unique environment with its nutritional restrictions inside macrophages is not only a trigger for pathogens to quickly adapt their up-take systems and own metabolism to the particular demands of their specialized niche, but also triggers ‘adaptive prediction’ (Brunke and Hube, 2014), including morphological differentiation or expression of virulence factors, which promote subsequent stages of pathogenesis.

In the following paragraphs, we discuss (i) how intracellular pathogens adapt their metabolism to utilize amino acids, carbohydrates, polyols, lipids and micronutrients (summarized in Table 1) and (ii) what impact these nutrients have on intracellular survival and proliferation (summarized in Table 2).

## 4. Utilization of macronutrients

### 4.1. Amino acids

Amino acids can be used as a source of energy, carbon, nitrogen and sulphur to maintain microbial metabolism and thus are an important nutrient source for intracellular pathogens. There are major differences in the metabolism of amino acids. For example, the majority of prokaryotes, plants and fungi is able to synthesize amino acids *de novo*, whereas higher eukaryotes synthesize only twelve out of 20 amino acids (non-essential amino acids) and require essential amino acids from external sources.

Host-derived amino acids are considered as a ‘nutritional rheostat’ for intracellular multiplication, because the basal microbial pool of amino acids is thought to be insufficient for intracellular replication even for normally prototrophic pathogens (Abu Kwaik and Bumann, 2013). Therefore, additional amounts of amino acids are required during an intracellular lifestyle. Furthermore, some pathogens, like *F. tularensis* (Ziveri et al., 2017) or *L. pneumophila* (Eisenreich and Heuner, 2016), have multiple intrinsic auxotrophies for amino acids and thus have to find special solutions to thrive intracellularly. In fact, the cysteine auxotrophy of *L. pneumophila* can be bypassed through the exploitation of the host proteasomal degradation system to boost the intracellular level of free available cysteine (Price et al., 2011).

Uptake and metabolism of different amino acids and nucleotides by *L. pneumophila* within macrophages is mediated via the phagosomal transporter family (*Pht*) and studies by Schunder et al. demonstrated that uptake and metabolism of amino acids is crucial within the *Legionella*-containing vacuole (LCV) of infected *Acanthamoeba castellanii* (Schunder et al., 2014). The acquisition of threonine and valine is executed by *phtA* and *phtJ*, respectively, and is required for differentiation into the replicative form (Fonseca and Swanson, 2014; Sauer et al., 2005). The transporter *phtC-D* facilitates thymidine uptake, crucial for intracellular proliferation (Fonseca et al., 2014). A similar important role is played by the uptake of serine, which is metabolised via the TCA cycle and represents a crucial intracellular energy supply (Eylert et al., 2010; Gillmaier et al., 2016). As discussed above, sensing the nutrient availability in intracellular compartments may also induce a ‘predictive adaptation’ response. For example, the arginine repressor ArgR senses arginine levels within the LCV and derepresses the transcription of a set of genes involved in detoxification, stress adaptation, amino acid metabolism and Icm/Dot-translocated substrates during intracellular growth (Hovel-Miner et al., 2010).

In *L. monocytogenes*, the transcriptional activity of PrfA, which

controls essential virulence attributes, is modulated by host-derived amino acids (Scorti et al., 2007). PrfA transcription is positively regulated by the transcription regulator CodY, which responds to the low availability of branched chain amino acids (BCAA) within host cells (Lobel and Herskovits, 2016; Lobel et al., 2015; Lobel et al., 2012). PrfA induces the expression of the *Listeria* virulence factors listeriolysin O and phospholipase B, which facilitate escape from the phagosomal compartment into the cytosol (de las Heras et al., 2011). Once cells have entered the reducing environment of the cytosol, host-derived glutathione can modulate PrfA to positively regulate the expression of the actin polymerization factor gene *actA*, which is essential for spreading into adjacent cells (de las Heras et al., 2011; Freitag et al., 2009; Reniere et al., 2015). In addition, glutamine can function as an environmental sensor, controlling the expression of virulence-related *Listeria* genes (Haber et al., 2017): the expression of virulence factors is induced when the listerial glutamine pool increases over a certain threshold, depending on the high affinity uptake system GlnPQ and probably due to modulation of PrfA. Interestingly, intracellular *Listeria* cells directly use host-derived amino acids for protein biosynthesis or modulation of gene expression and not for catabolism and energy supply (Grubmuller et al., 2014).

In *M. tuberculosis*, the uptake of aspartate and asparagine within macrophage phagosomes by AnsP1 and AnsP2 transporters is important for assimilation of nitrogen (Gouzy et al., 2014; Gouzy et al., 2013). The utilization of asparagine offers two important advantages for *M. tuberculosis* during intracellular stages, as this amino acid can not only serve as a nitrogen source, but can also contribute to reducing acidic stress within the phagosome. The latter is achieved by cleavage of asparagine to aspartate and ammonia, which neutralizes the phagosomal pH (Gouzy et al., 2014). A similar neutralization strategy of the

phagosomal compartment has been observed in *C. albicans* (Vylkova and Lorenz, 2014).

Since *F. tularensis* is auxotrophic for some amino acids, uptake of host-derived amino acids is essential (Meibom and Charbit, 2010). *F. tularensis* uses an amino acid uptake system similar to *M. tuberculosis*, which is also based on asparagine import by an AnsP transporter. In contrast to *M. tuberculosis*, however, asparagine is imported during the cytosolic replication stage within infected macrophages (Gesbert et al., 2014). Besides asparagine, *F. tularensis* can take up glutamate via the glutamate permease GadC within the phagosomal compartment. GadC-mediated glutamate uptake supports resistance against oxidative stress by modulating the redox status of the bacterium and positively affects escape from the phagosome into the cytosol (Ramond et al., 2014). As inactivation of *gadC* reduced the bacterial pool of TCA cycle metabolites, glutamate uptake seems to be necessary for bacterial energy supply (Ramond et al., 2014). In addition to GadC, two other amino acid permeases, one for isoleucine (IleP) and one for arginine (ArgP), facilitate the uptake of the respective amino acids during different stages of the intracellular lifestyle and contribute to phagosomal escape as well as cytosolic bacterial replication (Gesbert et al., 2015; Ramond et al., 2015; Ziveri et al., 2017).

Most serovars of *S. enterica* are prototrophic and able to synthesize all amino acids *de novo* using intermediates of primary carbon metabolism. Mutant strains deficient in amino acid biosynthesis pathways are attenuated in macrophage infections and in a murine model of systemic infection. Human-adapted serovars such as *S. enterica* serovar Typhi and Paratyphi A require supplementation by tryptophan and cysteine for growth in minimal media, indicating defective biosynthetic pathways. Since *S. Typhi* and *S. Paratyphi* are able to proliferate in host tissue, a continuous supply of these amino acids during growth in the

host is anticipated. A study by Popp et al. investigated the requirement for amino acids, which are non-essential for mammalian host cells (Popp et al., 2015). The work showed that mutant strains auxotrophic for proline were highly attenuated in proliferation in macrophages. Supplementation of the growth medium of infection macrophages with proline complemented intracellular proliferation, but only if the *Salmonella* pathogenicity island-2 type III secretion system (SPI2-T3SS) was functional in manipulating host cell endosomal transport. Work by Das et al. revealed that cationic amino acid transporters (CAT) of the host cell were up-regulated in *Salmonella* infected phagocytes and that host cell CAT were sequestered to the *Salmonella*-containing vacuole (SCV) (Das et al., 2010). In addition, *Salmonella* uses its arginine transporter ArgT for uptake of arginine from the SCV. This suggests that *Salmonella* in the SCV deploy host cell CAT to access the cytosolic pool of arginine. In line with this model, a *Salmonella* mutant deficient in arginine biosynthesis was attenuated in intracellular proliferation and systemic virulence (Das et al., 2010).

Amino acid utilization is also described for facultative intracellular fungal pathogens. The last enzyme in the catabolism of leucine, the HMG-CoA lyase Hcl1, plays a critical role for intracellular replication of *H. capsulatum* (Isaac et al., 2013). The degradation of this amino acid may be an important intracellular energy supply for *H. capsulatum* and this observation suggests therefore that the *H. capsulatum*-containing phagosome provides sufficient amounts of leucine to support growth (Isaac et al., 2013). The catabolism of leucine generates acetyl-CoA, which can be used through the glyoxylate cycle. This metabolic pathway is an important hub for the utilization of several alternative carbon sources used in the host, such as acetyl-CoA generated through degradation of amino acids, cholesterol or fatty acids. Interestingly, mutants of both, *M. tuberculosis* (McKinney et al., 2000; Munoz-Elias

and McKinney, 2005) and *C. albicans* (Childers et al., 2016; Lorenz and Fink, 2001), lacking genes of the glyoxylate cycle show reduced intracellular fitness and virulence. In fact, genes encoding enzymes of the glyoxylate cycle are up-regulated in *C. albicans* (Lorenz et al., 2004), *C. glabrata* (Kaur et al., 2007) and *Cr. neoformans* (Derengowski Lda et al., 2013; Fan et al., 2005) after phagocytosis by macrophages.

The opportunistic pathogenic fungus *C. albicans* undergoes a dramatic transcriptional reprogramming process upon phagocytosis by macrophages (Lorenz et al., 2004). This response involves the up-regulation of genes coding for amino acid and ammonia transporters, enzymes involved in alternative carbon source utilization as well as a repression of energy-consuming processes. Expression of amino acid permease and oligopeptide transporter genes is induced by the transcription factor Stp2, which is proteolytically activated through the plasma membrane located SPS amino acid sensor system, consisting of Ssy1 (sensor), Ptr3 (mediator) and Ssy5 (endoprotease) in the presence of amino acids as a sole carbon source (Miramon and Lorenz, 2016). This allows nitrogen assimilation and also promotes neutralization of the phagosomal compartment by release of ammonia – a process that induces hyphal morphogenesis, killing of and escape from macrophages (Miramon and Lorenz, 2016; Vylkova and Lorenz, 2014). The carbon backbone of amino acids is used by *C. albicans* as a sole carbon source and fulfils another important aspect, the maintenance of metabolic pathways to generate essential metabolites and energy (Vylkova et al., 2011). Similar to *C. albicans*, other fungal pathogens like *C. glabrata* and *Cr. neoformans* shift their metabolism to a starvation mode and activate the expression of genes coding for enzymes of the glyoxylate cycle, gluconeogenesis, fatty acid degradation and amino acid biosynthesis and uptake (Fan et al., 2005; Kaur et al., 2007; Lorenz et al., 2004; Rai et al., 2012). As in most cases, this up-regulation coincides with the

repression of protein biosynthesis (Fan et al., 2005; Kaur et al., 2007; Lorenz et al., 2004), suggesting that ingested fungal pathogens encounter both carbon and nitrogen deprivation inside phagocytes.

A main difference between *C. albicans* and *C. glabrata* is the ability of *C. albicans* to form true hyphae, while *C. glabrata* only grows in the yeast form (Brunke and Hube, 2013). The hyphal outgrowth from the phagosome may be a useful strategy of *C. albicans* to escape the harmful and nutrient-poor environment within hours (Hummert et al., 2010), while *C. glabrata* cells can remain intracellular for several days without damaging the host macrophage (Kasper et al., 2015; Seider et al., 2011). Therefore, it is not surprising that *C. albicans* does not require its own autophagy machinery for survival within macrophages (Palmer et al., 2007), whereas the viability of *C. glabrata* within the phagosomal compartment of macrophages is enhanced by autophagy, probably to efficiently recycle resources to maintain its own metabolism (Roetzer et al., 2010). Recently, it was shown that autophagy is also an essential cellular process for survival of *Cr. neoformans* within macrophages (Gontijo et al., 2017).

Besides the role of pathogen's autophagy machinery in intracellular adaptation, the host's autophagy machinery also plays an important role during the interaction of pathogens with macrophages. Host cells use autophagy to digest damaged proteins, degrade whole organelles and also intracellular microbes. Therefore, host cell autophagy can be disadvantageous for intracellular microbes and some have evolved strategies to block induction of autophagy (Deretic and Levine, 2009; Steele et al., 2015). *L. pneumophila*, for example, secretes the bacterial effector RacZ, which irreversibly disrupts macrophage Atg8 proteins to prevent degradation by autophagy (Choy et al., 2012). Autophagy limits early replication of *L. monocytogenes* within macrophages, and intraphagosomal bacteria co-localize with autophagy markers in initial stages of infection (Birmingham et al., 2007; Py et al., 2007). However, *L. monocytogenes* hijacks host cell proteins to counteract autophagy upon entering the cytosol (Dortet et al., 2011). *M. tuberculosis* remains in a self-modified phagosome, which prevents association with the host's autophagy machinery, and permeabilization of the phagosomal membrane increases association with autophagy markers (Watson et al., 2012). In contrast, the induction of host autophagy is used by some pathogens to gain nutrients (Deretic and Levine, 2009). *F. tularensis* induces autophagy, evades autophagic degradation and harvests nutrients from this process (Chong et al., 2012; Steele et al., 2013). Furthermore, *C. albicans* induces a shift of the cytosolic protein LC3-I to autophagosome-associated LC3-II, which indicates autophagy induction by this fungus (Smeekens et al., 2014). However, macrophage autophagy plays a role in nutrient restriction to *C. albicans*, as inactivation of autophagy in macrophages reduces the phagocytosis of *C. albicans* as well as fungistatic activity (Nicola et al., 2012).

In summary, intracellular pathogens seem to rely on the utilization of a set of host-derived amino acids to maintain their own metabolism, and each pathogen (e.g. *F. tularensis* and *Legionella* spp.) has its own requirements for nutrients due to different intrinsic auxotrophies. The examples discussed in this chapter show that amino acid uptake is achieved by specialized transporters and sophisticated regulatory mechanisms. Additionally, intracellular pathogens are also able to modulate the host to promote the release of free available amino acids by exploiting host transporters or protein turnover by autophagy.

#### 4.2. Carbohydrates and polyols

Glucose and glycolytic intermediates and metabolites are normally channelled into the glycolysis or other alternative pathways, such as the Entner-Doudoroff (ED), Embden-Meyerhof-Parnas (EMP) or pentose phosphate (PP) pathway (Harada et al., 2010; Hauslein et al., 2016). Glucose is generally a preferred nutrient source for the host and most pathogens. Within membrane-engulfed compartments, glucose is assumed to be less available to intraphagosomal pathogens (*Candida*, *Cryptococcus* and *Mycobacterium* spp.) since transcriptional profiling

indicates increased expression of alternative carbon source utilization genes (Derengowski Lda et al., 2013; Lorenz et al., 2004; McKinney et al., 2000). However, this may not be a general phenomenon for all pathogen-containing compartments. For example, parts of the alternative glucose degradation (ED) pathway, are necessary for intracellular growth of *L. pneumophila* (Harada et al., 2010). It was also shown that the polyol glycerol promotes the growth of *L. pneumophila* within macrophages. This intracellular growth depends on the glycerol-3-phosphate dehydrogenase and glucose, as well as glycerol, which are used for anabolic purposes (gluconeogenesis and PP pathway) (Hauslein et al., 2016). Recently, it was shown that catabolic degradation of *myo*-inositol promotes the intracellular growth of *L. pneumophila* within macrophages or amoeba (Manske et al., 2016).

Transcriptional profiling of *L. monocytogenes* grown in macrophages demonstrated that intracellular growth induces genes involved in the uptake of glycerol and glucose-6-phosphate as well as metabolic pathways associated with these molecules, namely the gluconeogenesis and PP pathway (Joseph et al., 2006). In line with this, <sup>13</sup>C-Isotopologue-profiling analysis demonstrated the dependence of intracellular *Listeria* spp. on host-derived C<sub>3</sub>-substrates as carbon sources, which were subsequently incorporated into amino acids (Eylert et al., 2008). Glycerol as a main C<sub>3</sub>-substrate is channelled into glycolysis to generate ATP, and the remaining pyruvate is converted to oxaloacetate via the pyruvate carboxylase PycA (Grubmuller et al., 2014; Schar et al., 2010). Glucose-6-phosphate enters glycolysis at an earlier step and is metabolised via the PP pathway to predominantly fulfil anabolic purposes (Grubmuller et al., 2014). Interestingly, glycerol and glucose-6-phosphate modulate the activity of the transcription factor PrfA, resulting in optimal expression of virulence genes, which represents a general mechanism of metabolic modulation of virulence (Joseph et al., 2008; Mertins et al., 2007; Stoll et al., 2008).

*M. tuberculosis* is also able to utilize a glycolytic C<sub>3</sub>-source at the midpoint of the glycolysis/gluconeogenesis pathway channelled into the PP pathway, demonstrating that this pathogen has access to glycolytic intermediates within the phagosomal compartment for anabolic purposes (Beste et al., 2013). Moreover, this anabolic gluconeogenic flux of intermediates of the TCA cycle is necessary for *M. tuberculosis* to maintain infection (Marrero et al., 2010).

*F. tularensis* similarly possesses glycerol as well as glycerol-3-phosphate transporters, which probably support intracellular carbon source utilization besides amino acids (Ziveri et al., 2017). Compared to *Listeria* spp., permeases for glucose-6-phosphate are missing in *F. tularensis*, demonstrating a completely different requirement of carbohydrates by two intracellular pathogens, which both can escape into the host cell cytosol.

*S. enterica* is a metabolic 'all-rounder' and is considered to be able to adapt to a wide variety of C-sources for growth inside macrophages. Equipped with fully functional EMD, PP, ED pathways, reductive and oxidative modes of TCA cycle, respiratory chains with oxygen and alternative electron acceptors, *S. enterica* can easily adapt to the changing availability of C- and energy sources. Furthermore, this pathogen can synthesize all cellular macromolecules from single C-sources as basic as C<sub>3</sub> or C<sub>2</sub>. Indeed, only a few mutations in carbon catabolic pathways led to decreased intracellular survival and replication, and the attenuation most likely results from toxicity of accumulated metabolites such as phosphorylated hexoses.

Proteomic analyses of *S. Typhimurium* in the murine model of systemic infection demonstrated that multiple nutrient sources as utilized in parallel (Steeb et al., 2013). Glycerol catabolism was most highly induced, and high levels of proteins involved in transport and catabolism of glucose, gluconate, lactate, and *N*-acetyl-glucosamine (GlcNAc) were determined. In addition, transport/catabolism of various amino acids, fatty acids and nucleotides was induced. As the analyses were performed with *Salmonella* recovered from spleens of infected mice, the parallel activity of metabolic pathways may result from various subpopulations in distinct microhabitats or type of host cells.

Transcriptomic profiling of *S. Typhimurium* in macrophages revealed strong up-regulation of EMD and PP pathways, while the expression of ED genes was not altered (Eriksson et al., 2003). The analysis also revealed up-regulation of genes for gluconate, gluconurate, galactonate and related carbonic acids, suggesting preferential use of these compounds in the SCV in macrophages.

Upon phagocytosis by macrophages, *C. albicans* not only up-regulates the expression of amino acid permease and oligopeptide transporter genes (see above); but also genes encoding lactate and GlcNAc transporters (Alvarez and Konopka, 2007; Lorenz et al., 2004; Miramon and Lorenz, 2016; Vieira et al., 2010). It is not known whether lactate and GlcNAc are used as nutrients within the phagosome or whether these metabolites serve as a host-derived signal that modulates virulence-associated functions. Clearly, growth with lactate as an alternative carbon source (as compared to glucose – the preferred carbon source) leads to a modulated cell wall architecture and increased stress resistance of *C. albicans* (Ene et al., 2012). It remains to be elucidated whether these phenotypes occur inside macrophages and whether they affect the intraphagosomal lifestyle of *C. albicans*. The uptake of GlcNAc through the Ngt1 transporter and GlcNAc signalling through Ngs1 induce the transcription of genes mediating hypha development and could thus support escape of *C. albicans* from macrophages (Alvarez and Konopka, 2007; Su et al., 2016).

Similar to *C. albicans*, membrane transporter-encoding genes of *Cr. neoformans* are induced upon internalization by macrophages. This mainly includes carbohydrate and polyol transporters as well as ammonia and amino acid permeases, indicating a restriction in nutrient availability encountered by intracellular *Cr. neoformans* cells (Derengowski Lda et al., 2013; Fan et al., 2005).

In summary, the utilization of carbohydrates is less investigated compared to amino acids, but it seems clear that all pathogens require carbohydrates for different anabolic (gluconeogenesis or PP pathway) or catabolic processes (glycolysis or ED pathway).

#### 4.3. Lipids

*M. tuberculosis* can feed well on host lipids within macrophages and metabolises fatty acids via  $\beta$ -oxidation and the glyoxylate cycle (Barisch and Soldati, 2017).  $\beta$ -oxidation can facilitate adaptation of *M. tuberculosis* to changing metabolite conditions during infection (Toledo and Benach, 2015). The glyoxylate cycle is essential to synthesize  $C_4$ -intermediates for the TCA cycle and gluconeogenesis, when acetyl-CoA is produced by fatty acid degradation in the absence of glucose. Cholesterol, a distinctive host membrane lipid, is not only essential for uptake of *M. tuberculosis* by macrophages, but also essential for survival within lysosomes (Gatfield and Pieters, 2000). *M. tuberculosis* requires the import system Mce4 and the catabolism of steroid rings to use cholesterol as a carbon source during its intracellular lifestyle in activated macrophages (Crowe et al., 2017; Pandey and Sassetti, 2008). Cholesterol breakdown generates acetyl-CoA and propionyl-CoA. Propionyl-CoA needs to be detoxified via the methylcitrate cycle or the methylmalonyl pathway. Both pathways supply TCA cycle intermediates that are used for energy generation (Munoz-Elias et al., 2006; Savvi et al., 2008). In addition, propionyl-CoA is used for the biosynthesis of methyl-branched long chain fatty acids, which are incorporated into virulence-associated bacterial cell wall lipids (Lee et al., 2013; Russell et al., 2010). Host phagosomal sphingomyelin is cleaved by *M. tuberculosis* through the activity of an outer membrane sphingomyelinase. As this enzyme is necessary for intraphagosomal replication of *M. tuberculosis*, the pathogen likely uses sphingomyelin as a carbon, nitrogen and phosphorus source (Speer et al., 2015). On the other hand, phospholipids can also serve as a carbon and energy source for intracellular growing *M. tuberculosis*, by degradation through cell wall anchored phospholipase C (PLC), which has its expression up-regulated during infection of macrophages (Raynaud et al., 2002). However, it seems as PLCs are only marginally required for virulence, and the up-

regulation of PLCs during intracellular phases of *M. tuberculosis* might rather be linked to a phosphate-limited phagosomal compartment (Le Chevalier et al., 2015).

Fatty acids catabolism of *S. enterica* is up-regulated in the murine infection model (Steeb et al., 2013), while transcriptional profiling of *Salmonella* in macrophages did not indicate a specific response to fatty acids as a nutrient source (Eriksson et al., 2003). As discussed for carbohydrates, the metabolic flexibility may allow intracellular *Salmonella* to readily switch between carbohydrates, fatty acids and further nutritional sources depending on local availability and preference.

Presumably, other intracellular pathogens can also use host lipids as an additional nutrient source via lipases or other lipid degrading enzymes. For example, transcriptional analysis of *C. albicans* engulfed by macrophages revealed an up-regulation of secretory lipase and phospholipase genes (Lorenz et al., 2004). An intracellular growth defect of a *Cr. neoformans* mutant lacking a phospholipase B (*plb1A*) suggested that the degradation of host phospholipids may promote intracellular proliferation (Evans et al., 2015). One earlier study suggests that *Cr. neoformans* can in fact use lipids derived from macrophages by phospholipase B (Wright et al., 2007).

## 5. Utilization of micronutrients during the intracellular lifestyle

### 5.1. Trace metals

Trace metals are often cofactors of transcription factors (zinc finger proteins) or enzymes, and trace metal limitation leads to dys- or non-functional proteins. Iron-sulphur clusters are essential for the enzymatic activity of essential metabolic enzymes such as aconitase, catalyzing the conversion of citrate into isocitrate (Miller and Auerbuch, 2015). Zinc has an important role as a structural and catalytic cofactor of many proteins, mainly transcription factors or enzymes, which function in diverse biological processes (Capdevila et al., 2016). Copper and manganese predominantly fulfil catalytic functions in superoxide detoxifying enzymes (SODs), cytochrome c oxidases (COXs) and DNA synthesis (Besold et al., 2016; Broxton and Culotta, 2016; Culotta et al., 2006; Juttukonda and Skaar, 2015). In contrast, high levels of iron, zinc or copper can lead to cell-toxic effects by generation of toxic radicals damaging DNA. For example, excess zinc can antagonize the uptake of other trace metals and can inhibit key enzymes by displacing other metals (Besold et al., 2016; Djoko et al., 2015). Consequently, trace metals are essential for both host and pathogen, and there is a constant tug of war for trace metals in the human body during infection. Thus, metal homeostasis is crucial and the metabolism of trace metals has to be tightly regulated. Within the host, micronutrients are often limited, and the host restricts access to essential trace metals to prevent microbial growth, a process termed 'nutritional immunity' (Hood and Skaar, 2012).

In the last decades, the role of trace metals for survival and replication of intracellular pathogens within macrophages has been extensively studied. The host immune system has evolved multiple sequestration strategies to limit the availability of trace metals (iron, zinc and manganese) from invading microorganisms (reviewed by (Becker and Skaar, 2014; Johnson and Wessling-Resnick, 2012; Zackular et al., 2015)). On the other hand, metal intoxication, mainly with copper and zinc, is used as an antimicrobial strategy by the host (Besold et al., 2016; Djoko et al., 2015). Therefore, intracellular pathogens not only need efficient import of trace metals, they also require potent export systems to prevent toxicity.

Iron is the most prominent example of an inorganic micronutrient essential for growth of all organisms and virulence of most intracellular pathogens (summarized in (Crawford and Wilson, 2015; Leon-Sicairens et al., 2015; Neyrolles et al., 2015)), and depletion of iron from host macrophages diminishes intracellular growth of pathogens (Paradkar et al., 2008). Therefore, it is not surprising that many intracellular pathogens can express high affinity uptake systems that compete with

host iron binding proteins. These high affinity uptake systems are highly regulated and encompass the (1) reductive pathway to exploit ferric iron from iron-chelating proteins or the environment, (2) receptor-mediated uptake of iron-containing hemoproteins from the host (hemoglobin, transferrin, lactoferrin) and (3) the siderophore-mediated iron acquisition (Leon-Sicairos et al., 2015).

Genetic or chemical inactivation of either high affinity transporter systems or transcription factors regulating the transport system often reduces intracellular fitness, as shown for *L. pneumophila* (Portier et al., 2015), *C. glabrata* (Seider et al., 2014; Srivastava et al., 2014), *H. capsulatum* (Hilty et al., 2011; Hwang et al., 2008; Newman and Smulian, 2013), *F. tularensis* (Perez and Ramakrishnan, 2014; Ramakrishnan et al., 2012) and *M. tuberculosis* (De Voss et al., 2000; Rodriguez and Smith, 2006). Iron availability is also critical for intracellular *S. enterica*. *Salmonella* processes several iron uptake systems such as EntC or Feo and can synthesize several siderophores. Transcriptomic analyses showed that in the J774-A.1 macrophage line derived from NRAMP1<sup>-/-</sup> mice, iron uptake systems are down-regulated suggesting non-limited iron supply. This situation is different in macrophages from NRAMP1<sup>+/+</sup> donors and especially in activated macrophages (Nairz et al., 2009) suggesting a key role for NRAMP1 in iron restriction. For example, NRAMP1 function is linked to expression of lipocalin-2 and antimicrobial peptides restricting the availability of iron-loaded siderophores (Nairz et al., 2015a). In addition, intracellular pathogens manipulate the host metabolism to acquire iron. For example, phagocytosed *M. tuberculosis* recruits holotransferrin to the phagosome and this molecule is internalized across the mycobacterial cell wall to acquire iron (Boradia et al., 2014). Upon filamentous growth, *C. albicans* expresses the multifunctional protein Als3 on the cell surface, which enables the fungus to utilize iron from host ferritin (Almeida et al., 2008; Liu and Filler, 2011). However, it is unclear whether this utilization pathway plays a role during interaction with macrophages. Recently it was shown that the disruption of the siderophore transporter LbtP and the resulting iron limitation response lead to a premature escape of *L. pneumophila* from infected cells (O'Connor et al., 2016). This example shows that *L. pneumophila* iron acquisition inside macrophages promotes intracellular survival and replication (Portier et al., 2015), while conditions that further lower iron availability or uptake options may drive the escape of the pathogen from its intracellular niche. Siderophore-mediated iron acquisition by Sit1 also improves intracellular survival of *C. glabrata* within macrophages (Nevitt and Thiele, 2011).

Besides iron restriction, zinc and manganese are sequestered by vertebrates intra- and extracellularly to protect against infection thus contributing to nutritional immunity (Kehl-Fie and Skaar, 2010).

Bacterial pathogens have evolved strategies to deal with low zinc concentrations by a zinc-responsive ZnuABC transport system (Cerasi et al., 2013), but so far there are rare observations that this system is essential, e.g. in *Salmonella* (Ammendola et al., 2007).

Accumulation of zinc and copper within *M. tuberculosis*-containing phagosomes is used by the host to intoxicate the microbe (Botella et al., 2012; Soldati and Neyrolles, 2012). Similarly to *M. tuberculosis*, the supplementation of macrophages with zinc reduces the ability of *L. monocytogenes* to replicate and a combination with vitamin A enhances the antimicrobial activity (Castillo et al., 2015). Interestingly, the pro-inflammatory stimulation of macrophages with IFN- $\gamma$  induces the recruitment of host cell transporters, like ATP7A and ZnT1, to the phagosome thereby increasing the concentration of toxic metals (Soldati and Neyrolles, 2012; White et al., 2009). Nevertheless, *M. tuberculosis* resists metal intoxication by expressing several efflux pumps of the P-type ATPase class and an inactivation of these efflux pumps affects intracellular survival and growth (Botella et al., 2011; Neyrolles et al., 2013; Rowland and Niederweis, 2012; Ward et al., 2010).

Fungal pathogens like *C. albicans* and *Cr. neoformans* activate the expression of zinc importers, and the zincophore Pra1 in the case of *C. albicans*, after engulfment by macrophages, indicating a zinc-restricted

intracellular environment (Cituelo et al., 2012; Do et al., 2016; Lorenz et al., 2004; Marcil et al., 2008). In line with this, the induction of zinc restriction in macrophages by GM-CSF induces export of zinc from the *Histoplasma*-containing phagosome and inhibits intracellular growth of *H. capsulatum*, while treatment with anti-inflammatory cytokines like Interleukin 4 (IL-4) increases zinc stores and promotes survival and persistence (Subramanian Vignesh et al., 2013; Subramanian Vignesh et al., 2016; Winters et al., 2010).

Excess of copper within the phagosome is used by host macrophages to kill ingested *M. tuberculosis* and an efficient detoxification system is required for *M. tuberculosis* cells to survive within the intraphagosomal compartment (Wolschendorf et al., 2011). The increased copper sensitivity combined with slow growth within macrophages of a strain lacking *SUR7* in *C. albicans* suggests that copper detoxification is important for survival within the *Candida*-containing phagosome (Douglas et al., 2012). Intriguingly, *C. albicans* possesses a P-type ATPase encoded by *CRP1*, mediating copper resistance. However, it is unclear, whether this efflux pump plays a role within the phagosomal compartment (Weissman et al., 2000). The survival of *Cr. neoformans* in macrophages is dependent on a balanced copper homeostasis, mediated by a Cuf1-induced expression of the copper transporter gene *CTR4* and the copper-detoxifying metallothionein genes *CMT1/2* (Ding et al., 2013; Waterman et al., 2007; Waterman et al., 2012). Pathogenic microorganisms possess a redundant manganese transport system (MntH in bacteria and Smf1/2 in fungi (Juttukonda and Skaar, 2015; Reddi et al., 2009)). The active expulsion of manganese through host NRAMP1 from the phagosome suggests that intraphagosomal pathogens require uptake of this trace element, and the host is limiting its availability (Juttukonda and Skaar, 2015). So far, however, the necessity of manganese import within macrophages has only been shown for *Shigella flexneri* (Runyen-Janecky et al., 2006). In contrast, the requirement of manganese acquisition systems is well studied for several extracellular-localized pathogens, which reside in an environment restricted for manganese due to sequestration by host calprotectin (Juttukonda and Skaar, 2015; Lisher and Giedroc, 2013).

The murine model for systemic *S. enterica* infections, i.e. mimicking typhoid fever, uses *Salmonella*-sensitive mouse strains such as C57BL/6 or BALB/c. These strains are NRAMP1-deficient and cannot control the proliferation of *Salmonella* in systemic sites. In contrast, NRAMP1-proficient strains are able to control the infection and much higher dose of *Salmonella* inoculums are required to induce systemic disease. Based on these observations, availability of zinc, iron, and further divalent cations is likely to be a limiting factor for intracellular growth of *Salmonella* (Nairz et al., 2009).

## 5.2. Vitamins

Some vitamins are essential for intracellular pathogens due to intrinsic auxotrophies. For example, *L. monocytogenes* requires lipoate (O'Riordan et al., 2003) and *C. glabrata* is auxotrophic for niacin (Ma et al., 2007). Vitamins are synthesized by many bacteria, fungi and plants, but rarely by mammals, which thus need to assimilate essential vitamins from the daily food and host cells express vitamin-specific transporters (Suzuki and Kunisawa, 2015). Within pro- and eukaryotic cells, vitamins execute diverse cellular functions (Suzuki and Kunisawa, 2015; Zempleni et al., 2009). Therefore, host cells and invading pathogens, including intracellular pathogens, have to acquire or synthesize essential vitamins.

To date the number of studies dealing with the importance of microbial vitamin acquisition or synthesis for intracellular fitness is low. Recent studies, however, show that bacterial and fungal mutants that lack certain vitamin-biosynthetic pathways are attenuated in intracellular fitness. While *H. capsulatum* requires the biosynthesis of riboflavin for intracellular proliferation in macrophages (Garfoot et al., 2014), *Mycobacterium marinum*, a fish and amphibian pathogen (Tobin and Ramakrishnan, 2008), needs its own biotin biosynthesis for

Fig. 1. Examples of metabolic pathways adopted by different facultative intracellular fungal (left) and bacterial (right) pathogens during intracellular stages within macrophages and discussed in this review. Different fungal and bacterial pathogens enter the phagosomal compartment of macrophages after engulfment. Left: *C. albicans*, *C. glabrata*, *H. capsulatum*, and *Cr. neoformans* can grow and replicate within a membrane-surrounded intracellular compartment. While capsulated *Cr. neoformans* cells can escape from their intracellular compartments via expulsion into the extracellular space (not shown), *C. albicans* can escape via hyphae, thereby piercing the phagosomal and cell membrane. All fungal pathogens activate a starvation mode and induce pathways to utilize alternative carbon sources.

Right: After phagocytosis, *S. enterica* and *L. pneumophila* redirect the host cell endosomal transport machinery to create their own nutrient-optimized intracellular compartment (SCV or LCV; indicated by the blue and green dots, respectively). Initially, *L. monocytogenes* and *F. tularensis* enter the phagosome, but rapidly escape into the nutrient rich host cell cytosol, thereby also avoiding phagosomal antimicrobial activities. *M. tuberculosis* resides within the phagosome, arrests the maturation into a phagolysosome and is able to acquire different host nutrient sources to replicate within the phagosome. ED, Entner-Doudoroff; EMP, Embden-Meyerhof-Parnas; LCV, *Legionella*-containing vacuole; PP, pentose phosphate; SCV, *Salmonella*-containing vacuole; TCA, tricarboxylic acid.

proliferation within macrophages (Yu et al., 2011). Biotin biosynthesis also contributes to virulence and escape of *F. tularensis* from the phagosome into the cytosol. Phagosomal escape in turn is essential for this pathogen to assimilate nutrients for proper growth (Feng et al., 2015; Feng et al., 2014; Napier et al., 2012). This implies that the availability of at least certain vitamins is limited to different classes of pathogens in macrophages. The uptake of lipoic acid, a cofactor required for enzymatic activity of pyruvate dehydrogenase, is essential for intracellular multiplication of *L. monocytogenes*, indicating a necessity of this enzymatic reaction for intracellular stages (O'Riordan et al., 2003). As a prototrophic organism, *S. enterica* does not depend on the supply of vitamins or their organic precursors from macrophages. Indeed, the attenuation of mutant strains defective in respective biosynthesis pathways indicate that this pathogen may not have evolved strategies to sequester vitamins from the macrophage host cell (Bäumler et al., 1994).

A specific strategy for nutrition of intracellular pathogens is the biogenesis of specific compartments that alleviate nutritional restrictions encountered in the canonical endocytic pathway. Two prominent examples are *L. pneumophila* and *S. enterica*, both forming pathogen containing vacuoles with unique properties. *Legionella* inhabits a vacuole with markers characteristic for endosomes, macropinosomes and endoplasmic reticulum (ER) (Finsel and Hilbi, 2015). This unique compartment is formed by the action of effector proteins transported via the Icm/Dot type IV secretion system, resulting in deviation of the

normal phagosomal maturation process and atypical fusion events, such as fusions with the ER. The unique environment of the LCV provides a range of nutrients for the intracellular replication of the pathogen (Manske and Hilbi, 2014). Several host cell transporters for amino acids, carbohydrates or fatty acids remain present in the LCV membrane and mediate transport into the LCV lumen. In addition, *Legionella* secretes various hydrolytic enzymes into the lumen of LCV, resulting in degradation host molecules for subsequent uptake by the pathogen.

*S. enterica* deploys the SPI2-T3SS and a cocktail of about 30 effector proteins to manipulate various mechanisms of the host cell (LaRock et al., 2015). A subset of these effector proteins, most prominently SifA, interferes with the function of microtubule motor proteins. This manipulation leads to recruitment of various endosomal compartments to the SCV and their fusion. These events allow the continuous extension of the SCV to accommodate the growing intracellular *Salmonella* population. Furthermore, various types of tubular vesicular extensions are formed, for example *Salmonella*-induced filaments or (SIF) (Liss and Hensel, 2015). Recent work by Liss et al. demonstrated that SCV and SIF form an interconnected network with rapid interchanges of membranes and luminal content. The formation of this network allows *Salmonella* to access nutrients present in the lumen of the redirected and fused vesicles (Liss et al., 2017).

In summary, successful intracellular pathogens have evolved efficient acquisition mechanisms to compete with the host for essential trace metals and vitamins. In contrast to other nutrients, high amounts

of iron, copper and zinc appear to be toxic for intracellular pathogens and are actively pumped into the pathogen-containing compartment. Thus, intracellular pathogens also require detoxification systems. Further, intracellular pathogens have different requirements for vitamins due to intrinsic auxotrophies and incomplete biosynthesis gene clusters, respectively. Therefore, some pathogens require efficient uptake systems hijacking vitamins from the host or rely on their own biosynthesis.

## 6. Conclusions

In this review we summarized the current knowledge on how different intracellular pathogens are specifically adapted to the metabolic conditions of the phagosomal compartment as well as the cytosolic environment with a focus on species-specific needs regarding specific nutrients utilized for intracellular adaptation and replication (summarized in Fig. 1). Despite these species differences, fungal pathogens seem to share a common transcriptional response leading to repression of energy consuming processes like protein biosynthesis and activation of alternative carbon- and nitrogen assimilation pathways (Fig. 1).

Studying strategies of nutrient deprivation as an antimicrobial mechanism of macrophages to restrict microbial transmission is more challenging than the search for toxic and microbicidal activities of macrophages. Due to different intracellular trafficking stages and fusion-events with other organelles or even the escape from a membrane-surrounded compartment, the availability of nutrients and the requirement could differ dramatically. Several studies observed that intraphagosomal pathogens employ nutrient acquisition strategies suggesting that the phagosome represents a niche with limited nutrient supply. However, the phagosome is not completely nutrient restricted. Amino acids seem to be a main nutrient source for all intracellularly adapted pathogens and can function as a regulatory signal for the pathogen. Additionally, carbohydrates, lipids and micronutrients are used to directly generate energy or maintain metabolic fluxes for anabolic purposes.

The struggle for nutrients at the host-pathogen interface has put evolutionary pressure on intracellular pathogens to evolve powerful microbial acquisition systems. Effective nutrient acquisition from the host is essential to successfully maintain the metabolism of the pathogen as a prerequisite to survive and replicate within this niche. Therefore, therapeutic strategies to selectively inactivate these acquisition pathways are promising options for the development of antimicrobial drugs.

## Acknowledgments

This work was supported by the Deutsche Forschungsgemeinschaft SPP1580 “Intracellular Compartments as Places of Pathogen – Host Interaction” (Hu528/15-1, 16-1, 16-2 to BH and HE1964/18-1, 18-2 to MH). We thank all members of the priority program for many helpful discussions.

### Fungal biotin homeostasis is essential for immune evasion after macrophage phagocytosis and virulence

**Marcel Sprenger**, Teresa Sofie Hartung, Stefanie Allert, Stephanie Wisgott, Maria Joanna Niemiec, Katja Graf, Ilse D. Jacobsen, Lydia Kasper and Bernhard Hube

Cell Microbiol. 2020 Feb 21;e13197.

doi: 10.1111/cmi.13197.

#### Summary

The vitamin biotin is essential for all organisms, including human pathogenic microbes like fungi of the genus *Candida* as well as their mammalian hosts. *Candida* spp. are auxotrophic for this vitamin and must thus possess an efficient uptake system to allow biotin acquisition during infection. This study characterized a conserved metabolic pathway facilitating biotin homeostasis in two medically important *Candida* species, *C. albicans* and *C. glabrata*.

Biotin-related genes are upregulated upon phagocytosis by macrophages and the transcription factor Vhr1 is mainly involved in this regulation. The intracellular proliferation of both *Candida* species was reduced by biotin pre-starvation and deletion of *VHR1* or the biotin importer gene *VHT1*. Moreover, *VHT1* was essential for full virulence of *C. albicans* and the colonization of certain mouse organs. This study showed the first time biotin acquisition of *C. albicans* and *C. glabrata* mediated by Vht1 is linked to immune evasion and virulence.

#### Own contribution

Marcel Sprenger planned, performed and evaluated all experiments, interpreted the data of following experiments: construction of deletion and complementation strains (*Cgvhr1*Δ, *Cgvhr1*Δ - *CgVHR1*, *Cgvht1*Δ, *Cgvht1*Δ - *CgVHT1*, *Cavht1*Δ/Δ, and *Cavht1*Δ/Δ - *CaVHT1*), their verification by PCR and Southern blot, growth and filamentation assays in different formats, RNA isolation and qRT-PCR, macrophage confrontation assays and animal experiments. The co-authors assisted in the generation and verification of mutant strains, the design and conceptualization of the study, the application and performance of the animal experiments, and editing of the initial manuscript. Marcel Sprenger wrote the manuscript and generated all figures.

**Abstract**

Biotin is an important cofactor for multiple enzymes in central metabolic processes. While many bacteria and most fungi are able to synthesise biotin *de novo*, *Candida* spp. are auxotrophic for this vitamin and thus require efficient uptake systems to facilitate biotin acquisition during infection. Here we show that *Candida glabrata* and *Candida albicans* use a largely conserved system for biotin uptake and regulation, consisting of the high-affinity biotin transporter Vht1 and the transcription factor Vhr1. Both species induce expression of biotin-metabolic genes upon *in vitro* biotin depletion and following phagocytosis by macrophages, indicating low biotin levels in the *Candida*-containing phagosome. In line with this, we observed reduced intracellular proliferation of both *Candida* cells pre-starved of biotin and deletion mutants lacking *VHR1* or *VHT1* genes. *VHT1* was essential for the full virulence of *C. albicans* during systemic mouse infections, and the lack of *VHT1* led to reduced fungal burden in *C. glabrata*-infected brains and *C. albicans*-infected brains and kidneys. Together, our data suggest a critical role of Vht1-mediated biotin acquisition for *C. glabrata* and *C. albicans* during intracellular growth in macrophages and systemic infections.

**1 | INTRODUCTION**

The ability to acquire macronutrients, such as carbon and nitrogen sources, and micronutrients, such as trace metals and vitamins, is of vital importance for all organisms. Vitamins, although required in very small quantities, are involved in numerous cellular processes (Combs & McClung, 2017; Dakshinamurti, 2005). During microbial infections,

vitamin availability becomes important at the host–pathogen interface. On one hand, the host vitamin status is important for immune functions, on the other hand, pathogens need to synthesise or acquire vitamins in order to proliferate in the host (Combs & McClung, 2017; Mikkelsen, Stojanovska, Prakash, & Apostolopoulos, 2017; Stephensen, 2001). In this study, we investigate the requirement of biotin (vitamin H or vitamin B7) for human pathogenic *Candida* species. This vitamin is known to be crucial for key metabolic pathways, like gluconeogenesis and amino acid and fatty acid metabolism, which require the activity of

biotin-dependent carboxylases (Knowles, 1989; Tong, 2013; Zemleni, Wijeratne, & Hassan, 2009).

While mammals need to take up biotin as part of their diet (Zemleni et al., 2009), many bacterial and fungal pathogens are able to synthesise biotin *de novo* (Garfoot, Zemska, & Rappleye, 2014; Magliano, Flipphi, Sanglard, & Poirier, 2011; Magnusdottir, Ravcheev, de Crecy-Lagard, & Thiele, 2015; Napier et al., 2012; Saemae, Booker, & Polyak, 2016). In contrast, yeasts belonging to the *Candida* genus, including opportunistic pathogens (Pfaller & Diekema, 2007), are biotin auxotrophs (Littman & Miwatani, 1963; McVeigh & Bell, 1951). Medically important *Candida* spp. colonise the oral cavity, urogenital, or gastrointestinal tract as harmless commensals (Huffnagle & Noverr, 2013), but can also cause disease ranging from superficial mucosal to systemic infections with dissemination throughout the body and infection of internal organs (Odds, 1988). *Candida albicans* is the most prevalent cause of systemic candidiasis, followed by *Candida glabrata* and other non-*albicans* *Candida* species (Horn et al., 2009; Lindberg, Hammarstrom, Ataollahy, & Kondori, 2019).

The fact that *Candida* species are successful pathogens despite biotin-auxotrophy and blocking biotin biosynthesis in fungi like *Histoplasma capsulatum* or *Aspergillus nidulans* does not reduce virulence (Garfoot et al., 2014; Purnell, 1973), suggests that there is sufficient biotin in the host to allow normal growth and virulence of fungal pathogens (Meir & Osherov, 2018). These findings, however, also implicate that fungal pathogens, especially *Candida* species, must possess efficient uptake systems to acquire biotin during infection. This may be especially challenging in nutrient-poor host compartments, like the macrophage phagosome. Macrophages are important effectors of the innate immune system, which can recognise, ingest, and kill microbes including *Candida* species (Erwig & Gow, 2016; Miramón, Kasper, & Hube, 2013). The compartmentalisation in phagosomes is assumed to be a major mechanism to control microbial growth by increasing the efficiency of antimicrobial activities, but also by restricting nutrients (Haas, 2007; Sprenger, Kasper, Hensel, & Hube, 2017). Indeed, transcriptional profiling of fungal responses to macrophage phagocytosis suggests that *C. albicans* and *C. glabrata* experience nutrient limitation inside the phagosome (Chew et al., 2019; Childers et al., 2016; Kaur, Ma, & Cormack, 2007; Lorenz, Bender, & Fink, 2004; Roetzer, Gratz, Kovarik, & Schüller, 2010). Both *C. albicans* and *C. glabrata*, however, can adapt to macrophage antimicrobial activities and phagosomal nutrient conditions, proliferate intracellularly, and escape from these phagocytes (Miramón et al., 2013). Survival strategies, although sharing basic concepts, differ between the two species. Phagocytosed *C. albicans* yeast cells rapidly start to form hyphae, damage macrophage membranes, and escape after host cell death and via hyphal outgrowth (Kasper et al., 2018; McKenzie et al., 2010; Vylkova & Lorenz, 2014; Westman, Moran, Mogavero, Hube, & Grinstein, 2018). In contrast, *C. glabrata* replicates as yeast cells, is able to persist intracellularly for several days without causing damage, and finally escapes from macrophage by unknown mechanisms (Kaur et al., 2007; Seider et al., 2011).

In this study, we investigated the relevance of biotin acquisition of *C. albicans* and *C. glabrata* for growth, during interaction with macrophages, and systemic infection.

## 2 | RESULTS

### 2.1 | Pathogenic *Candida* species require biotin or biotin precursors for growth

While many bacterial and fungal species are able to synthesise the essential vitamin biotin *de novo*, most multicellular eukaryotes (excluding plants) and many yeasts are biotin auxotrophic (Roje, 2007). To find out how different medically important *Candida* species cope with biotin limitation, we analysed growth of *C. albicans*, *C. glabrata*, *C. dubliniensis*, *C. parapsilosis*, *C. tropicalis* and *C. auris* in minimal medium lacking biotin or containing different biotin sources. As expected, all tested species grew well in the presence of biotin, but showed drastically reduced growth rates in the absence of biotin (Figures 1a,b and Figure S1). Growth defects in biotin-depleted media were more pronounced when *C. albicans* and *C. glabrata* were pre-starved in biotin-free medium prior to the experiment, suggesting that both yeasts can use biotin from intracellular stores (Figure 1b). In host niches like the gut, which are colonised by multiple microbes of the microbiota, *Candida* cells may have access to biotin biosynthesis intermediates such as 7-keto-8-aminopelargonic acid (KAPA) or des-thiobiotin (DTB) produced by these other microbes (Hill, 1997). While *C. albicans* and *C. tropicalis* grew in the presence of either KAPA or DTB, *C. dubliniensis* and *C. auris* only grew in the presence of DTB, and *C. glabrata* and *C. parapsilosis* were unable to effectively utilise these biotin intermediates (Figures 1a,b and S1a).

*Candida albicans*, in contrast to *C. glabrata*, is a polymorphic fungus that can grow as yeast or hyphae depending on the environmental conditions (Sudbery, 2011). The induction of germ tubes was unaffected by biotin pre-starvation or the availability of biotin, DTB or KAPA (Figure 1c). However, filament elongation was significantly reduced in medium lacking biotin or its precursors, as seen by reduced hyphal length after 4 hr with pre-starved *C. albicans* cells (Figure 1d) and reduced size of hyphal microcolonies after 24 hr (Figure 1e).

Mammalian cells can recycle biotin by proteolytic digestion of biotinylated proteins, releasing biocytin, which is further degraded to lysine and biotin (Zemleni, Hassan, & Wijeratne, 2008). To determine whether *Candida* spp. cells are able to utilise these potential host biotin sources, we analysed the growth of *C. albicans* and *C. glabrata* in the presence of biotinylated BSA or biocytin. Indeed, both species grew in the presence of biotinylated BSA or biocytin (Figure S1b).

Of note, biotin is not essential under all growth conditions. We found that the growth defect of *C. glabrata* and *C. albicans* in the absence of biotin was partly rescued when aspartate was added as a nitrogen source instead of ammonium sulfate (Figure S1c) or when casamino acids were present as the sole carbon and nitrogen source (Figure S3b,d). In fact, aspartate can be converted to the central metabolite oxaloacetate in a biotin-independent reaction (Yagi,

**FIGURE 1** *Candida* spp. are auxotrophic for biotin. Yeast growth of (a) biotin non-starved (pre-cultured in YPD) or (b) biotin pre-starved (pre-cultured in biotin-free minimal medium) *Candida* cells in minimal medium containing biotin or biotin precursors (2 µg/L) or no biotin (w/o supplement) at 30°C. (c–e) Hyphal growth of non-starved or pre-starved *Candida albicans* cells in RPMI1640 containing biotin or biotin precursors (2 µg/L) or no biotin (w/o supplement) at 37°C and 5% CO<sub>2</sub>. (c) Percentage of germ tube-forming cells at 2 hr. (d) Hyphal length at 4 hr (mean ± SD of individual hyphae from three replicates). (e) Microcolony size at 24 hr, as a measure for long-term hypha formation (each single dot represents one individual microcolony). Values are represented as mean ± SD (a,b) or mean + SD (c–e) of at least three replicates. For statistical analysis, a repeated measures ANOVA with Bonferroni's multiple comparison test was used (\* $p \leq .05$ , \*\* $p \leq .01$ , \*\*\* $p \leq .001$ ; comparing biotin or precursor supplementation to control w/o supplement and ### $p \leq .001$ ; comparing non-starved to pre-starved cells)

Kagamiyama, & Nozaki, 1982). This likely bypasses the need of the biotin-dependent pyruvate carboxylase for production of oxaloacetate by carboxylation of pyruvate (Ruiz-Amil, De Torriontegui, Palacian, Catalina, & Losada, 1965).

These data show that, under standard culture conditions, the presence of biotin, its precursors, or potential host biotin sources are essential for the growth of different pathogenic *Candida* species.

## 2.2 | *C. glabrata* and *C. albicans* genomes contain potential biotin-metabolic and regulatory genes

Biotin acquisition, biosynthesis, and regulation of these processes have been described in the model yeast *Saccharomyces cerevisiae* (Phalip, Kuhn, Lemoine, & Jeltsch, 1999; Stolz, 2009; Stolz, Hoja, Meier, Sauer, & Schweizer, 1999; Weider, Machnik, Klebl, & Sauer, 2006). To identify genes necessary for biotin acquisition and the maintenance of biotin homeostasis in the most frequently isolated *Candida* species, *C. glabrata* and *C. albicans*, we searched the genomes of these species for potential orthologs of *S. cerevisiae* biotin-related genes.

The biotin biosynthesis pathway was completely lost in the last common ancestor of *Candida* and *Saccharomyces* species, but has been partially rebuilt through horizontal gene transfer from bacterial

species, resulting in the *S. cerevisiae* *BIO2-5* incomplete biotin biosynthesis cluster which allows biotin synthesis from the precursor KAPA or DTB (Fitzpatrick, O'Gaora, Byrne, & Butler, 2010; Hall & Dietrich, 2007; Figure 2a). The *C. albicans* genome contains potential orthologs of the *S. cerevisiae* genes encoding the enzymes Bio2, Bio3 and Bio4 (CR\_01930C, *CaBIO2*; CR\_01920W, *CaBIO3*; CR\_01910C, *CaBIO4*) (Fitzpatrick et al., 2010; Figures 2b and Figure S4). Although *C. glabrata* is more closely related to *S. cerevisiae* than to *C. albicans*, we did not identify potential Bio2-4 orthologs in this yeast, indicating a loss of biotin biosynthetic genes (Figure 2b). Orthologs of the potential KAPA and 7,8-Diaminopelargonic Acid (DAPA) transporter Bio5 (Phalip et al., 1999), however, were identified in both genomes (CR\_01900C and CAGL0H03399g). The uptake of biotin or its precursor, DTB, is facilitated by the *S. cerevisiae* high-affinity H<sup>+</sup>-biotin symporter, Vht1 (vitamin H transporter 1) (Stolz et al., 1999). We found two putative *C. glabrata* orthologs (CAGL0K04609g, CAGL0K04565g), while the two best hits in *C. albicans* were CR\_06790C and CR\_06660W (Figure 2b). In addition, *C. albicans* CR\_03270W has recently been described as a putative biotin transporter gene (Gaur et al., 2008). All potential orthologs contain 10–12 putative transmembrane helices, a feature common in plasma membrane transporters (Sonnhammer, von Heijne, & Krogh, 1998). To narrow down potential functional orthologs of biotin or biotin precursor transporter genes, we analysed gene expression in *C. albicans* and *C. glabrata* at different biotin levels

**FIGURE 2** *In silico* identification of biotin transport, biosynthesis and regulatory genes. (a) Overview of *S. cerevisiae* biotin biosynthesis, transport and gene regulation. The incomplete biotin biosynthesis pathway consists of Bio5 (transporter for KAPA and DAPA), the metabolic enzymes Bio3 (7,8-diamino-pelargonic acid aminotransferase), Bio4 (desthiobiotin synthetase) and Bio2 (biotin synthase). The uptake of biotin (or DTB) from the environment is facilitated by the high-affinity transporter Vht1 (vitamin H transporter 1). The transcription factor Vhr1 regulates the expression of *BIO*-genes and *VHT1* in response to biotin availability. Biotin is covalently linked to biotin-dependent proteins (BDP) by the activity of Bpl1 (biotin:apoprotein ligase 1). The scheme is adapted from Stolz (2009). (b) Putative orthologs of *S. cerevisiae* biotin-related genes in *Candida glabrata* and *Candida albicans*. Gene names in brackets showed no biotin-dependent regulation (see Figure S2) and were excluded from further analysis

(Figure S2). Of the potential ScVHT1 orthologs, only the *C. glabrata* gene CAGL0K04609g (*CgVHT1*) and the *C. albicans* gene CR\_03270W (*CaVHT1*) showed clear biotin-dependent expression (Figure S2). In addition, the potential *C. albicans* ortholog (CR\_01900C, *CaBIO5*), but not the *C. glabrata* ortholog of ScBIO5, was induced upon biotin limitation (Figure S2). In *S. cerevisiae*, the expression of genes associated with biotin metabolism is induced by the transcriptional activator Vhr1 in response to low biotin (Weider et al., 2006). We found one potential ScVHR1 ortholog in *C. glabrata* and *C. albicans*—CAGL0M12496g (*CgVHR1*) and CR\_00630W (*CaVHR1*), respectively (Figure 2b). Both orthologs share a highly conserved N-terminal putative DNA-binding domain and a C-terminal putative activation domain with their *S. cerevisiae* ortholog (Weider et al., 2006). CAGL0M12496g is currently annotated as a pseudogene with a premature translational stop codon (<http://www.candidagenome.org/>). Sequencing of CAGL0M12496g in *C. glabrata* genomic DNA revealed a frameshift in comparison to the annotated sequence (four cytosines at ORF position 473–476 in the annotated sequence [Skrzypek et al., 2017], but only three cytosines in our strain, see Appendix S2). The predicted protein deduced from our sequence data lacks the early translational stop codon and has a similar length as the *S. cerevisiae* ortholog (689 and 640 amino acids, respectively; Appendix S2). Finally, the biotin protein ligase Bpl1 is needed for the transfer of biotin to biotin-accepting proteins in baker's yeast. The genes CAGL0I03806g (*CgBPL1*) and orf19.7645 (*CaBPL1*) represent potential orthologs in *C. glabrata* and *C. albicans*.

### 2.3 | VHT1 is essential for biotin-dependent growth of *C. glabrata* and *C. albicans*

To test whether *CgVHT1* and *CaVHT1* have a role in biotin acquisition, we generated deletion strains of the respective genes by targeted mutagenesis. Indeed, these strains were unable to grow in the presence of intermediate biotin levels (2 µg/L biotin) and required high amounts (2 mg/L) of this vitamin for growth comparable to that of the wildtype. A delayed growth was observed with elevated biotin concentrations (0.2 mg/L). The growth defect was restored after re-introduction of either *CgVHT1* or *CaVHT1* (Figure 3a,b). Similarly, *C. albicans* hyphal induction and extension after 2, 4 and 24 hr was significantly reduced in the *CaVht1Δ/Δ* mutant as compared to the wildtype in medium containing 2 µg/L or 0.2 mg/L of biotin (Figure 3c–e). Again, high amounts of biotin or reintegration of *CaVHT1* were able to restore wildtype-like filamentation. These data strongly indicate that *CgVHT1* and *CaVHT1* indeed encode biotin importers.

### 2.4 | Vhr1 is a transcriptional regulator of biotin-metabolic genes in *C. glabrata* and *C. albicans*

To elucidate whether *CgVhr1* and *CaVhr1* regulate biotin-related genes in *C. glabrata* and *C. albicans*, we analysed gene expression of potential target genes under biotin limitation (no biotin or 0.2 µg/L biotin) as compared to intermediate biotin levels (2 µg/L biotin) in wildtype strains and mutants lacking *CgVHR1* and *CaVHR1*. Both,

**FIGURE 3** *VHT1* is essential for biotin-dependent growth. Yeast growth of biotin pre-starved wt, mutant (*vht1Δ*), or complemented strain (*vht1Δ + VHT1*) of (a) *Candida glabrata* (37°C) or (b) *Candida albicans* (30°C) in minimal medium containing 2 µg/L, 0.2 or 2 mg/L biotin. (c–e) Hyphal growth of non-starved or pre-starved *C. albicans* cells in RPM11640 containing 2 µg/L, 0.2 or 2 mg/L biotin at 37°C and 5% CO<sub>2</sub>. (c) Percentage of germ tube-forming cells at 2 hr. (d) Hyphal length at 4 hr (mean + SD of individual hyphae from three replicates). (e) Microcolony size at 24 hr, as a measure for long-term hypha formation (each single dot represents one individual microcolony). Values are represented as mean ± SD (a,b) or mean + SD (c–e) of at least three replicates. For statistical analysis, a one-way ANOVA with Bonferroni's multiple comparison test was used (\*\*\*)*p* ≤ .001 comparing wt and *VHT1* deletion mutant; ###*p* ≤ .001 comparing *VHT1* deletion mutant to *VHT1* complemented strain)

*CgVHT1* and *CgBPL1* were induced upon biotin limitation in wildtype or the *CgVHR1*-complemented strain while *CgVHR1* itself was steadily expressed independent of the biotin levels. The up-regulation of *CgVHT1* and *CgBPL1* was almost abolished in the *Cgvhr1Δ* mutant (Figure 4a).

Similarly, *C. albicans*' incomplete biotin biosynthesis cluster genes *CaBIO2-5*, as well as *CaVHT1*, *CaBPL1* and *CaVHR1* showed the highest expression under biotin-limiting conditions in wildtype cells and the *CaVHR1*-complemented strain (Figure 4b). Expression of *CaBIO3*, *CaBIO4* and *CaBIO5* was strongly reduced in the absence of *CaVHR1*, while *CaVHT1* and *CaBIO2* expression was unaffected by *CaVHR1* deletion under biotin-limiting conditions and even increased in the presence of 2 μg/L biotin. *CaBPL1* showed a mixed expression pattern with slightly reduced expression in the *Cavhr1Δ/Δ* mutant

under biotin limitation, but higher expression in the presence of 2 μg/L biotin.

These data show that both *CgVhr1* and *CaVhr1* are important for the fungal response to environmental biotin availability. While *CgVhr1*, similar to its *S. cerevisiae* ortholog, activates genes associated with biotin import and intracellular transfer to proteins upon biotin limitation, *CaVhr1*-dependent activation seems to be limited to the biotin biosynthesis genes *CaBIO3-5*. Meanwhile, biotin uptake in *C. albicans* is reduced and depends on *CaVhr1* when sufficient environmental biotin is available.

*C. albicans* and *C. glabrata* mutants lacking *CgVHR1* and *CaVHR1* were further tested for growth under biotin limitation (0.2 μg/L biotin). In contrast to the deletion of *VHT1*, the deletion of *VHR1* did not lead to growth or hyphal defects under biotin limitation (Figure S3). In host

**FIGURE 4** *VHR1* regulates biotin-metabolic genes. Non-starved (a) *Candida glabrata* or (b) *Candida albicans* cells were cultivated in minimal medium with indicated biotin concentrations for 90 min (*C. glabrata*) or 180 min (*C. albicans*) at 37°C. Target gene expression was analysed by qRT-PCR and normalised to *CgACT1*, *CgEFB1*, *CgEFT2* and *CaTDH3*, *CaEFT2*. Values are represented as mean + SD of three independent experiments, whereby n-fold expression for each gene is shown relative to the wt in 2 μg/L biotin. For statistical analysis, a two-way ANOVA with Bonferroni post-tests was used (\* $p \leq .05$ , \*\* $p \leq .01$ , \*\*\* $p \leq .001$ ; comparing wt and *VHR1* deletion mutant; # $p \leq .05$ , ## $p \leq .01$ , ### $p \leq .001$ ; comparing *VHR1* deletion mutant to *VHR1* complemented strain; n.d., not detectable)

niches like the macrophage phagosome, *Candida* cells likely do not encounter their preferred carbon and nitrogen sources in high amounts, but rather alternative sources like amino acids (Kaur et al., 2007; Lorenz, 2013; Lorenz et al., 2004). Therefore, we combined biotin limitation with the presence of casamino acids as the sole carbon and nitrogen source, instead of the optimal nutrients glucose and ammonium sulfate. Under these conditions, the *Cgvrh1Δ* mutant grew less than the wildtype (Figure S3b), whereas the *Cavhr1Δ/Δ* mutant grew similarly to the wildtype (Figure S3g). This suggests that *C. glabrata* requires *CgVHR1* for growth under conditions that combine low biotin with limitations of optimal C- and N-sources.

## 2.5 | The fungal biotin pool influences intracellular fitness inside macrophages

Metabolic plasticity is essential for the adaptation of *Candida* species to the changing environment of different, often nutrient-limited, host niches including the macrophage phagosome (Lorenz, 2013; Miramón & Lorenz, 2017). Both *C. albicans* and *C. glabrata* are able to

survive macrophage phagocytosis and even replicate inside macrophages (*C. glabrata*, Seider et al., 2011) or form hypha and escape (*C. albicans*, McKenzie et al., 2010). Both species must have developed strategies to counteract macrophage killing activities, but also adapt to phagosomal nutrient conditions (Miramón et al., 2013). To elucidate how biotin impacts the fungal fitness inside macrophages, we first confronted biotin-starved (pre-incubation in medium without biotin) or biotin-fed (pre-incubation in medium with high biotin 2 mg/L) *C. glabrata* or *C. albicans* cells with primary human monocyte-derived macrophages (hMDMs). As a control, we used fungal cells pre-incubated in medium with intermediate biotin levels (2 µg/L) that are sufficient to promote growth. In macrophage confrontation assays, biotin pre-starvation increased the susceptibility of *C. glabrata* and *C. albicans* to phagocytosis-mediated killing (Figure 5a,c).

Moreover, biotin-starved *C. glabrata* cells were significantly reduced in intracellular replication in macrophages (Figure 5b) and biotin-starved *C. albicans* cells developed shorter filaments and showed reduced levels of hyphal outgrowth compared to fungal cells pre-cultivated with intermediate or high amounts of biotin (Figure 5d,e). To exclude that the observed effects were due to a

**FIGURE 5** Biotin pre-starvation reduces fungal fitness inside macrophages, while phagocytosis induces up-regulation of biotin-related *Candida* genes. (a,b) *Candida glabrata* or (c–e) *Candida albicans* cells were pre-cultivated in minimal medium without (biotin-starved), with 2 µg/L (control), or with 2 mg/L (biotin-fed) biotin before confrontation with human blood monocyte-derived macrophages (hMDMs). (a) Survival of *C. glabrata* after 3 hr (% of inoculum). (b) Intracellular replication of *C. glabrata* after 20 hr, shown as number of cell divisions –  $\log_2[1/1 - (\% \text{ daughter cells}/100)]$ . (c) Survival of *C. albicans* after 3 hr (% of inoculum). (d) Length of hyphae formed 10 hr after phagocytosis. (e) Outgrowth of *C. albicans* hyphae from macrophages after 10 hr (% of ingested hyphae piercing the macrophage membrane). (f) Survival in hMDMs (after 3 hr; % of inoculum) of *C. glabrata* cells pre-cultivated in minimal medium without (niacin-starved), with 0.4 mg/L (control) or with 400 mg/L (niacin-fed) niacin. (g,h) hMDMs were infected with non-starved (g) *C. glabrata* or (h) *C. albicans* cells and fungal RNA was isolated after 3 hr. Target gene expression was analysed by qRT-PCR and normalised to *CgACT1*, *CgEFT2* and *CaEFT2*, *CaACT1*. Expression is shown relative to wt (grown without hMDMs with 0.2 mg/L biotin). Values are represented as scatterplot with mean ± SD (a–c, e and f), with each single dot corresponding to one blood donor (total at least seven different donors in at least two independent experiments). Values in d, g and h are represented as mean + SD of individual hyphae from three replicates (d) or three replicates (g,h). For statistical analysis, a repeated measures ANOVA was performed followed by Dunnett's multiple comparison test (\*\* $p \leq .01$ , \*\*\* $p \leq .001$ ; compared to control condition)

general detrimental effect of vitamin limitation on fungus-macrophage interactions, we infected macrophages with *C. glabrata* cells pre-starved for niacin (nicotinic acid), a vitamin needed for *C. glabrata* to

overcome NAD<sup>+</sup> auxotrophy (Domergue et al., 2005). Nicotinic acid starvation did not reduce *C. glabrata* survival inside macrophages (Figure 5f), indicating that the observed effect of biotin starvation is

FIGURE 6 Legend on next page.

specific. Up-regulation of biotin homeostasis and biosynthesis genes after phagocytosis by macrophages suggests that *C. glabrata* and *C. albicans* indeed experience biotin limitation inside macrophages (Figure 5g,h). Combined, these data indicate that biotin is crucial for survival and proliferation of *C. glabrata* and *C. albicans* in macrophages and that biotin availability for *C. glabrata* and *C. albicans* upon macrophage phagocytosis is limited.

## 2.6 | VHR1 and VHT1 are essential for fungal fitness within macrophages

Next, we wanted to know whether disturbance of biotin uptake or biotin-dependent regulation would affect fungal fitness after macrophage phagocytosis. Therefore, we confronted hMDMs with biotin-fed *C. glabrata* or *C. albicans* *VHT1* and *VHR1* knockout strains and evaluated survival and intracellular proliferation of phagocytosed fungal cells (Figure 6).

The *Cgvrh1Δ*, but not the *Cgvht1Δ* mutant, was significantly attenuated in intracellular survival as compared to the complemented strain or the wildtype (Figure 6a). Similarly, the *Cavhr1Δ/Δ*, but not the *Cavht1Δ/Δ* mutant, showed reduced survival rates. To rule out that stored biotin from the pre-culture compensates the need for *VHT1* early after infection, we did parallel survival assays with pre-starved fungal strains (Figure S5). Indeed, pre-starved *Cavht1Δ/Δ* cells showed significantly lower survival rates than the wildtype. However, survival of the *Cgvht1Δ* mutant was not reduced. In addition, a lower survival rate of *vhr1Δ* mutants was only observed when fungal cells were pre-grown in biotin-containing medium (Figure 6a,c), but not when biotin-starved fungal cells were used (Figure S5).

Even after biotin feeding, *C. glabrata* intracellular replication was reduced for both the *Cgvrh1Δ* and *Cgvht1Δ* mutants (Figure 6b). Also, *C. albicans* hyphae formed early after phagocytosis were shorter in both *Cavhr1Δ* and *Cavht1Δ* as compared to the wildtype or the complemented strain and both mutants showed reduced rates of hyphal outgrowth (Figure 6c–e).

While *C. glabrata* can replicate inside macrophages without causing substantial damage (Seider et al., 2011), *C. albicans* hyphal growth and other factors cause macrophage lysis within hours (Kasper et al.,

2018; McKenzie et al., 2010; Vylkova & Lorenz, 2014). Therefore, we looked at macrophages confronted for 24 hr with *C. albicans* and measured macrophage lactate dehydrogenase (LDH) release to determine host cell lysis. In addition, we quantified the sizes of *C. albicans* microcolonies as a measure for sustained hyphal growth during contact with macrophages. While the *Cavht1Δ/Δ* mutant formed smaller microcolonies and was severely attenuated in macrophage damage, the *Cavhr1Δ/Δ* showed wildtype-like microcolonies and cytotoxicity (Figure 6f,g).

Besides biotin, precursors like KAPA or DTB may support *C. albicans* growth depending on its *BIO2-5* partial biosynthesis cluster (see above). Such precursors may potentially be provided by co-inhabiting bacteria, for example, during gut colonisation, but are likely not available during direct *C. albicans*-host interactions, as these intermediates are not produced by host cells. We constructed a *C. albicans* mutant lacking *CaBIO2-5* and found that the *BIO2-5* cluster is indeed necessary for growth with KAPA and DTB, but not biotin (Figure S4a). Intracellular survival, hyphal growth and damage of macrophages were unaffected in the *CaBio2-5Δ/Δ* mutant (Figure S4b–e), indicating that KAPA or DTB utilisation is dispensable for the *C. albicans*-macrophage interaction.

Collectively, these data indicate that in both *Candida* species, *Vhr1*-regulated processes are important for short-term responses to macrophage antifungal activities and intracellular proliferation. *Vht1*-dependent biotin acquisition is needed for survival of *C. albicans* cells that have experienced biotin limitation prior to phagocytosis. *Vht1* also becomes relevant for *C. glabrata* replication and early and sustained intracellular growth of *C. albicans* hyphae and hypha-induced damage of macrophages.

## 2.7 | The biotin transporter Vht1 is required for colonisation of the brain during systemic infection

Our *in vitro* growth experiments show that both *C. albicans* and *C. glabrata* similarly require *VHT1* for biotin acquisition, and mutants lacking *VHT1* need at least  $\times 1,000$  more biotin than wildtype cells for proliferation (Figure 3). To learn more about the availability of and requirement for biotin during *Candida* infections, we analysed both

**FIGURE 6** Genes related to biotin homeostasis are necessary for fungal fitness within macrophages. Wildtype (wt), mutant (*vht1Δ*), or complemented strains (*vht1Δ + VHT1*) of (a,b) *Candida glabrata* or (c–g) *Candida albicans* cells were pre-cultivated in YPD + 2 mg/L biotin before confrontation with human blood monocyte-derived macrophages (hMDMs). (a) Survival of *C. glabrata* strains after 3 hr, (% survival of inoculum). (b) Intracellular proliferation of *C. glabrata* after 20 hr, shown as number of cell divisions –  $\log_2[1/1 - (\% \text{ daughter cells}/100)]$  ( $n = 3$ ). (c) Survival of *C. albicans* strains after 3 hr (% survival of inoculum). (d) Length of hyphae formed 10 hr after phagocytosis. (e) Outgrowth of hyphae from macrophages after 10 hr (% of ingested hyphae piercing the macrophage membrane). (f) Macrophage damage by *C. albicans* after 24 hr (% cytotoxicity; 100% refers to full lysis). (g) Microcolony size at 24 hr, as a measure for long-term hypha formation. Exemplary microscopy pictures of microcolonies of *C. albicans* wt and *Cavht1Δ/Δ + CaVHT1* on infected macrophages are shown; scale bar: 100  $\mu\text{m}$ . Values are represented as scatterplots with mean  $\pm$  SD (a–c, e and g) or mean + SD of individual hyphae from four donors in two independent experiments (d,f). Each single dot in a–c and e corresponds to one blood donor (total of at least four different donors in at least two independent experiments). Scatterplot in (g) shows a single dot for one individual microcolony (five donors of two independent experiments). For statistical analysis, a repeated measures ANOVA with Bonferroni's multiple comparison test was performed (\* $p \leq .05$ , \*\* $p \leq .01$ , \*\*\* $p \leq .001$  comparing wt and deletion mutant; ### $p \leq .01$ , #### $p \leq .001$  comparing deletion mutant to the respective complemented strain)

*Candida* species in established systemic infection mouse models (Jacobsen et al., 2010; Jacobsen, Lüttich, Kurzai, Hube, & Brock, 2014). First, we infected mice via the tail vein with biotin pre-starved or biotin-fed *C. glabrata* wildtype, *Cgvrh1Δ* or *Cgvht1Δ* mutant, or the respective complemented strains. As expected from previous studies, systemic infection with *C. glabrata* caused no clinical symptoms and the only alteration upon necropsy was moderate splenomegaly, indicating an immune response to infection (Jacobsen et al., 2010) (not shown). Fungal burdens of infected organs were highest at Day

2 post-infection and decreased over time for all tested strains (Figures 7a and Figure S6). The biotin transporter mutant *Cgvht1Δ* was strongly attenuated in colonisation of the brain and caused less MCP-1 (monocyte chemoattractant protein 1; CCL-2) production, while the complemented strain showed wildtype-like behaviour (Figures 7a and Figure S7). In contrast, mice infected with the *Cgvrh1Δ* or *Cgvht1Δ* mutant showed wildtype-like fungal burdens and comparable cytokine levels in the kidney, liver and spleen (Figures S6a–c and S7). Since, according to our *in vitro* experiments,

**FIGURE 7** VHT1 is required for *in vivo* persistence of *Candida glabrata* and virulence of *Candida albicans*. (a) Five CD-1 mice per group were intravenously infected with biotin-starved *C. glabrata* wildtype (wt), mutant, or complemented strains ( $2.5 \times 10^7$  yeast cells/20 g body weight in 100  $\mu$ L PBS) on Day 0. The fungal burden of the brain was determined by quantifying cfu in tissue homogenates at indicated time points. (b–d) Balb/C mice were intravenously infected with biotin-starved *C. albicans* wildtype, mutant, or complemented strains ( $2 \times 10^5$  yeast cells/20 g body weight in 100  $\mu$ L PBS) on Day 0 and (b) survival of eight mice was followed up for 21 days. The fungal burden of (c) brain and (d) kidneys was evaluated by quantifying cfu in tissue homogenates of five mice at indicated time points. Statistical analysis was performed with a one-way ANOVA on datasets from the same day to compare the strains, followed by Dunn's multiple comparison test. Survival curves were compared using the log rank (Mantel-Cox) test. (\* $p \leq .05$ , \*\* $p \leq .01$ , \*\*\* $p \leq .001$  comparing wt and VHT1 deletion mutant; # $p \leq .05$ , ## $p \leq .01$ , ### $p \leq .001$  comparing VHT1 deletion mutant to VHT1 complemented strain). Dashed lines represent the detection limit and dots below this line mean no cfu were detected

CgVht1 in particular is essential for full fitness and proliferation in biotin-poor microniches, we concluded that infecting CgVht1Δ cells may either find sufficient, accessible biotin for proliferation in these organs or that these cells persist in a non-proliferating stage. To provide proof that *C. glabrata* can remain viable in the absence of nutrients, we incubated the different *C. glabrata* strains in PBS without carbon, nitrogen or vitamin sources. The numbers of colony forming units (cfu) dropped over time, but stayed above 10% of the initial cell count, confirming that a fraction of *C. glabrata* cells can survive for 2 weeks, even in the absence of nutrients, and independent of CgVHR1 or CgVHT1 (Figure S6d).

Fungal burdens after infection with biotin pre-starved *C. glabrata* were slightly (but not significantly) increased as compared to non-starved *C. glabrata* in the liver, kidneys and brain on Day 2, but not on Day 7 and 14 (Figures 7a and S6a,c). Thus, biotin pre-starved *C. glabrata* may be slightly better adapted to early conditions during *in vivo* infection; however, the biotin status before infection has no substantial impact on fungal persistence. Secondly, we infected mice via the tail vein with biotin pre-starved *C. albicans* wildtype, Cavhr1Δ/Δ or Cavht1Δ/Δ mutant cells, or the respective complemented strains. Mouse morbidity was analysed by monitoring the development of clinical symptoms over a maximum of 21 days and mice were euthanized after reaching humane endpoints. The Cavht1Δ/Δ mutant was significantly attenuated in virulence, whereas the Cavhr1Δ/Δ mutant showed wildtype-like virulence (Figure 7b). Additionally, to gain insights into the organ-specific *C. albicans* fungal loads, a time course experiment analogous to the *C. glabrata* infection model was performed. We found that the Cavht1Δ/Δ mutant showed significantly lower fungal burdens in the brain and kidneys (Figure 7c,d), while those of the liver and spleen were comparable to the wildtype (Figure S6f,g). Correspondingly, the inflammatory response in the Cavht1Δ/Δ-infected brain and kidney but also liver was reduced, while the complemented strain induced a wildtype-like cytokine response (Figure S7).

Based on these data we conclude that Vhr1-dependent regulatory processes are dispensable for *in vivo* persistence of *C. glabrata* and virulence of *C. albicans*. However, Vht1-mediated biotin acquisition is required for persistence of *C. glabrata* in the mouse brain and virulence of *C. albicans*.

### 3 | DISCUSSION

*Candida albicans* and *C. glabrata* are two successful opportunistic pathogenic fungi. These two yeast species are able to rapidly adapt to changing environments with varying nutrient availability (Miramón & Lorenz, 2017). Both *C. glabrata* and *C. albicans* are auxotrophic for the essential micronutrient biotin and, thus, must have found ways to acquire this vitamin during commensal growth and systemic infection (Ahmad Hussin et al., 2016; Firestone & Koser, 1960). On mucosal surfaces, *C. albicans* and *C. glabrata* live in close proximity to other microbes, which are often able to synthesise biotin and likely provide this vitamin or biosynthesis intermediates to colonising *Candida* cells

(Hill, 1997). While *C. albicans* contains the incomplete biotin biosynthesis cluster *BIO2-5*, which enables this fungus to synthesise biotin when growing in the presence of KAPA or DTB (Figures 1, 2 and S4; Ahmad Hussin et al., 2016; Fitzpatrick et al., 2010), *C. glabrata* has apparently lost the biotin biosynthesis pathway (Figure 2) and cannot utilise these biotin precursors (Figure 1). This underlines the remarkable metabolic flexibility of *C. glabrata*, which can thrive in the host despite loss of several metabolic genes and resulting auxotrophies, such as NAD<sup>+</sup>, pyridoxine and thiamine (Brunke & Hube, 2013; Dujon et al., 2004; Kaur, Domergue, Zupancic, & Cormack, 2005). Presence or absence of *BIO2-5* genes in other medically important yeasts (Fitzpatrick et al., 2010) similarly correlated with their ability to utilise biotin precursors (Figure S2): *C. tropicalis* (possessing *BIO2-5*), grew on KAPA and DTB while *C. dubliniensis* and *C. auris* (possessing *BIO2* only) grew on DTB and *C. parapsilosis* (lacking *BIO2-5*) was unable to utilise either biotin precursor. The *BIO2-5* cluster may therefore be an advantage for *C. albicans* (and *C. tropicalis*) over *C. glabrata* (and *C. dubliniensis*, *C. auris* and *C. parapsilosis*), allowing for better host colonisation in the presence of bacteria. Therefore, these genes may be seen as commensal factors. However, these genes are likely dispensable during systemic infection, as mammals are biotin auxotrophs and provide no biosynthesis intermediates. In agreement, *BIO2-5* was dispensable for *C. albicans*-macrophage interaction (Figure S4).

The ability of *C. albicans* to undergo a morphological transition between yeast and hyphae is considered to be a main virulence attribute of this fungus (Jacobsen et al., 2012). Our data show that biotin is necessary for *in vitro* proliferation of *C. glabrata* and *C. albicans* yeast cells, but also for *C. albicans* hyphal growth (Figure 1). These data are supported by a previous study (Ahmad Hussin et al., 2016), which showed that biotin enhances *C. albicans* germ tube formation.

We have identified two major players of biotin homeostasis in *C. albicans* and *C. glabrata*—the ortholog of the *S. cerevisiae* biotin transporter Vht1 and the ortholog of the *S. cerevisiae* regulator of biotin-metabolic genes Vhr1. As mutants lacking *VHT1* were unable to grow *in vitro* unless high amounts of biotin were present and as *VHT1* expression was highly up-regulated in medium with low biotin in both *Candida* spp., we conclude that Vht1 is the main factor facilitating biotin acquisition in both, *C. albicans* and *C. glabrata* (Figures 3, 4 and S2). Genomes of other biotin-auxotrophic *Candida* spp. such as *C. tropicalis*, *C. dubliniensis*, *C. auris* and *C. parapsilosis*, also contain potential *VHT1* orthologs (Skrzypek et al., 2017), indicating that the biotin uptake machinery is conserved among other medically important *Candida* species.

Our data show that Vhr1 regulates the expression of biotin-metabolic genes, including *VHT1* in *C. albicans* and *C. glabrata*. While *C. glabrata* Vhr1 induces CgVHT1 expression upon biotin limitation, *C. albicans* Vhr1 was required for keeping CaVHT1 expression low under biotin-replete conditions (Figure 4). This suggests that a yet unknown regulator activates CaVHT1 expression in *C. albicans*. A CgVhr1Δ mutant was still able to express *VHT1* to some extent, suggesting the presence of additional regulators in *C. glabrata* as well. This may also explain why mutants lacking *VHR1* were still able to grow under biotin-limiting conditions (Figure S3) or showed

wildtype-like fitness *in vivo* (Figures 7 and S6). In contrast, a *Cgvrh1Δ* mutant was outcompeted by the wildtype in a previous infection study, suggesting an involvement of *CgVHR1* in *in vivo* fitness (Brunke et al., 2015). However, that mutant was generated in a strain background with amino acid auxotrophies. Such auxotrophies alone have no impact on *C. glabrata* fitness in the mouse (Jacobsen et al., 2010), but may be detrimental when combined with the absence of *Vhr1*-dependent regulation. Our data, however, show that *VHR1* is required for survival and proliferation in macrophages (*C. albicans* and *C. glabrata*) as well as growth when biotin limitation is combined with the replacement of glucose by casamino acids (Figure S3). These data suggest that *Vhr1*-dependent regulation becomes important in specific niches, when biotin limitation is combined with the limitation of other nutrients and/or antimicrobial activities of immune cells (see below).

Our data obtained from macrophage confrontation assays implies that the *Candida*-containing phagosome is limited in biotin, as biotin-pre-starvation reduced *Candida* survival, as the biotin transporter gene *VHT1* was up-regulated in both *Candida* species upon biotin pre-starvation and after phagocytosis, and as deletion of *VHT1* led to slower replication of *C. glabrata* and slower hyphal extension of *C. albicans* inside macrophages (Figures 3, 5, 6 and S5). This concept of biotin limitation inside the phagosome is supported by studies in bacterial pathogens like *Francisella* spp. and *Mycobacterium* spp., which require a functional *de novo* biotin biosynthesis pathway for intracellular fitness within macrophages (Feng et al., 2015; Napier et al., 2012; Rengarajan, Bloom, & Rubin, 2005; Yu et al., 2011). Correlating with the reduction in hyphal formation of a *Cavht1Δ/Δ* mutant during the course of macrophage interaction, we observed a reduction in macrophage damage—a phenotype confirmed by a previous study (O'Meara et al., 2018).

*Vhr1* was similarly important for replication (*C. glabrata*) or early hypha formation in macrophages (*C. albicans*), but not for sustained *C. albicans* filamentation and late macrophage damage. Of note, a *Cavhr1Δ/Δ* mutant exhibited wildtype-like *VHT1* expression in macrophages (not shown). In addition, *VHR1* was only necessary for *Candida* survival under conditions where *VHT1* was dispensable (when biotin was high before phagocytosis, Figure S5). These data suggest that *CaVhr1* functions during early stages of macrophage interaction are independent of *Vht1* regulation and become dispensable at later stages. Instead, *CaVht1*-dependent biotin uptake is needed for sustained proliferation inside macrophages. In *C. glabrata* we observe reduced *CgVHT1* expression in the absence of *CgVHR1* (not shown), which likely limits biotin import and consequently replication after phagocytosis.

Together, our macrophage confrontation data suggest that *Vht1*-dependent biotin uptake is required for sustained proliferation of *C. glabrata* and *C. albicans* inside macrophages, while initial fitness depends on *VHT1*-independent *Vhr1* functions in fungal survival.

Our main conclusions on the importance of biotin during *Candida* infection are based on *in vivo* data with *C. glabrata* and *C. albicans vht1Δ* mutants, which are unable to synthesise and acquire biotin unless high amounts are present (Figure 3). Our data

clearly show that *Vht1* is essential for the full virulence of *C. albicans* (Figures 7 and S6). Fungal organ burdens, however, were reduced in the kidney and brain, but not in the spleen or liver. Similarly, *C. glabrata* persistence in mice was not generally reduced upon *VHT1* deletion (Figures 7 and S6). In fact, *VHT1* deletion mutants of *C. glabrata* showed wildtype-like fungal burden in the kidney, liver, and spleen and reduced cfu numbers were only observed in mouse brains. These data indicate that biotin availability is high enough to support *Candida* growth in organs like the liver and spleen, while access to biotin is limited in the brain. In line with this, avidin-based histology staining suggested that hepatocytes and proximal tubular epithelial cells in the kidney contain high amounts of biotin (Combs & McClung, 2017; Cooper, Kennedy, McConnell, Kennedy, & Frigg, 1997), while biotin levels in the extracellular space of the brain tissue are lower (8 nM in rabbit [2 µg/L]) (Spector & Johanson, 2007). Such levels would be sufficient to promote growth of *Candida* wildtype cells, but not *VHT1* deletion strains (Figure 3). An alternative explanation is that certain nutrients, like aspartate or other amino acids, may bypass the need for biotin in certain host niches as suggested by our *in vitro* data (Figures S1 and S3).

Of note, biotin levels available in humans may be substantially lower than in mice, as a recent study showed a 40-fold higher biotin concentration in mouse plasma compared to human plasma (Carfrae et al., 2020). In line with this, the same study showed that growth of bacterial pathogens, which lack biotin transporters and are deficient in biotin biosynthesis, is diminished in human plasma, but not mouse (Carfrae et al., 2020).

Biotin may become dispensable for colonising *Candida* cells in cases of weak or no fungal metabolic activity or proliferation. Fungal burdens of *C. glabrata* in brains, but not kidney, liver, or spleen of mice increase between 12 hr and 3 days post-infection, which may indeed point to *C. glabrata* replication in the brain, but not in the other tested organs soon after infection (Beyer et al., 2018). This exciting possibility of non-proliferating *C. glabrata* cells in the host may also contribute to the high tolerance of *C. glabrata* towards fungistatic antifungal drugs. Similarly, increases of *C. albicans* fungal burdens in mouse kidney and brain, but not in liver or spleen (Lionakis, Lim, Lee, & Murphy, 2011) point to replication in those organs in which we observed reduced cfu of the *Cavht1Δ/Δ* mutant.

Collectively, our data show for the first time that *Vht1*-dependent fungal biotin acquisition is linked with intracellular proliferation of the opportunistic fungal pathogens *C. albicans* and *C. glabrata* in macrophages and *in vivo* persistence of *C. glabrata* and virulence of *C. albicans* in mice. Our results underline the importance of micro-nutrients, such as biotin, for fungal pathogens.

## 4 | EXPERIMENTAL PROCEDURES

### 4.1 | Ethics statement

Human blood was taken from healthy volunteers with written, informed consent. The blood donation protocol and use of blood for

this study were approved by the institutional ethics committee of the university hospital Jena (Ethik-Kommission des Universitätsklinikums Jena, Permission No. 2207-01/08). Animal experiments were performed in compliance with the European and German animal protection laws and were approved by the ethics committee "Beratende Kommission nach §15 Abs. 1 Tierschutzgesetz" and the responsible Federal State authority Thüringer Landesamt für Verbraucherschutz, Bad Langensalza, Germany (Permit No. 03-026/16, HKI-19-005). All mice were cared for in accordance with the principles outlined in the European Convention for the Protection of Vertebrate Animals Used for Experimental and Other Scientific Purposes.

#### 4.2 | Strains and general growth conditions

All strains used in this study are listed in Table S1. *Escherichia coli* was cultivated in liquid lysogeny broth with 50 µg/ml ampicillin for plasmid generation. For growth on solid medium, 2% agar was added. *Candida* strains were pre-cultured overnight in liquid Yeast Peptone Dextrose (YPD) broth (2% glucose, 2% peptone and 1% yeast extract) at 30 or 37°C, with shaking at 180 rpm for 14–16 hr. The biotin concentration in standard YPD is 10–20 µg/L (Ogoshi et al., 2014 and own observations). As gene deletion of *VHT1* led to strong growth defects in standard media, we routinely pre-cultured strains for experiments including the biotin transporter mutant *vht1Δ* in YPD + 2 mg/L biotin. Stationary phase yeast cells from pre-cultures were washed three times in PBS and the cell number was adjusted in PBS or culture medium.

For biotin and niacin pre-starvation, the YPD-grown, PBS-washed cell suspension was adjusted to an OD of 0.2 in minimal medium either without biotin (0.69% yeast nitrogen base [YNB] without biotin, amino acids, with ammonium sulfate [Formedium]; 2% glucose) or without niacin (0.69% YNB without niacin, amino acids, with ammonium sulfate [Formedium]; 2% glucose) and incubated for further 24 hr at 30 or 37°C and 180 rpm. Media with defined biotin concentrations were prepared on the basis of biotin-free medium (see above), with addition of 0.2 µg/L biotin (low biotin), 2 µg/L biotin (intermediate, standard), 0.2 mg/L biotin (elevated biotin) or 2 mg/L (high biotin).

#### 4.3 | Growth assays

Twenty microliters of a yeast cell suspension ( $5 \times 10^6$  cells/ml) were added to 180 µL media in a 96-well plate (Tissue Culture Test Plate, TPP Techno Plastic Products AG). The growth was monitored by measuring the absorbance at 600 nm every 30 min for 100 cycles at 30 or 37°C using a Tecan Reader (Plate Reader infinite M200 PRO, Tecan Group GmbH) with orbital shaking (30 s, amplitude: 6 mm, wait: 10 s) before each measurement and multiple reads per well. All experiments were done in technical duplicates and, at least, biological triplicates.

Filamentation of *C. albicans* was induced in biotin-free RPMI1640 medium (PAN-Biotech) with L-glutamine (Thermo Fisher Scientific)

either without biotin or with 2 µg/L of biotin/KAPA/DTB at 37°C and 5% CO<sub>2</sub> in a 24-well plate. Briefly,  $5 \times 10^4$  cells/well were incubated for 2 and 4 hr to allow formation of short hyphae. In parallel, to measure long hyphae in vitro, 100 cells/well were incubated for 24 hr to generate microcolonies originating from single yeast cells that formed radially branching filamentous hyphae (McCall, Kumar, & Edgerton, 2018). Following this, cells were fixed by adding one-tenth of the volume of 37% paraformaldehyde. Microscopy images were recorded using the Zeiss Axio Vert.A1 (Carl Zeiss Microscopy). Germ tube formation (2 hr) and hyphal length (4 hr) were measured for at least 200 cells/sample and the diameter of at least 10 microcolonies was determined (both in at least three replicates).

#### 4.4 | *C. glabrata* mutant generation

For construction of *C. glabrata* *vhr1Δ* and *vht1Δ* mutants, the upstream and downstream homologous regions of CAGL0M12496g (*VHR1*) and CAGL0K04609g (*VHT1*) were first subcloned with flanking restriction enzyme recognition sites (5' SphI- and 3' SacII for upstream region of *VHR1*, 5' SphI and 3' NcoI for upstream region of *VHT1*, 5' SpeI- and 3' SacI for downstream regions of *VHR1* and *VHT1*) using the TOPO Cloning Kit (Invitrogen). The homologous regions were then excised and cloned into the plasmid pTS50 (Schwarz Müller et al., 2014) to generate cassettes containing the *NAT1* selection marker (Schwarz Müller et al., 2014; Table S3) surrounded by gene-specific regions. Integration was confirmed by restriction digestion. Deletion constructs were amplified from generated plasmids using P1 and P4 primers (Table S2) and purified with QIAquick PCR purification kit (Qiagen). Next, 4 µg of the PCR product was transformed into the parental strain wildtype strain ATCC2001 or a tryptophan-auxotrophic derivative (*trp1Δ*) using a modified heat-shock method (Sanglard, Ischer, Monod, & Bille, 1996 with heat shock: 15 min at 45°C). Mutants were selected for on YPD agar plates with 250 µg/ml nourseothricin. Growth of *vht1Δ* clones was facilitated by adding 2 mg/L biotin to selective agar plates.

Complemented strains were generated by reintegrating *VHR1* and *VHT1* into the *TRP1* locus. This locus was chosen as tryptophan auxotrophy (*trp1Δ*) had no negative impact on *C. glabrata* in vivo fitness and in vitro mutant growth phenotypes (Jacobsen et al., 2010; Yanez-Carrillo et al., 2015). In detail, the *TRP1* gene and its 5' upstream region (−984 bp to +750 bp) was PCR-amplified with primers introducing flanking SphI restriction sites and ligated into the SphI-linearized pUC19 vector (In-Fusion HD Cloning Kit) to generate pUC19-*TRP1*. Subsequently, the *TRP1* 3' downstream region (+751 bp to +1,570 bp) was PCR-amplified with primers introducing XmaI and SacI restriction sites and was ligated into the XmaI/SacI opened plasmid pUC19-*TRP1* to create the final p*TRP1*. Plasmids p*TRP1*-*VHR1* and p*TRP1*-*VHT1* were generated by PCR amplifying the coding sequences of *VHR1* and *VHT1* together with the up- and downstream intergenic regions with primers introducing 15 bp flanks of the empty p*TRP1* (*VHR1*) or Sall and XbaI restriction sites (*VHT1*). Constructs were cloned into XbaI-digested p*TRP1*

(to generate pTRP1-VHR1) or SphI and XbaI-digested pTRP1 (to generate pTRP1-VHT1). Resulting plasmids were confirmed by sequencing. The TRP1 or TRP1-VHR1/TRP1-VHT1 cassettes were amplified by PCR, purified and transformed into a *trp1Δ* background strain to generate tryptophan prototrophic mutants or complemented strains, respectively. Resulting clones were selected for on solid minimal medium. All deletions and re-integrations were confirmed by PCR and Southern blot.

#### 4.5 | *C. albicans* mutant generation

*Candida albicans* *vhrl1Δ/Δ* (CR\_00630WΔ/Δ) and *vht1Δ/Δ* (CR\_03270WΔ/Δ) mutants were generated with a gene disruption method (Wilson, Davis, & Mitchell, 1999) and lithium acetate transformation protocol (Walther & Wendland, 2003). Briefly, the Arg-, His- and Ura-auxotrophic parental strain BWP17 was sequentially transformed with 10 μg of PCR-amplified and purified *HIS1* and *ARG4* deletion cassettes, which were flanked by 100 bp of the target homology region, resulting in disruption of the open reading frames of both alleles of CR\_00630W (*VHR1*) or CR\_03270W (*VHT1*). Primers used for PCR amplification and verification are listed in Table S2. Growth of *vht1Δ/Δ* clones was facilitated by adding 2 mg/L biotin to selective agar plates. Homozygous uridine-auxotrophic deletion mutants were then transformed with the StuI-linearized empty Clp10 plasmid (Murad, Lee, Broadbent, Barelle, & Brown, 2000) to generate prototrophic mutants or with StuI-linearized Clp10-VHR1 or Clp10-VHT1 plasmids to generate complemented strains. For the generation of Clp10-VHR1 or Clp10-VHT1, the coding sequences of *VHR1* as well as *VHT1* together with their native up- and downstream intergenic regions were cloned into Clp10 using KpnI and Sall (Clp10-VHR1) or XhoI (Clp10-VHT1). Constructed plasmids were verified by sequencing and the correct integration of deletion and complementation cassettes was confirmed by PCR and Southern blot.

#### 4.6 | Isolation and differentiation of hMDMs

Human peripheral blood mononuclear cells (PBMCs) from buffy coats donated by healthy volunteers were separated through Lymphocytes Separation Media (Capricorn Scientific) in Leucosep tubes (Greiner Bio-One) by density centrifugation. Magnetically labelled CD14-positive monocytes were selected for by automated cell sorting (autoMACs; MiltenyiBiotec). To differentiate monocytes into adherent hMDMs,  $1.7 \times 10^7$  cells were seeded into 175 cm<sup>2</sup> cell culture flasks in RPMI1640 media with L-glutamine (Thermo Fisher Scientific) containing 10% heat-inactivated foetal bovine serum (FBS; Bio&SELL) and 50 ng/ml recombinant human macrophage colony stimulating factor (M-CSF) (Immunotools) and incubated for 5 days at 37°C and 5% CO<sub>2</sub> until the medium was exchanged. After another 2 days, adherent hMDMs were detached with 50 mM EDTA in PBS and seeded in 6-well plates ( $1 \times 10^6$  hMDMs/well), 12-well plates ( $4 \times 10^5$  hMDMs/well), 24-well plates ( $2 \times 10^5$  hMDMs/well) or 96-well plates ( $4 \times 10^4$

hMDMs/well) in RPMI with 50 ng/mL M-CSF and incubated overnight. Prior to macrophage infection, medium was exchanged with serum- and biotin-free RPMI medium with L-glutamine (Thermo Fisher Scientific) to exclude biotin uptake by *Candida* prior to phagocytosis.

#### 4.7 | Macrophage killing assay

Fungal survival was quantified as described previously (Seider et al., 2014). Briefly, macrophages in 24-well plates were stimulated for at least 24 hr with 20 ng/mL of recombinant human IFN-γ (Immunotools) in RPMI containing 50 ng/mL M-CSF and 10% FBS (see above) to favour a pro-inflammatory macrophage phenotype. Intracellular fungal survival was evaluated after 3 hr of coinocubation with *C. glabrata* or *C. albicans* at a multiplicity of infection (MOI) of 1. Extracellular *Candida* cells were removed by washing three times with PBS and intracellular yeast cells were released by lysing the macrophages with 0.1% Triton-X-100 for 10 min. Appropriate dilutions were plated in duplicate on YPD plates containing 2 mg/L biotin and incubated for 1–2 days at 37°C. Colonies were counted with an automated colony counter ProtoCOL3 (Synbiosis, Cambridge, UK). To correct for inoculation differences between strains, colony numbers determined from intracellular lysates were normalised to colony numbers from plated culture inocula before calculating survival.

In experiments investigating the influence of niacin, hMDMs were seeded in 96-well plates and stimulated for at least 24 hr with 5 ng/mL of recombinant human IFN-γ (Immunotools) in RPMI1640 medium containing 50 ng/mL M-CSF and 10% FBS. Before confrontation with yeast cells, macrophages were washed with RPMI1640 medium without FBS and niacin. Niacin-free RPMI1640 medium was self-made and contains L-glutamine, phenol red, and sodium bicarbonate, but lacks niacinamide. The medium was adjusted to pH 7.2 and filter sterilised. Intracellular fungal survival was evaluated after 3 hr of coinocubation with *C. glabrata* at an MOI of 1 in technical triplicates. The following steps were performed as described above.

#### 4.8 | Differential staining after macrophage infection

Macrophages ( $1.5 \times 10^5$  hMDMs/well) were allowed to adhere onto coverslips in a 24-well plate overnight in RPMI containing 50 ng/mL M-CSF and 10% FBS and infected with *C. albicans* at an MOI of 2 for 10 hr. Phagocytosis was synchronised on ice for 30 min followed by two washing steps with pre-warmed medium to remove unbound *Candida* cells. The staining protocol was adapted from Kasper et al. (2018). Briefly, infected macrophages were fixed with Roti-Histofix 4% and stained with 50 μg/mL Concanavalin A conjugated with Alexa Fluor 647 (ConA-AF647; Thermo Fisher Scientific) at 37°C for 30 min to visualise external *Candida* cells. After permeabilisation with 0.5% Triton-X-100, extra- and intracellular fungal cells were stained with 35 μg/mL Calcofluor White. Coverslips were mounted with Mowiol mounting medium and fluorescence images were recorded using the

Zeiss AXIO Observer.Z1 (Carl Zeiss Microscopy). Outgrowth rates of intracellular hyphae and hyphal length of internalised *C. albicans* were calculated by manually counting a minimum of 100 yeast cells/sample.

#### 4.9 | Macrophage damage assay

Macrophages were allowed to adhere in 96-well plates overnight in RPMI containing 50 ng/mL M-CSF and 10% FBS and infected in technical triplicates with *C. albicans* at an MOI of 2 for 24 hr at 37°C and 5% CO<sub>2</sub>. Macrophage lysis was determined by measuring the release of LDH into the cell culture supernatant using the Cytotoxicity Detection kit (Roche). A low (non-infected cells) and a high control (cells lysed with 0.2% Triton-X-100) were performed to calculate the percentage of cytotoxicity. In the same samples, the diameter of micro-colonies was measured to determine *C. albicans* hyphal length after 24 hr (≥10 colonies per sample).

#### 4.10 | Determination of intracellular replication in macrophages

The protocol was adapted from Dagher et al. (2018) with minor changes. Prior to infection, *C. glabrata* cells were stained with 0.2 mg/mL fluorescein isothiocyanate (FITC) in carbonate buffer (0.15 M NaCl, 0.1 M Na<sub>2</sub>CO<sub>3</sub>, pH 9.0) for 30 min. Afterwards, yeast cells were washed three times in PBS and macrophages were infected at an MOI of 2 for 20 hr. To evaluate intracellular replication, macrophages were washed three times with PBS and lysed with 0.5% Triton-X-100 for 10 min. Released yeast cells were washed once with PBS, then with 2% BSA in PBS, and counterstained with 50 µg/mL ConA-AF647 in PBS at 37°C for 30 min. The ConA-AF647-stained yeast cells were washed two times with PBS and fixed with Roti-Histofix 4% (Roth) for at least 20 min at room temperature. The ratio of FITC-positive and -negative yeast cells was evaluated with BD FACS Verse (BD Biosciences, Franklin Lakes) counting 10,000 events. Data analysis was performed using the FlowJO 10.2 software (FlowJO LLC, Ashland). The gating strategy was based on the detection of single, ConA positive cells and exclusion of cellular debris. The assessment of intracellular replication with FACS allows the relative distinction between mother and daughter cells.

#### 4.11 | Fungal RNA isolation

For preparation of RNA from in vitro cultured *Candida* cells, stationary phase yeast cells were washed three times in PBS and 2 × 10<sup>7</sup> *Candida* cells/mL were inoculated into minimal medium with different biotin concentrations. At indicated time points, cells were harvested and centrifuged (4,000g, 10 min and 4°C). The cell pellet was washed with ice-cold water, centrifuged again, and immediately frozen in liquid nitrogen. For preparation of RNA from phagocytosed *Candida* cells, stationary phase yeast cells were washed three times in PBS.

Macrophages (1 × 10<sup>6</sup> hMDMs/well) were infected at an MOI of 10 in serum and biotin-free RPMI (PAN Biotech) with L-glutamine (Thermo Fisher Scientific). Phagocytosis was synchronised for 30 min on ice and unbound *Candida* cells were removed by two washing steps with warm RPMI medium. After 3 hr of incubation at 37°C and 5% CO<sub>2</sub>, infected macrophages were washed three times with ice-cold PBS and lysed with 750 µL RLT buffer (Qiagen) containing β-mercaptoethanol. Phagocytosed fungal cells were collected by using a cell scraper to loosen the host cells and centrifuged (20,000g, 12 min and 4°C). The fungal cells were washed once with RLT buffer to remove most of the host RNA and immediately frozen in liquid nitrogen.

The isolation of the fungal RNA was performed as previously described (Lüttich, Brunke, & Hube, 2012). The fungal RNA from infected host cells was treated with 3 U Baseline-ZERO DNase (Biozym) in a total volume of 50 µL at 37°C for 45 min. The RNA was then precipitated by adding 1 volume of isopropyl alcohol and one-tenth volume of sodium acetate (pH 5.5). The quantity of the RNA was determined using the NanoDrop Spectrophotometer ND-1000 (NRW International GmbH).

#### 4.12 | Expression analysis by reverse transcription-quantitative PCR

DNase-treated RNA (600 ng) was transcribed into cDNA using 0.5 µg of oligo-dT<sub>12-18</sub>, 100 U Superscript III Reverse Transcriptase and 20 U RNaseOUT Recombinant RNase Inhibitor (all: Thermo Fischer Scientific) in a total volume of 35 µL for 2 hr at 42°C followed by heat inactivation for 15 min at 70°C. The cDNA was diluted from 1:5 to 1:20 in Diethyl pyrocarbonate (DEPC)-treated water and used for quantitative PCR with EvaGreen QPCR Mix II (Bio&SELL) performed in a CFX96 thermocycler (Bio-Rad). Primers (Table S2) were used at a final concentration of 500 nM. Target gene expression was calculated using the ΔΔCt method (Pfaffl, 2001), with normalisation to the housekeeping genes *CgACT1*, *CgEFB1*, *CgEFT2* for *C. glabrata* or *CaACT1*, *CaTDH3*, *CaEFT2* for *C. albicans*.

#### 4.13 | Mouse model of systemic *C. glabrata* infection

Female, specific-pathogen-free CD-1 mice (Charles River, Germany; 8–10 weeks, 20–22 g) were randomly assigned into groups of five upon arrival and housed in individually ventilated cages. All *Candida* strains were either pre-starved for or fed with biotin for 24 hr before infection. On Day 0, mice were intravenously challenged with 2.5 × 10<sup>7</sup> cfu/20 g body weight in 100 µL PBS via the lateral tail vein. The health status was monitored at least twice a day. On days 2, 7 and 14, five mice per strain were euthanised with an overdose of ketamine (10 mg/20 g body weight) and xylazine (0.5 mg/20 g body weight) applied intraperitoneally.

#### 4.14 | Mouse model of systemic *C. albicans* infection

Female, specific-pathogen-free BALB/cAnNRj mice (Janvier, France; 8 weeks, 18–22 g) were randomly assigned into groups of four (survival) and five (kinetics) upon arrival and housed in individually ventilated cages for the course of the experiment. On Day 0, mice were intravenously challenged with biotin pre-starved  $2 \times 10^5$  cfu/20 g body weight in 100  $\mu$ L PBS via the lateral tail vein. The health status was monitored at least twice a day. Mice which reached the humane endpoints (corresponding to moderate suffering and determined by a scoring system based on body weight, general appearance, changes in posture and behaviour, and body surface temperature) were euthanised with an overdose of ketamine (10 mg/20 g body weight) and xylazine (0.5 mg/20 g body weight) applied intraperitoneally. To determine the kinetics of fungal burden and inflammatory response in different organs, groups of five mice per strain were sacrificed 24 and 72 hr post-infection as described above.

#### 4.15 | Quantification of fungal burden and cytokine levels in infected tissues

The mouse spleen, liver, kidneys and brain were removed aseptically, weighed and homogenised in tissue lysis buffer (200 mM NaCl, 5 mM EDTA, 10 mM Tris, 10% glycerol, 1 mM phenylmethylsulfonyl fluoride, 1  $\mu$ g/ml leupeptin and 28  $\mu$ g/ml aprotinin; pH 7.4) using an Ika T10 basic Ultra-Turrax homogeniser (Ika, Staufen, Germany). To determine fungal burden, serial dilutions of homogenates were cultivated on YPD plates containing 2 mg/L biotin and 80  $\mu$ g/mL chloramphenicol. Colonies were counted after 24–48 hr of incubation at 30–37°C with an automated colony counter ProtoCOL3 (Synbiosis, Cambridge, UK). The fungal burden was calculated as cfu per gram of tissue.

For cytokine profiling, tissue homogenates were immediately centrifuged (1,500g, 15 min, 4°C) and supernatants were stored at –80°C. For cytokine measurement, frozen tissue homogenates were thawed on ice and centrifuged once (1,500g, 15 min, 4°C). The supernatants were diluted in supplied assay diluent supplied by manufacturer and enzyme and cytokine levels were determined by commercially available mouse enzyme-linked immunosorbent assay (ELISA) kits (Interleukin 1 $\beta$  [IL-1 $\beta$ ], monocyte-chemoattractant protein-1 [CCL-2 or MCP-1], Interleukin 6 [IL-6] and Interferon- $\gamma$  [IFN- $\gamma$ ] ELISA Ready SET Go! eBioscience, Thermo Fisher Scientific and myeloperoxidase [MPO] DuoSet, R&D systems) according to the manufacturer's instructions.

#### 4.16 | *In silico* analysis and statistical analysis

Information about gene orthologs was obtained from the *Candida* Genome Database (Skrzypek et al., 2017) and the *Saccharomyces* Genome Database (Cherry et al., 2012). Potential orthologs were

identified by BLAST search, based on *S. cerevisiae* protein sequences. Direct comparison of two sequences was done using BLAST (<https://blast.ncbi.nlm.nih.gov/Blast.cgi>). Transmembrane prediction analysis was done using TMHMM Server v. 2.0 (prediction of transmembrane helices in proteins, <http://www.cbs.dtu.dk/services/TMHMM/>) and TMPred (membrane-spanning region prediction, [https://embnet.vital-it.ch/software/TMPRED\\_form.html](https://embnet.vital-it.ch/software/TMPRED_form.html); Hofmann & Stoffel, 1993). Data are reported as scatterplot with mean  $\pm$  SD, line charts with mean  $\pm$  SD, or bar charts showing mean  $\pm$  SD. Data were analysed using GraphPad Prism 5 (GraphPad Software, San Diego) and a one-way analysis of variance (ANOVA) with Bonferroni's or Dunn's multiple comparison test. For statistical analysis of matched observations in macrophage experiments and experiments on wildtype filamentation, a repeated measures ANOVA with Dunnett's or Bonferroni's multiple comparison test was performed. To represent the scattering of hyphal length, we illustrate the mean and standard deviation of all measured hypha in three replicates, but have used the mean of each replicate for statistical analysis. Reverse transcription-quantitative PCR data were statistically analysed using a two-way ANOVA with Bonferroni's post-tests to evaluate differences between the strains and biotin concentrations. Statistically significant results are marked with a single asterisk or hash meaning  $p \leq .05$ , double asterisks or hashes meaning  $p \leq .01$  or triple asterisks or hashes meaning  $p \leq .001$ , n.d., not detectable. If symbol/colour explanations apply to several graphs in a row, one legend is given for neighbouring sub-panels on the right.

#### ACKNOWLEDGEMENTS

We gratefully acknowledge Isabell Nold, Patrick Scherer, Yi Enn Cheong and Aylina Kulle for their technical help with genotypic mutant characterisation, measurement of hyphal length and cfu counting. We thank Nadja Jablonowski, Daniela Schulz and Dorothee Eckardt for isolation of PBMCs and excellent technical assistance; Annika König, Daniel Fischer, Fabrice Hille, Lina Dally, Mark S. Gresnigt and Sophie Austermeier for their support during cultivation of hMDMs; Michael K. Mansour for his advice on the FACS-based replication assay; Bianca Schulze and Karolin Pohl (née Mielke) for technical support during FACS experiments; Sascha Brunke and Philipp Kämmer for support during the animal application processes; Birgit Weber, Katja Schubert and Alessia Montesano for their help with mouse experiments and Franziska Gerwien, Daniela Schulz, Nadja Jablonowski, Antonia Last, Sophie Austermeier and Simone Schiele for their help in processing organ samples, and Jakob L. Sprague for proofreading of the manuscript. The auto-MACS system was kindly provided by the research group Fungal Septomics, ZIK Septomics Jena. We thank the Mycotic Diseases Branch, Centers for Disease Control and Prevention (CDC), Atlanta, USA, for providing *Candida auris* strain B8441. This work was supported by the Deutsche Forschungsgemeinschaft SPP 1580 (Hu 528/17-1).

#### CONFLICT OF INTEREST

The authors have no conflict of interest.

## AUTHOR CONTRIBUTIONS

M.S., L.K., K.G., I.D.J. and B.H. were involved in the conception or design of the study. M.S., T.S.H., S.A., S.W., M.J.N. and L.K. contributed to the acquisition, analysis, or interpretation of the data. M.S., L.K. and B.H. wrote the manuscript.

2

3

4 **FIGURE S1 Growth of pathogenic *Candida* species depending on biotin, biotin**  
 5 **biosynthesis intermediates, biotin-containing compounds, or aspartate.**

6 Yeast growth of biotin pre-starved (pre-cultured in biotin-free minimal medium) *Candida* spp.  
 7 cells in minimal medium (A) containing biotin or biotin precursors (each 2 µg/L) or no biotin  
 8 (w/o supplement), (B) biocytin, biotinylated BSA or BSA (each 2 µg/L) and (C) 0.4 %  
 9 aspartate (Asp) or 0.5 % ammonium sulfate (AS) as nitrogen source with or without 2 µg/L  
 10 biotin at 30°C. Values are represented as mean ± SD of at least three replicates.

11

12 **FIGURE S2 Biotin limitation induces up-regulation of putative orthologs of**  
 13 ***S. cerevisiae* VHT1 and BIO5.**

14 Non-starved (A) *C. glabrata* (ATCC2001) and (B) *C. albicans* (SC5314) wild type strains  
 15 ( $2 \times 10^7$  cells/mL) were cultivated in medium with indicated biotin concentrations for 3 h at  
 16 37 °C and 180 rpm. Transcript abundance of the putative *VHT1* orthologs CAGL0K04609g,  
 17 CAGL0K04565g, CR\_06790C, CR\_06660W and CR\_03270W as well as the putative *BIO5*  
 18 orthologs CAGL0H03399g and CR\_01900C was analyzed by quantitative RT-PCR and  
 19 normalized to the housekeeping genes *CgACT1*, *CgEFB1* and *CaTDH3*, *CaEFT2*. Values  
 20 are represented as mean + SD of three independent experiments, whereby n-fold expression  
 21 for each gene is shown relative to 2 µg/L biotin.

22

23

24

25 **FIGURE S3 *VHR1* is mostly dispensable for biotin-dependent growth *in vitro*.**

26 Yeast growth of biotin pre-starved *C. glabrata* wt, mutant (*Cgvhr1* $\Delta$ ) and complemented  
27 strains (*Cgvhr1* $\Delta$  + *CgVHR1*) (A) in minimal medium with addition of 0.2 or 2  $\mu$ g/L biotin or  
28 (B) on solid minimal medium with either casamino acids (CAA) as a sole carbon- and  
29 nitrogen source or glucose and ammonium sulfate without or with biotin by spotting serial  
30 dilutions ranging from  $10^6$  to  $10^1$  cells at 37 °C. A representative picture out of three  
31 independent experiments is shown. (C) Yeast growth and (D-F) hyphal growth of biotin pre-  
32 starved *C. albicans* wt, mutant (*Cavhr1* $\Delta/\Delta$ ) and complemented strains (*Cavhr1* $\Delta/\Delta$  +  
33 *CaVHR1*) in (C) minimal medium at 30 °C and (D-F) in RPMI1640 at 37 °C and 5 % CO<sub>2</sub> with  
34 addition of 0.2 or 2  $\mu$ g/L biotin. (D) Percentage of germ tube-forming cells at 2 h. (D) Hyphal  
35 length at 4 h (mean + SD of individual hyphae from three replicates). (E) Microcolony size at  
36 24 h (each single dot represents one individual microcolony). Values are represented as  
37 mean  $\pm$  SD (A,C, and F) or mean + SD (D-E) of at least three replicates. (G) Serial dilutions  
38 ranging from  $10^6$  to  $10^1$  biotin pre-starved *C. albicans* cells were spotted on solid minimal  
39 medium with either CAA as a sole carbon- and nitrogen source or glucose and ammonium  
40 sulfate without or with biotin. A representative picture out of three independent experiments  
41 is shown.

42

43 **FIGURE S4 *CaBIO2-5* allows utilization of biotin precursors but is dispensable for**  
 44 **macrophage infectivity.**

45 (A) Yeast growth of biotin pre-starved *C. albicans* wt or *Cabio2-5Δ/Δ* mutant in minimal  
 46 medium containing biotin or biotin precursors (each 2 μg/L) at 30 °C of five biological  
 47 replicates. (B) *C. albicans* wild type (wt) and mutant (*bio2-5Δ/Δ*) were pre-cultivated in YPD  
 48 with 2 mg/L biotin before confrontation with human blood monocyte-derived macrophages  
 49 (hMDMs). (B) Survival after 3 h (% survival of inoculum). (C) Length of hyphae formed 10 h  
 50 after phagocytosis. (D) Outgrowth of *C. albicans* hyphae from macrophages after 10 h (% of  
 51 ingested hyphae piercing the macrophage membrane). (E) Macrophage damage by  
 52 *C. albicans* after 24 h (% cytotoxicity; 100 % refers to full lysis).

53 Values in C are represented as mean + SD of individual hyphae from four donors in two  
 54 independent experiments. Values are represented as mean ± SD (A), mean + SD (E) or as  
 55 scatterplot with mean ± SD (B,D) with each single dot corresponding to one blood donor  
 56 (total at least six (B) or four (C-D) different donors in at least two independent experiments).

57

58

59 **FIGURE S5 Biotin pre-starvation affects survival within macrophages.**

60 Wild type (wt), mutant (*vht1Δ*), or complemented strains (*vht1Δ* + *VHT1*) of (A) *C. glabrata* or  
 61 (B) *C. albicans* cells were biotin pre-starved for 24 h in minimal medium without biotin before  
 62 confrontation with human blood monocyte-derived macrophages (hMDMs). Survival of  
 63 *C. glabrata* (A) and *C. albicans* (B) strains after 3 h (% survival of inoculum). Values are  
 64 represented as scatterplot with mean  $\pm$  SD, with each single dot corresponding to one blood  
 65 donor (at least five different donors in two independent experiments). For statistical analysis,  
 66 a Repeated Measures ANOVA with Bonferroni's multiple comparison test was performed  
 67 (\*  $p \leq 0.05$ , \*\*  $p \leq 0.01$ , \*\*\*  $p \leq 0.001$  comparing wt and deletion mutant; ##  $p \leq 0.01$ ,  
 68 ###  $p \leq 0.001$  comparing deletion mutant to the respective complemented strain).

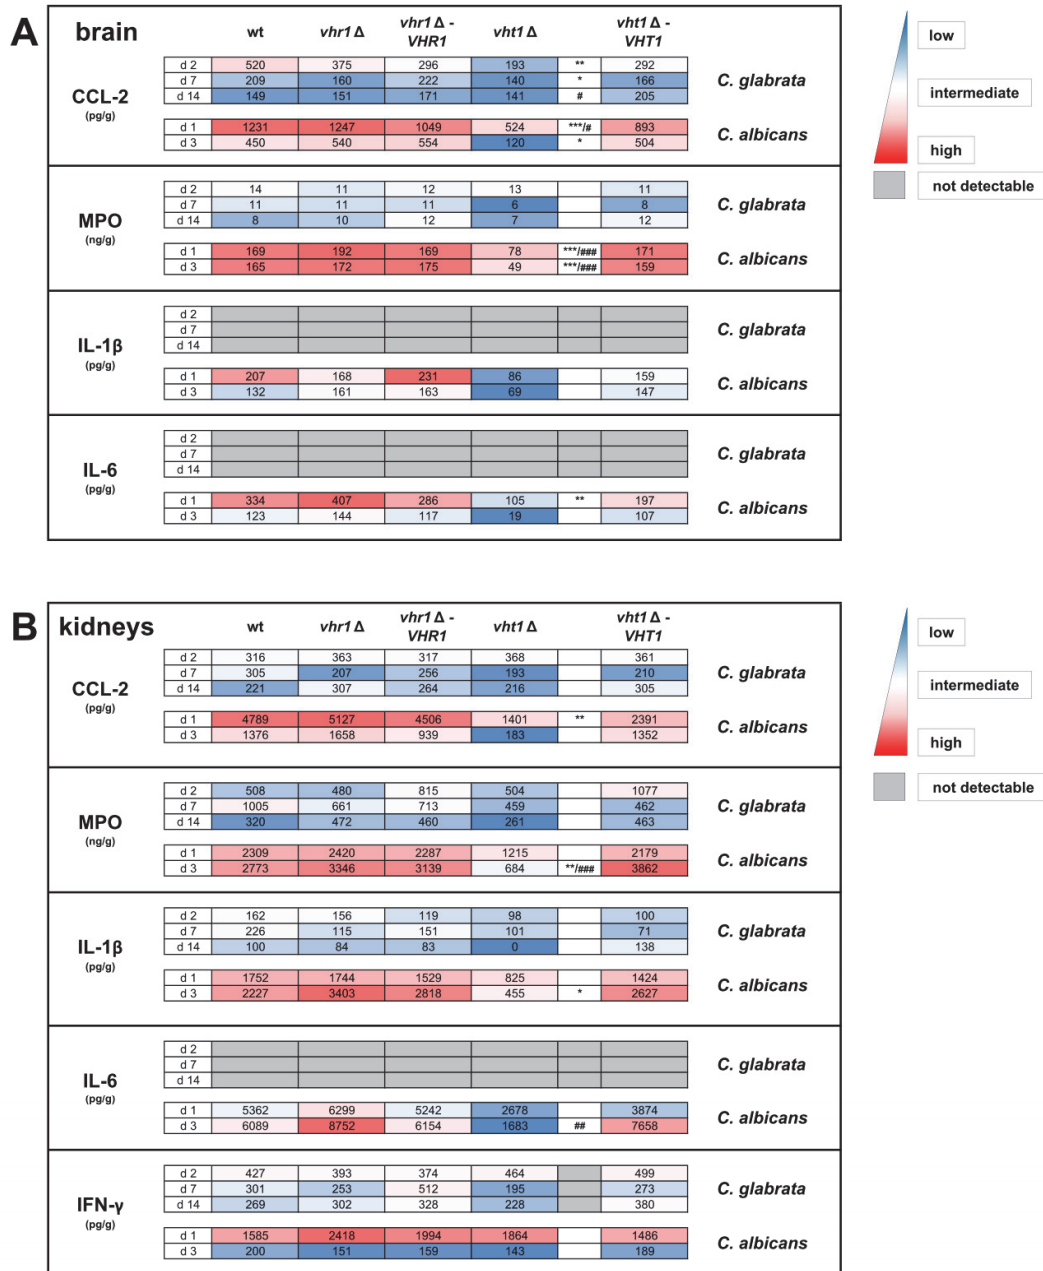

69

70 **FIGURE S6 Fungal burden in mouse organs after systemic *C. glabrata* and *C. albicans***  
 71 **infection and long term viability of *C. glabrata*.**

72 (A-C) Fungal burden in organs of mice infected either with biotin-starved (gray) or biotin-fed  
 73 (black) *C. glabrata* wild type, mutant or complemented strains. Five mice per group were  
 74 intravenously infected with  $2.5 \times 10^7$  yeast cells/20 g body weight on day 0. The fungal burden  
 75 was determined by quantifying cfu in tissue homogenates of (A) liver, (B) spleen and (C)  
 76 kidney. (D) The viability of biotin-fed *C. glabrata* cells in PBS was monitored over 14 days,  
 77 determined by cfu plating at indicated time points and normalized to inoculum control (d 0;  
 78 set as 100 %) in four independent experiments. (E-F) Fungal burden in liver (E) and spleen  
 79 (F) of mice infected intravenously with  $2 \times 10^5$  *C. albicans* wild type, mutant or complemented  
 80 strain cells/20 g body weight on day 0. Each dot represents the fungal burden in the  
 81 respective organ of one mouse. No statistically significant differences were observed for

82 liver, spleen and kidney. Dashed lines represent the detection limit and dots below this line  
83 mean no cfu were detected in the respective organ.

84 **FIGURE S7 Inflammatory response during systemic *C. glabrata* and *C. albicans***  
85 **infections.**

86 Five mice per group were intravenously infected with  $2.5 \times 10^7$  *C. glabrata* or  
87  $2 \times 10^5$  *C. albicans* cells/20 g body weight on day 0 and sacrificed at indicated time points.  
88 The cytokine and MPO amount in tissue homogenates of (A) brain, (B) kidneys, (C) liver and  
89 (D) spleen was quantified by ELISA, normalized to the body weight of the respective mouse,  
90 and the mean values are represented. A color code ranging from red (highest) to blue  
91 (lowest) is shown for both *Candida* species and each cytokine separately and tables  
92 highlighted in grey means not detectable. Statistical analysis was performed with a one-way  
93 ANOVA on data sets from the same day to compare the wild type with the mutant or the  
94 mutant with his respective complemented strain, followed by Dunn's multiple comparison test  
95 (\*  $p \leq 0.05$ , \*\*  $p \leq 0.01$ , \*\*\*  $p \leq 0.001$  comparing wt and deletion mutant; ##  $p \leq 0.01$ , ###  $p \leq$   
96 0.001 comparing deletion mutant to the respective complemented strain).

97 **Table S1. Strains used in this study.**

name	internal ID	designation/ genotype	reference
<b>C. albicans strains</b>			
SC5314	C55	clinical isolate	(Gillum, Tsay, & Kirsch, 1984)
BWP17	M130	<b>parental strain</b> (derivative of SC5314) <i>ura3::limm434/ura3::limm434</i> <i>his1::hisG/his1::hisG</i> <i>arg4::hisG/arg4::hisG</i>	(Wilson, Davis, & Mitchell, 1999)
BWP17 Clp30 (Ca wt)	M1477	<b>isogenic wild type</b> <i>ura3::limm434/ura3::limm434</i> <i>his1::hisG/his1::hisG</i> <i>arg4::hisG/arg4::hisG</i> <i>RPS1/rps1::Clp30-URA3-HIS1-ARG4</i>	(Citiulo et al., 2012)

**Summary:**

For a better understanding and treatment of infections caused by *C. glabrata*, it is essential to investigate the molecular basis of fungal virulence and resistance. The established RNA interference (RNAi) system in *C. glabrata* uses Dicer and Argonaute genes from *Saccharomyces castellii* and results in 30 and 70% knockdown of reporter genes and putative virulence genes. The screening of an RNAi mutant library identified new virulence-related genes involved in the maintenance of cell integrity, antifungal drug and ROS resistance, which could be promising targets for the treatment of *C. glabrata* infections.

The yeast *Candida glabrata* is a major opportunistic pathogen causing mucosal and systemic infections in humans. Systemic infections caused by this yeast have high mortality rates and are difficult to treat due to this yeast's intrinsic and frequently adapting antifungal resistance. To understand and treat *C. glabrata* infections, it is essential to investigate the molecular basis of *C. glabrata* virulence and resistance. We established an RNA interference (RNAi) system in *C. glabrata* by expressing the Dicer and Argonaute genes from *Saccharomyces castellii* (a budding yeast with natural RNAi). Our experiments with reporter genes and putative virulence genes showed that the introduction of RNAi resulted in 30 and 70% gene-knockdown for the construct-types antisense and hairpin, respectively. The resulting *C. glabrata* RNAi strain was used for the screening of a gene library for new virulence-related genes. Phenotypic profiling with a high-resolution quantification of growth identified genes involved in the maintenance of cell integrity, antifungal drugs, and ROS resistance. The genes identified by this approach are promising targets for the treatment of *C. glabrata* infections.

## INTRODUCTION

The yeast *Candida glabrata* is an opportunistic human pathogen that causes relatively benign mucosal or fatal systemic infections. The incidence of infections caused by this *Candida* species has significantly increased particularly in immune-deficient patients, in addition to those that undergo chemotherapy, treated with broad-spectrum antibiotics for prolonged time, or have undergone a higher number of invasive surgeries (Pfaller and Diekema, 2007). In healthy humans, *Candida* species colonize the oral cavity, vagina, and gut (Mårdh et al., 2002; Moyes and Naglik, 2011). In many studies, *C. glabrata* and *C. albicans* are considered the most common causes of candidiasis (Fidel et al., 1999; Brunke and Hube, 2013). While *C. glabrata* is a distant relative of *C. albicans*, it is a close relative of bakers' yeast *Saccharomyces cerevisiae*

(Dujon et al., 2004). In evolutionary time scales, *C. glabrata* only “recently” became pathogenic (Brunke and Hube, 2013; Ahmad et al., 2014). The mechanisms behind *C. glabrata* pathogenicity are thus far not well understood, but appear to differ greatly from *C. albicans*. Immune evasion strategies, possibly via intracellular survival and replication in macrophages contribute to the virulence of *C. glabrata* (Seider et al., 2011, 2014; Brunke and Hube, 2013; Kasper et al., 2014). *C. glabrata* also readily rearranges its genome (Ahmad et al., 2014) at a frequency one order of magnitude higher than in *C. albicans* (Gabaldón and Fairhead, 2018). Genome rearrangements could be evolutionary advantageous for this yeast, allowing it to adapt rapidly to its host environment and to antifungal treatments.

Research focused on *C. glabrata* pathogenicity can benefit greatly from the development of molecular tools. In *S. cerevisiae*, the strategy of gene deletion has been used for decades as an approach to study gene function. However, Giaever et al. (2002) found that approximately 1000 mutants (representing ~17% of all *S. cerevisiae* genes) failed to grow as a result of a specific gene deletion in haploids, proving that these genes are essential for this yeast. The genome of *C. glabrata* has 5283 predicted coding sequences, and extensive research has been devoted to the creation of a whole genome deletion library for this haploid yeast (Schwarzmueller et al., 2014). Large-scale gene deletions for *C. glabrata* proved less feasible than for *S. cerevisiae* due to gene essentiality or technical reasons (lower homologous recombination rates). However it must be assumed that *C. glabrata* contains a similar number of essential genes as *S. cerevisiae*.

Other techniques, such as down-regulating gene expression can provide alternative ways to study genes' functions. The RNA interference (RNAi), which relies on manipulating the levels of a gene's transcript, has become a widespread tool to analyze the function of genes in organisms ranging from protozoa to human. Unlike gene deletions, RNAi can be applied to any gene, even those that are essential. It has, however, not found many applications in baker's yeast, which naturally lack important components of the RNAi machinery (Drinnenberg et al., 2009). The RNAi approach relies on the activity of two proteins, Dicer (ribonuclease III) and Argonaute (the carrier of small interfering RNA [siRNAs]). The process is initiated by the cleavage of double stranded RNA (complementary to the target transcript) by Dicer into siRNAs, which are then loaded on Argonaute and, by base-pair interaction, target the gene's transcript. This ultimately interferes with gene expression by down-regulation. RNAi is found widely in nature (plants, animals, and fungi), and provides evolutionary advantages by protecting these organisms from viruses, taking part in gene silencing, heterochromatin organization, and chromosome segregation (Tijsterman et al., 2002; Martienssen et al., 2005; Moazed, 2009).

Remarkably, although RNAi is well preserved among some fungi (Drinnenberg et al., 2009), it has been lost in several budding yeasts such as *S. cerevisiae* and *C. glabrata*. The aim of this study was to develop a RNAi system for *C. glabrata* and to

use it as a tool to identify and functionally analyze genes known to be putatively required for virulence.

## RESULTS

### Introduction of RNAi Into *C. glabrata*

For the reconstitution of an RNAi mechanism in *C. glabrata*, two heterologous *Saccharomyces castellii* genes, *DCR1* and *AGO1* (coding for Dicer and Argonaute, correspondingly) were introduced into the *C. glabrata* genome. For this purpose we first evaluated the activity of several constitutive and inducible promoters by their ability to induce expression of a functional enzyme, deoxyribonucleoside kinase of *Drosophila melanogaster* (**Supplementary Figure S1**, Methods). The *dNK* gene encoding this enzyme was successfully expressed in *C. glabrata* and different enzyme activity was observed when expressed from different promoters (**Supplementary Figure S1**). For the expression of *DCR1* and *AGO1* genes in the *C. glabrata*, we used the strong constitutive promoters *TEF1* and *TDH3* of *C. glabrata* (**Figure 1A** and **Supplementary Figure S1**). The plasmid carrying the *DCR1* and *AGO1* constructs (P1062, **Supplementary Table S2**) was linearized by *SphI* and integrated into the genome of three standard laboratory *C. glabrata* strains, BG2, CBS138 and BG14 (**Table 1**).

To first prove that the RNAi pathway can function in *C. glabrata*, we generated silencing constructs targeting the two genes *URA3* (encoding orotidine 5'-phosphate decarboxylase) and *ADE2* (encoding phosphoribosylaminoimidazole carboxylase) in the *C. glabrata* genome. They are part of the uracil (*URA3* gene) and adenine (*ADE2* gene) biosynthesis pathway and are popular auxotrophic markers in yeast genetics. Lack or loss of function of these genes products result in following phenotypes: requirement of uracil/adenine for growth, accumulation of *p*-ribosylaminoimidazolecarboxylate (red pigment) in the absence of *ADE2* transcript, and resistance to 5-FOA without *URA3*. We used two different silencing constructs for these genes (antisense and hairpin), which we introduced into the *lys2* auxotrophic variant of BG2 carrying RNAi genes (Y1662, **Table 1**) by transforming it with integrative plasmids. The design of silencing constructs was similar to that used by Drinnenberg et al. (2009), where the antisense constructs consisted of 339 bp of antisense DNA strand of the gene and hairpins had 339 bp of both antisense and sense DNA strand separated by 79 bp “loop” (**Supplementary Data**). *SalI* linearized the plasmids with antisense constructs, and *SmaI* linearized hairpin plasmids before the transformation. For the expression of silencing constructs we selected the strong inducible *C. glabrata* promoter *CUP1* (**Figure 1A** and **Supplementary Figure S1**).

Two to three selected transformants of the RNAi strain carrying different silencing constructs were grown on different selective media (**Figure 1B**). We observed a decreased growth among transformants carrying antisense constructs (*URA3*, *ADE2*) under conditions of *CUP1* promoter induction (medium supplemented with copper) on minimal medium lacking uracil or adenine. For hairpin constructs (*URA3*, *ADE2*), a growth inhibition by several orders of magnitudes was observed with

and without *CUP1* promoter induction. Apparently, the *CUP1* promoter was leaky (Supplementary Figure S1) and the hairpin constructs had a strong effect on gene expression. In agreement with this, silencing of the *URA3* gene with the hairpins allowed growth on 5-FOA (Figure 1B), a compound, which is toxic to cells with an active *URA3* gene. Further, *ADE2* silencing with hairpins resulted in accumulation of the red pigment *P*-ribosylamino imidazole on adenine-limited media (10 mg/L), which indicates a block in adenine synthesis (Figure 1B). These results show a strong silencing of model target genes by both *URA3* and *ADE2* hairpin constructs.

To confirm our phenotypic observations, the expression of *URA3* and *ADE2* genes was studied by qRT-PCR in transformants carrying either antisense or hairpin silencing constructs (Figure 1C). Compared to the control strain, both *ADE2* antisense and *URA3* antisense constructs caused 1.4-times and 2-times down-regulation, respectively, of their target genes

specifically in the medium with copper (Figure 1C). In contrast, gene expression in transformants with hairpin constructs was repressed further than that even in the medium without copper, with only slight additional increase in the presence of Cu ions (Figure 1C).

The experiment showed that the reconstituted RNAi pathway in *C. glabrata* is functional and can be applied for gene silencing in this yeast.

### Knock-Down of a Known Virulence Gene

In addition to model genes, we designed silencing constructs for *PUP1/CAGL0M12947g* gene of *C. glabrata* to be tested in our RNAi system in *C. glabrata* CBS 138 strain. The deletion of this gene, encoding a mitochondria localized protein, decreases the virulence of azole resistant strain DSY565 of *C. glabrata* in an immuno-compromised mouse model (Vermitsky et al., 2006; Ferrari et al., 2011). Both DSY565 and CBS 138 strains are

fluconazole resistant. As estimated in our lab, the CBS138 strain has fluconazole MIC of 129 mg/L, which is higher than that of DSY565 (fluconazole MIC of 64 mg/L, Vale-Silva et al., 2017). To achieve a stable integration for silencing constructs in the genome, we targeted the 18S rDNA locus of *C. glabrata* CBS 138 strain with RNAi. For a constitutive expression level, the promoter *PGK1* of *C. glabrata* was selected (**Supplementary Figure S1**).

We constructed two recombinant plasmids carrying antisense or hairpin constructs for the *PUP1* (**Supplementary Table S2**). These vectors (P1125 and P1151) were linearized with *SacII* (this restriction site is present in the 18S rDNA sequence) and transformed into CBS 138-based *C. glabrata* master strain Y1699 carrying both *DCR1* and *AGO1* genes (**Table 1**). The plasmid linearization in 18S rDNA region generated homologous regions for ends-in homologous recombination with 18S rDNA loci. To check the stability of the plasmids' integration into the genome, the recombinant colonies were grown for several generations on non-selective YPD medium. The strains were analyzed by PCR to confirm the presence of antisense or hairpin "bullets" and

integration of both *DCR1* and *AGO1*. Then 90% of all strains carrying the inserts were stable for 60 generations.

Using this approach, we constructed two strains, Y1843 and Y2172, which carry antisense and hairpin constructs for the *C. glabrata PUP1* gene, respectively. As survival in macrophages may be one important virulence determinant of *C. glabrata* (Brunke and Hube, 2013), we used a macrophage-confrontation assay for the analysis of fitness of our mutant. In this macrophage confrontation assay, the strains carrying the *PUP1* antisense and hairpin constructs showed decreased intracellular survival of 42% (for antisense construct) and 29% (for hairpin construct) of their mean values compared to the empty-vector control strain Y1848 (**Figure 2**). While the silencing constructs reduced survival comparing to the control (ANOVA,  $p = 0.02$  and  $p = 0.1$ ), the difference between the antisense and hairpin transformants survival was not significantly different (ANOVA,  $p = 0.42$ ). Compared to the control strain, the *PUP1* gene expression was 10-fold lower in the *PUP1* antisense strain, and 1000-fold lower in *PUP1* hairpin strain (**Supplementary Figure S2**). The ratio of gene size to antisense region was  $\sim 2$ . Our results of the

down regulation of *PUP1* gene by silencing constructs prove that our RNAi system can be used to study gene functions in an infection model and show that *PUP1* is required for *C. glabrata* survival in macrophages.

### Construction of RNAi Gene Library to Detect New Virulence-Associated Genes of *C. glabrata*

To use our RNAi system as a basis for the identification of infection-relevant *C. glabrata* genes, we constructed a library of *C. glabrata* genome fragments on a plasmid vector (P1226) carrying an ARS-like sequence, which results in about 10 copies per cell (Hanic-Joyce and Joyce, 1998) (Figure 3A). The expression cassette for genomic fragments contained the strong constitutive promoter *TEF1* and the terminator *CYC1* of *C. glabrata*. The resulting gene-library plasmids were isolated from 400,000 bacterial transformants, and 40% of these carried inserts ranging from 1 to 5 kb in size as estimated by *Sau3AI*

enzyme digestion of the plasmid DNA. The constructed gene library therefore represented at least a 10× genome coverage of *C. glabrata* as estimated by the number of clones and their plasmid insert sizes. This library was used to transform the BG2-based *C. glabrata* strain with the reconstituted RNAi pathway, Y1662 (Figure 3). In this case, both sense and antisense DNA fragments (depending on the orientation of the ligated genomic fragments) could determine the transformant's phenotype. We expected that the sense fragments lead to gene up-regulation, while the antisense fragments lead to gene down-regulation (silencing).

### RNAi Gene Library Phenotypic Screening Identifies Putative Virulence-Associated Genes

A total of 1080 *C. glabrata* strains with the gene library were selected randomly from ~5000 colonies obtained after transformation, and subjected to phenotypic profiling in search

of novel virulence-related genes involved in ROS tolerance, and antifungal drug resistance (Figure 3), attributes that help *C. glabrata* survive in the host. In addition, we selected medium with SDS for the large-scale cloning of genes responsible for *C. glabrata* cell integrity, and pH indicator for monitoring the colonies surface pH (Figure 3). Later can be explored further as targets for the development of new antifungals to destroy the cell or studied for its pH alteration properties in macrophages.

In the first round of screening, 1080 transformants were analyzed for their growth capacity in two replicates at high resolution using a robotic platform. The plating and growth screening were carried out on solid media containing fluconazole, amphotericin B, menadione, hydrogen peroxide, SDS, or the pH indicator bromocresol green. As shown in Figure 4, the *C. glabrata* transformant colonies varied in their growth phenotypes with a high correlation between two replicates. In comparison to the control medium (YNB with 2% glucose), the addition of selected compounds in most conditions resulted in more divergent transformant phenotypes (colony sizes) relative to the control transformant with an empty vector (used for the normalization and has value 1). Transformants with colony size

different to the control strain under the conditions studied are of interest for further study, as the genes, which can contribute to this superior or diminished growth, are potential antifungal targets. Several transformants were resistant or sensitive to different stress conditions (Figure 4).

The second round of screening was performed for the sensitivity to the potent new antifungal peptides 6, 9, and 11 developed by Larsen et al. (2015). For this, we used selected transformants with stress-related phenotypes (identified in the first round, 139 transformants) and 54 previously untested randomly picked up transformants. Transformants were tested in replicate and 11 transformants proved to be sensitive or resistant to one or all of the antifungal peptides tested (Table 2).

In total, we randomly selected 82 gene library transformants for sequencing, all of which showed increased or decreased stress sensitivity, and/or changed resistance to antifungal drugs tested, for sequencing. The inserts of the isolated plasmids were sequenced from the promoter *TEF1* and the terminator *CYC1* and 24 inserts sequences, which were obtained in full, contained one gene (or portion of a gene) in either the sense or anti-sense orientation (Table 2). The *C. glabrata*

CAGL0G05335g gene, (*TPS2*) encoding a subunit of trehalose-6-phosphate synthase/phosphatase complex and known to be associated with virulence in *C. albicans* (Van Dijck et al., 2002), was found on two plasmids. Most of the genes isolated were so far uncharacterized (Table 2). Potential gene functions predicted from orthologs of identified genes in other species cover numerous cellular processes including RNA processing and transcription regulation, adhesins, trehalose biosynthesis, ethanol production, protein folding, chromosome maintenance and recombination, and metabolite transport. We also found two clones with antisense fragments to genes, whose orthologs in *S. cerevisiae* are essential: CAGL0H00891g (*S. cerevisiae* *IQG1* encodes protein required cytokinesis (Epp and Chant, 1997), and CAGL0A01430g [*S. cerevisiae* *TRP5* gene encodes tryptophan synthase and whose mutations results in tryptophan auxotrophy (Braus, 1991)].

Seven transformants proved to be sensitive to one or to all antifungal peptides tested (Table 2). For example, transformant 81C6 (5N2) was sensitive to peptide 6, 9, and 11 (Table 2 and Figure 5), and was found to carry the plasmid with antisense fragment to the *C. glabrata* CAGL0J02464g gene, which encodes a putative isopeptidase, that is possibly able to directly cleave or modify the tested peptides. Four transformants proved to be resistant to one or to all antifungal peptides tested (Table 2). Transformant 81E12 (2A3) was resistant to peptide 9 (Table 2 and Figure 5), and was found to carry the plasmid with sense fragment of the *C. glabrata* CAGL0B01683g/*TMN2* gene's open reading frame, which ortholog in *S. cerevisiae* is a membrane protein, which take part in endosome-vacuolar trafficking. The degradation of other antimicrobial peptides by targeting to yeast vacuole was reported by other studies (Lis et al., 2009; Muñoz et al., 2013).

In addition sensitivity to antifungal drugs, the transformant 3F3 displayed more acidic colony surface on medium with pH indicator bromocresol green, as the colonies of this strain

had darker yellow color than the control strain (Figure 6A), indicating acid pH ( $\leq 3$ ) of 3F3 colonies. The observed properties of 3F3 on bromocresol green could affect its survival after phagocytosis. Sequencing of the insert of the gene library plasmid isolated from 3F3 showed that it carried an antisense insert of the uncharacterized gene of CAGL0K11968g of *C. glabrata*. In *S. cerevisiae*, the gene-ortholog has a 3-hydroxyisobutyryl-CoA hydrolase activity and a role in the stress-activated MAPK cascade with its mutation affecting the fluid-phase endocytosis<sup>1</sup>. Indeed, vacuolar staining revealed that as in deletion mutants of *S. cerevisiae*, the down-regulation of this gene in *C. glabrata* affects the vacuolar morphology (Figure 6B). We tested the 3F3 strain in our macrophage model, where it was 50% more susceptible to killing after macrophage phagocytosis (Figure 6C). The macrophages phagosome maturation is accompanied with high level of ROS, and one of *C. glabrata* strategies to proliferate inside the macrophages is lowering ROS (Seider et al., 2011). Our study of 3F3 strain showed that it had lowered proliferating properties inside the macrophages (lowered survival). The expression of the 3F3 plasmid (antisense) was also found to confer hydrogen peroxide sensitivity in RNAi strain but not in wild type (Supplementary Figure S3).

In summary, using high resolution of mitotic growth screening of gene library in RNAi strain we cloned several putative virulence-related genes.

### RNAi Gene Library Antisense Plasmids Inhibit the Expression of Their Target Genes

Further studies are needed to verify each isolated gene by the gene overexpression studies or gene deletions. Moreover, the antisense and truncated gene constructs may have off target effects on other gene expression as observed in mammalian cells (El-Brolosy and

"#", location on the graph, **Figure 4**. "+", resistant. "-", sensitive.

Stainier, 2017; Ma et al., 2019; Wilkinson, 2019), and studying the global gene expression of these strains could give more information on this in future studies. In this study, to rule-out the possibility of off-target gene inhibitions we have investigated the target gene expression of 10 antisense constructs in both wild type and RNAi strains.

For this purpose we took ten gene library antisense plasmids (2C23, 2E5, 81E20, 6D19, 3F3, 2I5, 82N22, 81N8, 83K11, and 2G7) and transformed them into the wild type and RNAi strains. Two transformants of each plasmid were selected for the analysis. The RNA was extracted from their cultures grown in YNB

with 2% glucose and gene expression was studied by qRT-PCR (**Figure 7** and **Supplementary Figure S4**). Plasmids 2C23, 2E5, 81E20, 2I5, and 82N22 had stronger gene expression inhibition in RNAi strain than in WT. Plasmids 6D19, 3F3, 81N8, 83K11, and 2G7 proved to inhibit the target genes in RNAi strain but not in the WT strain (**Figure 7**). This suggests that the gene inhibition is indeed mediated through RNAi. Phenotypes observed during the robotics screening were re-confirmed for most plasmids after the re-transformation (**Supplementary Figure S3**). While some of the phenotypes were unique to RNAi transformants (H<sub>2</sub>O<sub>2</sub> sensitivity in 2I5, 3F3, 82N22, and 81E20), 2I5 conferred

the amphotericin resistance to both RNAi and wild type strain (**Supplementary Figure S3**).

## DISCUSSION

The yeast *C. glabrata* is an important opportunistic human pathogen, which has become of interest over recent decades, particularly due to its increasing occurrence and resistance to antifungal drugs.

Unlike for *S. cerevisiae* and *C. albicans*, there are no extensive genetics toolboxes available for *C. glabrata* and thus this yeast remains poorly studied. Gene deletions in this yeast for gene function elucidations are not easy to obtain. With a higher rate of non-homologous recombination in *C. glabrata* than that in *S. cerevisiae* (Cormack and Falkow, 1999; Corrigan et al., 2013), longer homology regions are required for more efficient gene knockouts in *C. glabrata*; haploid asexual nature of *C. glabrata* prohibits many techniques based on mating developed for *S. cerevisiae*. In this study, we developed a new tool for *C. glabrata* based on RNA interference (RNAi), which relies on gene silencing through double-stranded RNA intermediates and siRNA. This ancient mechanism of protection from foreign DNA and chromatin organization is lost in Hemiascomycetes (Axelson-Fisk and Sunnerhagen, 2006) with the exception of *Saccharomyces castellii* (Drinneberg et al., 2009). We therefore cloned the *DCR1* and *AGO1* genes from *S. castellii* and overexpressed them in *C. glabrata* together

with silencing constructs. Judging from our data on silencing of metabolic genes (endogenous *ADE2* and *URA3* genes), the introduced RNAi pathway is functional and can be applied to additional genes of interest in this yeast. We found that gene silencing was stronger with hairpin compared to antisense constructs in this study similarly to Drinneberg et al. (2009). Although our data indicate that the *CUP1* promoter used for RNAi is leaky, the antisense constructs resulted in decreased gene expression and detectable phenotypes only upon its induction by copper. In contrast, the hairpin constructs displayed high inhibition of gene expression regardless of the *CUP1* promoter induction, which suggests that the designed hairpins are very effective in our system.

Our RNAi tool proved to be active when we tested it with an established virulence-associated gene *CAGL0M12947g* (*PUP1*) of *C. glabrata*, which was shown by deletion to be important for a survival in a mouse model (Ferrari et al., 2011). Here, we showed that down-regulation of this gene affects survival in human macrophages. Its ortholog (*RCI37/YIL077C*) is poorly studied in *S. cerevisiae*. Although it is known to localize in the mitochondria and interact with the respiratory chain (Morgenstern et al., 2017), the mechanistic connections of its *C. glabrata* ortholog to virulence remain unknown.

We were interested to apply the developed RNAi for the discovery of new virulence-associated genes of *C. glabrata*. We did this by using the RNAi strain with a gene library as the basis for screening of virulence-related phenotypes and the identification of responsible genes. To this end we created a

library of random genome fragments in the expression vector. In contrast to hairpin constructs, this approach is feasible on the genomic level (the library represents 10-fold genome coverage),

and we can assume that a significant portion of clones will carry the antisense regions of genes to induce RNAi. Since the inhibitory effect of the antisense constructs was less efficient than

hairpins in our model and required a high expression level, the gene library was constructed using the strong constitutive *TEF1* promoter and a multi-copy vector.

Our primary interest was to discover genes, which affect *C. glabrata* resistance to antifungal drugs, and to stress conditions that *C. glabrata* may face during survival in macrophages. Therefore, we selected the following conditions for cell growth *in vitro*, which have overlap in their targets in yeast. In our screening we selected fluconazole and amphotericin B, which are both antifungal drugs currently in use against candidiasis, and which target the plasma membrane. Although the mechanism of action of many azole drugs and resistance to them are quite extensively studied (Vale-Silva and Sanglard, 2015), the molecular mechanism of amphotericin B action and resistance remains poorly understood. We also tested hydrogen peroxide and menadione since ROS are elevated upon amphotericin B exposure (Mesa-Arango et al., 2014), and are produced inside

the macrophages phagosomes (Seider et al., 2014), and resistance against ROS is important for pathogen survival. SDS was tested to mimic damage to the plasma membrane. In addition, we used new antifungal drugs for the *C. glabrata* gene library screening including three peptidomimetics with an arginine-[ $\beta$ -(2,5,7-tri-tert-butylindol-3-yl)alanine]-arginine motif, which were recently developed (Larsen et al., 2015), and are effective against *S. cerevisiae* as well as *Zygosaccharomyces bailii*, known to spoil food. Interestingly, *C. glabrata* was previously shown to be resistant to these peptides (Larsen et al., 2015) and finding the resistance genes in pathogenic yeasts can help to develop potent antifungals further.

The frequent and large size differences of transformants colonies in our screening indicated that a broad range of genes was covered by the RNAi library strains. We selected representative resistant and sensitive transformants for sequencing of their plasmid inserts to determine the original

genome loci. Using this approach, we found that several positive clones of our RNAi library corresponded to putative virulence-associated genes. This shows that our approach allows us to recover genes with relevance for *C. glabrata* pathobiology, which can be exploited further for the development of treatments for *C. glabrata* infections.

The gene down-regulation and expression of truncated genes might affect the expression of other genes in the genome, their genes network as described for mammalian cells (El-Brolosy and Stainier, 2017; Ma et al., 2019; Wilkinson, 2019). This effect, genetic compensation, is also common for gene knockouts in yeasts (He and Zhang, 2006; Teng et al., 2013). The expression of antisense constructs spanning the coding regions in *S. cerevisiae* from the plasmid vectors were reported to inhibit the *ATH1* and *CAR1* gene expression (Park et al., 2001; Jung and Park, 2005) suggesting the natural antisense interference without RNAi (Donaldson and Saville, 2012). The whole genome sequencing and global gene expression profiling can give more information on any off-target effects of isolated gene library clones in the future studies. When we analyzed ten antisense constructs, all 10 down-regulated the target genes, and 5 of 10 worked through the RNAi because they did not down-regulate the gene expression in the wild type strain without RNAi pathway.

Three of the genes identified in our screen were predicted glycosylphosphatidylinositol (GPI)-anchored proteins and adhesins (CAGL0L00157g, CAGL0E00231g, and CAGL0I11011g), and the expression of their antisense regions leads to sensitivity to fluconazole, amphotericin B, menadione, hydrogen peroxide, and SDS. GPI-anchored proteins are abundant membrane and cell wall proteins with multiple roles, and their biosynthesis is reportedly linked ergosterol biosynthesis and azole drug response, Ras signaling (Yadav et al., 2014). The GPI-anchored proteins are therefore important antifungal targets, and are in the focus of drug discovery studies (Mann et al., 2015). It is important to note that the antisense region of the 2C23 isolate of our study included a part of the GPI-anchored protein transmembrane domain (CAGL0L00157g), which is a fragment of 17 other GPI-genes sequences in the *C. glabrata* genome. This suggests that the construct affected several GPI proteins, likely resulting in altered plasma membrane structure.

The 6K21 strain, which was sensitive to antifungals and ROS, carried the overexpression plasmid for a sense fragment of transporter gene CAGL0J01661g, whose ortholog in *S. cerevisiae* (YPR011C) encodes a mitochondrial transporter for adenosine 5'-phosphosulfate (APS) and 3'-phospho-adenosine 5'-phosphosulfate (PAPS), the deletion of which causes the decreased glutathione and methionine levels and temperature sensitive phenotype (Todisco et al., 2014), and glutathione is known ROS scavenger (Jamieson, 1998).

Our results point at the *TPS2* gene, encoding trehalose-6 phosphate phosphatase of *C. glabrata*, as a potential drug target with virulence-associated roles in this yeast. The *TPS2* antisense construct expression resulted in sensitivity to fluconazole, amphotericin B, and other stressors. The deletion of *TPS2* in both *S. cerevisiae* and *C. albicans* causes the accumulation of increased amounts of trehalose-6 phosphate upon stress, which is toxic to the cell, and results in thermo-sensitive phenotype

(De Virgilio et al., 1993; Van Dijck et al., 2002). In *C. albicans*, it was also found to reduce the virulence as the survival of infected mice in systemic infection model was increased (Van Dijck et al., 2002). Indeed, the deletion of this gene leads to impaired growth in *C. albicans*, and other species, and the gene product itself is considered as a potential target for antifungal therapy (Van Dijck et al., 2002; Pianalto and Alspaugh, 2016).

The transformant 3I5 carried a gene library plasmid with a complete *ADH1* open reading frame in the sense direction. It proved to be sensitive to fluconazole, amphotericin B, peptides, SDS, and reactive oxygen species. The *ADH1* gene is encoding alcohol dehydrogenase, responsible for the conversion of acetaldehyde to ethanol. In *C. albicans*, the expression of the *ADH1* and azole resistance is inversely correlated in clinical isolates (Siikala et al., 2011). On the contrary, increased abundance of the Adh1 protein was previously observed in an azole resistant strain of *C. glabrata* (Rogers et al., 2006). Since we do not have the data on the *ADH1* expression in 3I5 strain, further study is needed.

Due to their low toxicity, the peptidomimetics are potent antifungal drugs (Larsen et al., 2015). A mode of action of these peptides is likely the interaction with sphingolipids, as determined by the analysis of deletion mutants' library in *S. cerevisiae* (Larsen et al., 2015). Larsen et al. (2015) pointed out that higher resistance in pathogenic yeasts (*C. albicans* and *C. glabrata*) to these compounds might be due to the secretion of extracellular proteases, which sequester or degrade the antifungals. One of the isolated *C. glabrata* antisense plasmids carried part of the CAGL0J02464g gene, whose orthologs have SUMO (Small Ubiquitin-like Modifier)-specific isopeptidase and protein deSUMOylation activities. The encoded isopeptidase could be important for the resistance to peptidomimetics in this yeast and could be involved in their direct cleavage, in support of the hypothesis proposed by Larsen et al. (2015). In addition, fragments of two putative aminoacyl-tRNA genes were found with our system affecting the peptidomimetics resistance. We hypothesize that they could directly interact with peptidomimetics or their targets by acylating them. Aminoacyl-tRNA dependent acylation is involved in several cellular processes and resistance to antifungal peptides reported in other species (Raina and Ibba, 2014). Acylation of membrane lipids is known to change the membrane surface and subsequently the affinity of the membrane to antifungal peptides in other species (Ernst and Peschel, 2011; Raina and Ibba, 2014). The direct acylation of macromolecules using aminoacyl-tRNA can change their activity, recognition or directs them to degradation (Katz et al., 2016).

Taking a step further, we validated the importance of one of the identified target in the macrophage model. We confirmed the vital importance of the *C. glabrata* CAGL0K11968g gene affecting colony pH and vacuolar function with this screening method. With the antisense construct for this gene the *C. glabrata* strain was less viable upon exposure to human macrophages.

We have thus established a working RNAi system for the investigation of *C. glabrata* pathobiology. Our initial testing showed that the system can be used to interfere with the expression of a broad range of genes, including those assumed

to be essential for *C. glabrata*. The RNAi strains can be used in *in vitro* stress tests and in interaction with immune cells, which will be invaluable in attributing functions to the many genes of *C. glabrata*, which are unannotated so far. Our screening of a RNAi library with genome fragments is a first step into that direction. Especially, as this method enables us to tackle new genes, which are central for fungal growth and survival, we believe that it will allow us to find important new potential targets for *C. glabrata* antifungals, a yeast that is notorious for its inherent and acquired resistances.

## MATERIALS AND METHODS

### Growth Conditions

All strains used in this study were grown in rich medium (YPD [yeast extract 1%, peptone 2%, glucose 2%, Bactoagar 2%]) or synthetic minimal medium (YNB [yeast nitrogen base without amino acid and ammonium sulfate] 1.9 g/L, glucose 2%, ammonium sulfate 0.5%) at 25°C, unless stated otherwise. For the uracil-deficient mutant BG14, 50 mg/L uracil was added to the YNB medium. For the lysine-deficient mutants, 40 mg/L lysine was added to the minimal medium. *C. glabrata* transformants carrying plasmids with the *LYS2* gene as a selectable marker were selected and propagated on YNB medium. For *C. glabrata* transformants carrying the *Streptoalloteichus hindustanus ble* gene as a selective marker, 200 µg/ml of zeocin was added to the YPD medium. For the induction of the *CUP1* promoter, 0.05 mM CuSO<sub>4</sub> was added to the YNB medium.

For gene library yeast transformants different compounds were added to YNB medium as follows: amphotericin B (0.05 and 0.25 µg/ml), fluconazole (50 and 400 mg/L), SDS (0.01 and 0.0025%), hydrogen peroxide (3 and 12 mM), menadione (0.02 and 0.06 mM), and antifungal peptidomimetics (peptide 6 [H-Arg-Tbt-Arg-Phe-NH<sub>2</sub>], 9 [H-Arg-Tbt-Arg-hPhe-NH<sub>2</sub>], and 11 [H-Arg-Tbt-Arg-[NPhe]-NH<sub>2</sub>] (Larsen et al., 2015) at 25 µg/ml. Gene library transformants were propagated at 37°C.

### RNA Extraction and qRT-PCR

Total RNA was extracted from the *C. glabrata* cultures grown in selective media (supporting plasmids propagation) using the PureLink RNA Mini Kit (Thermo Fisher Scientific). The concentration and purity of RNA were determined by NanoDrop spectrophotometer. The isolated RNA was treated with DNase I (RNase-Free DNase Set, Qiagen) according to the manufacturer's recommendations. The RNA integrity was checked by electrophoresis using precast RNA MOPS agarose gels (Sigma-Aldrich). Five microgram of pure RNA was used for the synthesis of cDNA. The SuperScript III Reverse Transcriptase kit with RNaseOUT Ribonuclease Inhibitor and random primers (Thermo Fisher Scientific) was used. The cDNA produced was used as a template with gene-specific primers in qRT-PCR reactions with the SYBR GreenER qPCR SuperMix (Thermo Fisher Scientific). qRT-PCRs were run in duplicate in the RotorGene 2000

cyler (Corbett Research) under the conditions specified by Thermo Fisher Scientific. The take off and amplification values were obtained using the RotorGene 2000 software. The β-actin gene was treated as the endogenous reference gene (housekeeping gene), while Y1848 was used as untreated strain. Primer pairs for the 3'-region of the gene ORFs of interest of *C. glabrata* were used in qRT-PCR experiments as follows for the: *ACT1* (OP33 and OP34; ACT1-1 and ACT1-2), *ADE2* (OP31 and OP32), *URA3* (OP27 and OP28), *PUP1* (947-1 and 947-2), CAGL0L00157g (157-1 and 157-2), CAGL0E00231g (231-3 and 231-4), CAGL0G05335g (5335-3 and 5335-4), CAGL0E00539g (539-1 and 539-2), CAGL0K11968g (968-1 and 968-2), CAGL0H00891g (891-1 and 891-2), CAGL0A01430g (1430-3 and 1430-4), CAGL0H07623g (7623-1 and 7623-2), and CAGL0I11011g (11-1 and 11-2) (Supplementary Table S1). The gene expression fold change was calculated by the  $\Delta\Delta Ct$  method (Livak and Schmittgen, 2001).

### Macrophage Culture and Infection With Yeast

Human monocyte-derived macrophages (hMDMs) were prepared according to the protocol used before (Seider et al., 2011, 2014). Monocytes were isolated from human peripheral blood (donated by healthy volunteers with written consent) with CD14 magnetic beads by automated cell sorting (autoMACs, MiltenyiBiotec). CD14-positive monocytes differentiated to M2 macrophages for 7 days in RPMI1640 media with L-glutamine (Thermo Fisher Scientific) with 10% heat-inactivated FCS (Bio&Sell GmbH), and with 50 ng/ml recombinant human macrophage colony stimulating factor (rh M-CSF; Immunotools). Adherent MDMs were detached with 10 mM EDTA in PBS and seeded in 96-well plates (4 × 10<sup>4</sup> hMDMs/well) in RPMI with 50 ng/ml rh M-CSF and 10% FCS and incubated overnight. Prior macrophage infection yeast cells from a stationary YNB culture were washed three times with PBS. M2 macrophages were infected by adding the yeast cells at multiplicity of infection of one (MOI 1) in RPMI w/o FCS. The cells were further diluted and incubated for 3 h at 5% CO<sub>2</sub> and 37°C. Unattached yeast cells were removed by washing the macrophages two times with 60 µl PBS. Next, 20 µl of 0.5% Triton X-100 was added to lyse the macrophages, and incubated 10 min under gentle shaking. After the incubation, cells were diluted, plated on YPD, and incubated at 37°C for 1 day. After incubation, the yeast CFU were counted. The reference strain Y1848 carrying empty vector was used to normalize obtained data and was set to 100% survival.

### Robotics Screening

Individual transformants of the *C. glabrata* RNAi strain (Y1662) containing the gene library plasmids were grown overnight in flat bottom polystyrene 96-well plates in 200 µl of liquid YNB at 37°C (12 plates in total). The next day, yeast transformants were plated onto the solid media YNB supplemented with antifungal drugs

[amphotericin B (0.05 and 0.25 µg/ml) or fluconazole (50 and 400 µg/ml)], ROS generating compounds [menadione (0.02 and 1.06 mM) and hydrogen peroxide (3 and 12 mM)], surfactant (SDS 0.01 and 0.0025%) and a pH indicator (bromocresol green 0.01 g/ml, YNB medium pH was adjusted to 4.5) using a robotic system (Siger RoToR HDA robot). Each 96-well plate liquid culture was plated on solid medium in duplicate, and four were combined onto one 384 format solid medium plate. The colonies growth was scored by the colony size in pixels from the digital images of the plates during 96 h of incubation.

### Vacuolar Staining and Fluorescent Microscopy

Cells were re-suspended in 10 mM HEPES buffer pH 7.4 supplemented with 5% glucose. The fluorescent dye CMAC-Ala-Pro (7-amino-4-chloromethylcoumarin, 1-alanyl-L-proline amide, Yeast Vacuolar Marker Sampler Kit [Thermo Fisher Scientific]) was added to the cell suspension at 100 µM and then incubated in the dark for 30 min. The staining was visualized by fluorescent microscopy (automated inverted wide-field microscope Observer Z1 [Carl Zeiss] equipped with a sCMOS camera).

### Statistical Analysis

The software packages R (Version 1.1.463– ©2009–2018 RStudio, Inc.), JMP®, Pro 13.0.0 (SAS Institute Inc., Cary, NC, United States, 1989–2019) and Minitab®18.1, were used to analyze the obtained data.

### DEDICATION

In loving memory of JP who sadly deceased on May 18, 2014.

### DATA AVAILABILITY

All datasets generated for this study are included in the manuscript and/or the **Supplementary Files**.

### ETHICS STATEMENT

The protocols for the experiments with macrophages were approved by the ethical commissions of the Lund University and the Hans Knöll Institute, Jena.

### AUTHOR CONTRIBUTIONS

OI and JP designed the study. OI, KA, KK, KB, and TS developed the RNAi tool. LK, SB, MS, BH, TH, BG, and OI performed the macrophage experiments. CB, KF, JS, BR, and OI analyzed the gene library. OI, KA, WK, and JP wrote the manuscript. All authors commented on and reviewed the manuscript.

### FUNDING

This study was supported by grants from the Swedish Research Council (2012-02842 and 2016-01164), the Lawsky Foundation, the Royal Physiographic Society of Lund, the Erik Philip-Sörensen Foundation, and the Jörgen Lindström Foundation.

### ACKNOWLEDGMENTS

We thank Paul Joyce (Concordia University, Canada) for providing a plasmid vector carrying ARS-like sequence, pMIR4, Brendan Cormack (The Johns Hopkins University School of Medicine, United States) for providing the BG2 and BG14 strains, and Kate Campbell (Chalmers University of Technology, Sweden) for the help with R-script. JP passed away before the submission of the final version of this manuscript. OI accepts responsibility for the integrity and validity of the data collected and analyzed.

doi: <https://doi.org/10.1101/690503>

#### Summary:

Predatory interactions among microbes are considered as a major evolutionary driving force for defense against phagocytic killing. The transcriptional response induced in *C. parapsilosis* upon confrontation with the fungivorous amoeba *Protostelium aurantium* highlights fungal copper- and redox homeostasis as primary targets during intracellular killing. Site-directed mutagenesis confirmed the role of the copper exporter Crp1 and the thioredoxin peroxidase Prx1 in copper and redox homeostasis, respectively and identified methionine biosynthesis as a metabolic target during predation. Both genes contributed to survival of *C. parapsilosis* encountering *P. aurantium*, but *PRX1* additionally impacts on the survival within human macrophages. The fact that both genes are conserved within the entire *Candida* clade suggested that they could be part of a basic toolkit to survive phagocytic attacks.

#### Own contribution:

Marcel Sprenger assisted the macrophage experiments for fungal RNA isolation, performed and analyzed the macrophage survival experiments for the revised manuscript. Marcel Sprenger edited the manuscript.

### Summary

Predatory interactions among microbes are considered as a major evolutionary driving force for biodiversity and the defence against phagocytic killing. Here we show that confrontation with the fungivorous amoeba *Protostelium aurantium* triggers selective predatory responses in three different yeasts of the genus *Candida*. While *C. albicans* escaped initial recognition, *C. glabrata* was rapidly taken up, but remained undigested with prolonged survival. Phagocytic killing and feeding by *P. aurantium* were highly effective for the third major pathogen, *C. parapsilosis*. These three different outcomes of the confrontation with the predator were reflected by distinct transcriptional responses, indicating fungal copper- and redox homeostasis as primary targets during intracellular killing. Gene deletions for the highly expressed copper exporter *Crp1* and the peroxiredoxin *Prx1* confirmed their role in copper and redox homeostasis, respectively and identified methionine biosynthesis as a metabolic target during predation. Both, intact Cu export and redox homeostasis contributed to the survival of *C. parapsilosis* not only when encountering *P. aurantium*, but also in the presence of human macrophages. As both genes were found to be widely conserved within the entire *Candida* clade, our results suggest that they could be part of a basic tool-kit to survive phagocytic attacks by environmental predators.

## Introduction

Members of the genus *Candida* are among the leading causative agents of fungal infections worldwide with *Candida albicans* being responsible for the majority of candidiasis cases, followed by *C. glabrata* and *C. parapsilosis* (Dadar *et al.*, 2018). All three *Candida* species are known to be commensals being frequent residents of the oral cavities, the gastrointestinal tract or the skin. Environmental reservoirs for any of these species have rarely been documented, but recent isolations of *C. parapsilosis* or *C. albicans* from pine and oak trees, respectively, suggest that these might exist (Bensasson *et al.*, 2018, Robinson *et al.*, 2016, Maganti *et al.*, 2012). *C. glabrata*, in turn, has been enriched from fermented foods and grape juice (Greppi *et al.*, 2015, Morrison-Whittle *et al.*, 2018). Within the human host, all three are able to counteract the phagocytic attacks of macrophages and neutrophilic granulocytes to some extent, using different strategies and molecular tool-kits (Erwig & Gow, 2016).

An outer layer of mannoproteins masks pathogen-associated molecular patterns (PAMPs) on the surface of *C. albicans*, hence hindering their initial recognition via cell wall  $\beta$ -glucans (Seider *et al.*, 2010). Even after its ingestion, *C. albicans* can escape from innate immune phagocytes following a morphological switch from yeast to hyphae which triggers the cytolytic death of the host cell (Uwamahoro *et al.*, 2014, Wellington *et al.*, 2014, Kasper *et al.*, 2018). *C. parapsilosis* is also able to survive the restricted phagosomal environment and forms pseudohyphae after internalization by macrophages (Toth *et al.*, 2014). However, its rates of ingestion and killing by neutrophils and macrophages were reported to be higher than for *C. albicans* (Linden *et al.*, 2010, Sasada & Johnston, 1980, Toth *et al.*, 2014). Intracellular filamentation, in turn, is not the typical escape strategy for *C. glabrata*, which can survive and even replicate inside modified phagosomal compartments of macrophages (Kasper *et al.*, 2015).

Estimates indicate that *C. glabrata* may be separated from the other two *Candida* species by more than 300 million years (Pesole *et al.*, 1995), and hence, well before their time as commensals. Comparative genome analysis of *C. glabrata* and its closest relatives have suggested that adaptations preceding its commensal stage may have facilitated traits that later enabled pathogenicity (Gabaldon *et al.*, 2013, Turner & Butler, 2014, Gabaldon & Fairhead, 2019). The increasing clinical records of fungal infections originating from species even without any clear history of commensalism have further raised questions on the role of environmental factors as early promoters of virulence-associated traits.

Predator-prey interactions are considered as drivers of an evolutionary arms race and frequently occur also among microbes. Humans and higher animals are indirectly affected as some microbial defences against phagocytic predators are thought to be effective against innate immune cells such as macrophages and neutrophilic granulocytes. These trained defences may have favoured certain microbes to establish commensalism or appear as new pathogens (Casadevall *et al.*, 2019). Experimental studies have corroborated this idea using well-known model organisms such as *Dictyostelium discoideum* or *Acanthamoeba castellanii* (Steenbergen *et al.*, 2003, Steenbergen *et al.*, 2001, Van Waeyenbergh *et al.*, 2013, Hillmann *et al.*, 2015, Koller *et al.*, 2016). *Protostelium aurantium* is a representative of a widely spread group of amoebae with a fungivorous life-style (Aguilar *et al.*, 2007, Ndiritu *et al.*, 2009, Shadwick *et al.*, 2009a, Zahn *et al.*, 2014, Hillmann *et al.*, 2018). The amoeba was recently found to feed on a wide range of basidiomycete and ascomycete yeast species with *C. parapsilosis* being the most efficient food source, while *C. albicans* and *C. glabrata* were discriminated at the stage of recognition or intracellular processing, respectively (Radosa *et al.*, 2019). In this study, we investigated the responses of *C. albicans*, *C. glabrata*, and *C. parapsilosis* when confronted with the fungivorous predator. Our findings demonstrate that copper and redox homeostasis are central targets during phagocytic predation by *P. aurantium* and suggest that such basic anti-phagocytic defence strategies may have been trained during an arms race with an environmental predator.

## Results

### The predation responses of the three *Candida* species reflect their different prey patterns

While *C. albicans* and *C. glabrata* can escape *P. aurantium* at the stage of recognition or intracellular processing, respectively, *C. parapsilosis* serves as a comparably efficient food source (Radosa et al., 2019). To elucidate common, as well as species-specific reactions to the presence of the predator, we conducted high-throughput RNA sequencing of each of the three *Candida* species in co-cultures with *P. aurantium*. Yeast cells were confronted with trophozoites of *P. aurantium* for 30 and 60 minutes prior to sampling for RNA isolation. For *C. parapsilosis*, a total of 667 genes were upregulated ( $\log_2FC > 1.5$ ), and 588 genes were downregulated ( $\log_2FC < -1.5$ ), while in *C. albicans*, a total of 903 genes were significantly upregulated, and 937 genes were downregulated at both time points (Fig. 1A). In *C. glabrata*, 1218 genes were upregulated, while only 273 genes were found to be downregulated (Fig. 1A). A complete list of DEGs for each species and time point is listed in Dataset S1.

To address the biological significance of up- and downregulated genes, we analysed their annotations for the enrichment of defined categories in molecular function, cell component and biological process (Fig. 1B, Fig. S1, Dataset S2). Overall, the enriched categories for all three *Candida* species partially overlapped, most likely resulting from general metabolic adaptations, e. g. when grouped by molecular function, transferase and ligase activity were categories common to all three fungi among the upregulated genes. However, for *C. glabrata*, there was no significantly enriched biological process among the downregulated genes (Fig. S1) Also, transporter and kinase activity were the only two molecular functions which were enriched among the downregulated genes of *C. glabrata*. In sharp contrast, transporters were found to be generally upregulated in *C. albicans* and *C. parapsilosis*. Higher expression of RNA binding, helicases, and nucleotidyl transferases was unique to *C. parapsilosis*, the preferred prey, implicating that transcription and translation could be most severely affected in this fungus. The finding that the nucleolus and that the biological process categories for RNA metabolism and ribosome biogenesis were all enriched only in *C. parapsilosis* provides additional support for this idea. Further, the extracellular region and the cell wall were more severely affected in *C. parapsilosis* than in *C. albicans* or *C. glabrata* (Fig. 1B).

**Fig. 1: Differentially gene expression in *C. parapsilosis*, *C. albicans* and *C. glabrata* in response to *P. aurantium*.** **A**, Total numbers of differentially expressed genes (DEGs) of *Candida* spp. in the presence of *P. aurantium* after 30 and 60 min. Genes were considered as differentially expressed when the  $\log_2$  fold-change in the transcript level was  $\geq 1.5$  or  $\leq -1.5$  and  $p \leq 0.01$  according to EdgeR at either of the two tested time points. **B**, Gene ontology (GO) clusters for cellular components enriched in up- and downregulated genes of *C. parapsilosis* (blue) and their expression in *C. glabrata* (green) and *C. albicans* (orange) **C**, Principle component analysis (PCA) for read count values from orthologous genes of the three *Candida* species. PC1 and PC2 explain about 68% of the overall variance within the data set and clearly separate all *C. glabrata* samples (green, top left) from those of *C. albicans* (orange) and *C. parapsilosis* (blue). For the two latter species, there is an additional separation between control time point at 0 min (round) and time points 30/60 min (square/diamond). **D**, Venn diagram displaying an overlap in the differential expression of orthologues at 30 and 60 min. Of 3,735 orthologues in total, 2,201 were differentially expressed orthologues (DEOs) and 79 were common (3.6%) to all three species.

**The core response of *C. albicans*, *C. parapsilosis*, and *C. glabrata* to the presence of *P. aurantium***

A principal component analysis was used to determine the dynamic variations in the orthologous DEGs. The response of *C. glabrata* to amoeba predation showed less variation between the time points (see the cluster dendrogram in Fig. S2) and was clearly distinguishable from *C. parapsilosis* and *C. albicans* (Fig 1C). For the latter two, it was evident, that their transcription profiles at time point 30 and 60 min clustered

closer together and displayed a higher variance when compared to the initial time point. To identify a commonly responsive gene set of all three fungi, we compared the differential expression among all their orthologues (DEOs). Overall, 3735 orthologous genes showed differential expression at either one of the two time points (Fig. 1D). Within all three *Candida* species, 79 genes were differentially regulated, representing a core response to the presence of *P. aurantium* (Fig. 1D). Among those, 48 genes were commonly induced, and eight genes were commonly repressed in all three species at either of the time points, while 23 genes showed opposite regulation between the species (Fig.2).

**Fig. 2: Heat map of expression for all 79 differentially expressed orthologues (DEOs) during the confrontation with *P. aurantium*.** All DEOs were grouped according to their transcript profile at 30 min and 60 min *p.i.* and considered as commonly induced or commonly repressed if they shared the expression pattern within all three species. DEOs were considered as oppositely regulated if their expression differed between two species. Red and blue colors represent down- and upregulated genes, respectively. Gene names are based on the orthologues of *C. albicans*.

The corresponding sets of genes were further analysed for significantly shared GO terms in biological processes (Dataset S3). Enriched categories included the sulfur amino acid metabolic process (GO:0000096) comprising genes such as *SAM2*, *MET3*, *ECM17* (*MET5*), *MET15*, *MET16*, all playing a role in the metabolism of methionine. A plethora of genes, predicted to be involved in organo-nitrogen compound biosynthetic process (GO:1901566) such as the amino acid biosynthesis enzymes *ILV2* and *ARG8*, a P-type calcium-transporting ATPase encoded by *SPF1* or genes with role in fatty acid beta-oxidation (GO:0006635) like *ANTI*, *FOX2* or *POXI-3*, were commonly induced as well. The most highly enriched GO term was found to be “negative regulation of helicase activity” comprising three *MCM* genes: *CDC54* (*MCM4*), *CDC46* (*MCM5*) and *MCM3*; all known to be a part of MCM complex, necessary for unwinding the DNA double helix and triggering fork progression during DNA replication (Bochman & Schwacha, 2009).

Noteworthy is further the induction of the *DURI,2* gene, encoding the urea amidolyase and shown to be important for the survival of *C. albicans* in macrophages (Navarathna *et al.*, 2012). No GO category was found to be enriched within the eight commonly downregulated genes. Nevertheless, three out of eight genes, namely *OLE1*, *SCT2* and *AURI*, function in lipid biosynthetic processes and most probably play an important role in the integrity of cell membrane. Interestingly, GO enrichment analysis revealed the glycolytic process through fructose-6-phosphate (GO:0061615) as a highly overrepresented category within the oppositely regulated set of genes: all genes annotated to this category, namely *TPH1*, *PFK1* and *PFK2*, were downregulated in *C. albicans* and *C. parapsilosis*, while in *C. glabrata* they showed an increase in transcript level.

### ***P. aurantium* predation targets copper and redox homeostasis in *C. parapsilosis***

Of all three species, *C. parapsilosis* represented the preferential food source for *P. aurantium*, and thus, we conducted a deeper characterization of the 1255 DEGs (667 genes with  $\log_2FC > 1.5$ , and 588 genes with  $\log_2FC > -1.5$ ) from *C. parapsilosis* using

the GO Slim tool which maps DEGs to more general terms and broad categories (Skrzypek *et al.*, 2017). Most genes could not be categorized, were involved in unknown biological processes, or mapped to regulation as a general category. These were not analysed further. Transport and stress response were the two most frequent biological processes and were further selected to search for more specific categories (Fig. 3). The extra-nuclear transport of ribonucleoproteins was highly enriched as could be expected from the results obtained from the general enrichment analysis for *C. parapsilosis*. We further found the transport of transition metal ions to be overrepresented with several genes encoding orthologous proteins for the transport of Fe and Zn being deregulated in response to *P. aurantium* (Tables S1 and S2).

**Fig. 3: GO Slim categorization of the DEGs from *C. parapsilosis* during the confrontation with *P. aurantium*.** **A**, All 1255 DEGs from 30 min and 60 min after the confrontation with *P. aurantium* were categorized according to GO SLIM processes. **B**, Genes mapped to the GO SLIM categories *transport* and *response to stress* were further analyzed for more specific GO Terms. Categories with the highest enrichment (top 7 for *transport* and top 5 for *response to stress*) are displayed as a 2D dot plot for the number of genes in the respective cluster and fold enrichment (p-value <0.005).

Two Cu transporters were among the most highly deregulated genes in *C. parapsilosis* (Table 1.) The most upregulated gene upon amoeba predation (log<sub>2</sub>FC of approx. 9 at 30 min and 8 at 60 min) was found to be CPAR2\_203720. This gene is an orthologue to *C. albicans* CRP1 (orf19.4784), encoding a copper-transporting P1-type ATPase, which

mediates copper resistance and is induced by high copper concentrations (Weissman *et al.*, 2000).

Interestingly, the second most downregulated gene at 30 min ( $\log_2FC = -9.8$ ), we identified CPAR2\_602990, an orthologue of *C. albicans* *CTR1* (orf19.3646) with copper importing activity. Four other genes annotated as copper transporters were also repressed at both time points.

**Table 1: Expression of *C. parapsilosis* genes involved in the transport of Cu ions (GOID 6825)**

name	$\log_2FC$ 30 min	$\log_2FC$ 60 min	Description	Ortholog in <i>C. albicans</i>

CPAR2_602990	-9.79	- Inf	Ortholog(s) have copper uptake transmembrane transporter activity, role in copper ion import, high-affinity iron ion transport and cytoplasm, nucleus, plasma membrane localization	C6_00790C_A/CTR1

The differential expression of these genes was validated by quantitative real-time PCR and further tested, whether they would also respond to phagocytosis by monocyte-derived human primary macrophages (MDMs). Only for the Cp*CRP1* gene, expression in response to *P. aurantium* and MDMs was fully in accordance, while the expression of Cp*CTR1* was regulated in an opposite manner when the yeast encountered MDMs (Fig. 4A+B). We further investigated the expression of Cp*CRP1* and Cp*CTR1* during copper excess and depletion. As expected, the putative copper exporter gene Cp*CRP1* showed induction when *Candida* was treated with 100  $\mu M$  of Cu, and repression in the presence of the copper chelator BCS (Fig. 4C). Even though the expression of Cp*CTR1* was not significantly influenced by the presence of BCS in the media, remarkable downregulation of this gene was measured at high copper concentration. It is noteworthy that differences in the expression levels for both genes, Cp*CRP1* and Cp*CTR1*, were more pronounced during encounters with *P. aurantium* than with macrophages or the metal itself.

**Fig. 4: Expression of copper and redox homeostasis genes.** Expression of the *CRP1* (CPAR2\_203720), *CTR1* (CPAR2\_602990), and *PRX1* (CPAR2\_805590) of *C. parapsilosis* was analyzed by qRT-PCR using total RNA isolated after the exposure to *P. aurantium* (A, D), human monocyte-derived macrophages (MDMs, B, D), and in the presence of the copper ion chelator BCS or CuSO<sub>4</sub>. All data show average expression levels relative to time point 0 based on three biological and three technical replicates. Error bars indicate the standard deviation.

Intriguingly, four genes encoding superoxide dismutases (SODs) of the Cu/Zn type (CPAR2\_500330, CPAR2\_500390, CPAR2\_213540, CPAR2\_213080) and one Fe/Mn-SOD (CPAR2\_109280) were strongly repressed in the presence of *P. aurantium* (Table 2).

In contrast, genes involved in the thioredoxin antioxidant pathway were found to be highly upregulated, such as CPAR2\_304080, CPAR2\_500130 or CPAR2\_805590. The latter one is an orthologous gene to *C. albicans PRX1*, a thioredoxin-linked peroxidase, shown to be primarily involved in the reduction of cellular organic peroxides (Srinivasa *et al.*, 2012). More than a 5-fold increase in transcript level was observed in *C. parapsilosis* after 30 min of co-incubation with *P. aurantium*. This upregulation further increased up to 9-fold after another 30 min of co-incubation with the predator but remained unaffected in response to primary macrophages (Fig. 4D).

\*only genes with p < 0.01 according to EdgeR are displayed

### *C. parapsilosis* is exposed to ROS during phagocytosis by *P. aurantium*

The induction of genes involved in redox homeostasis prompted us to analyse whether this occurred as a direct response to ROS production by the amoeba. When co-incubating *C. parapsilosis* with *P. aurantium* in the presence of the superoxide ( $O_2^{\bullet-}$ ) indicator dihydroethidium (DHE), an increase in red fluorescence of cultures was specific to the presence of amoebae and reached a maximum after 10 min of co-incubation (Fig. 5A). Fluorescence microscopy of single cells of *P. aurantium* using either DHE or the alternative ROS sensor CellROX® Deep Red further revealed that ROS production was locally specific to *P. aurantium* actively feeding on *C. parapsilosis* (Fig. 5B) suggesting that yeast cells are exposed to increased levels of ROS upon phagocytic processing in *P. aurantium*.

**Fig. 5: ROS production by *P. aurantium* during phagocytosis of *C. parapsilosis*.** A, ROS were determined indirectly as the increase in DHE oxidation over 30 min in co-incubations of *C. parapsilosis* with *P. aurantium*. Data represent mean RFU ( $\lambda_{ex}$  522/  $\lambda_{em}$  605 nm) of three independent samples over 30 min. B, ROS production was primarily localized to feeding cells of *P. aurantium*. Cells were co-incubated with *C. parapsilosis* in the presence of ROS sensitive probes DHE or CellROX® Deep Red and images were taken after 30 min.

### Copper and redox homeostasis contribute to the resistance against *P. aurantium* and macrophages

The expression profile and its similarity to its orthologue of *C. albicans* suggested a role for Crp1p of *C. parapsilosis* in detoxification of high Cu levels. Deleting CpCRP1 ( $\Delta/\Delta crp1$ ) displayed no apparent growth defect in SD medium at 30°C and the mutant strain tolerated even high concentrations of Cu above 1 mM. Its sensitivity towards this transition metal changed dramatically when cells were exposed to a more acidic pH on solid or in liquid media (Fig. 6). At a pH of 3, CpCRP1 proved to be essential for

growth at Cu concentrations between 500 and 1000  $\mu\text{M}$ , indicating that the function of Crp1p could be crucial under the acidic conditions of the phagolysosome.

**Fig. 6: Crp1 protects *C. parapsilosis* from high Cu levels at acidic pH.** **A**, The  $\Delta/\Delta crp1$  mutant strain showed a pH-dependent copper sensitivity in comparison to the wildtype during growth at pH 3. **B**, Increased sensitivity of  $\Delta/\Delta crp1$  mutant strain to high Cu concentrations in liquid medium with malt extract broth (pH=3) in comparison to the wildtype and complementation strains. Data represent the mean and standard deviation of three biological replicates with asterisks indicating statistical significance in an unpaired Student's t-test between the values obtained for the  $\Delta/\Delta crp1$  strain and the wild type (\*\*\*,  $p < 0.001$ ).

We also addressed the antioxidant function of *PRX1* in *C. parapsilosis*, by subjecting a homozygous mutant ( $\Delta/\Delta prx1$ ) to oxidative stress delivered by hydrogen peroxide ( $\text{H}_2\text{O}_2$ ) and *tert*-butyl hydroperoxide (*t*-bOOH). The sensitivity of the mutant towards  $\text{H}_2\text{O}_2$  was nearly indistinguishable from the wild type, and even the organic peroxide had only a mild effect on the growth of  $\Delta prx1$  on a solid medium supplemented with adenine, uracil, and 9 amino acids (Fig. 7A). However, the impact of oxidative stress was more severe when these supplements were omitted from the medium. Under these conditions, growth in liquid medium was significantly reduced for  $\Delta/\Delta prx1$  even in the absence of an external stressor (Fig. 7B). When using 11 selective dropouts with each one lacking a different component, we found that a lack of methionine was responsible for the growth defect of  $\Delta/\Delta prx1$ . The Omission of methionine from the normal

medium, in combination with the organic peroxide, affected the wild type and the mutant strains to similar extents (Fig. 7C).

**Fig. 7: The antioxidant role of *PRX1* in *C. parapsilosis*.** **A**, Growth of *C. parapsilosis* on solid SD media with or without amino acid drop-out supplement (DO) in the presence of tBOOH or H<sub>2</sub>O<sub>2</sub> as oxidative stressors. **B and C**, Growth of the wildtype and the  $\Delta prx1$  null mutant in liquid SD media, supplemented with drop-out solutions, selectively missing one essential amino acid (**B**) and in the presence of tBOOH (**C**). Growth was measured as optical density at 600 nm. Data represent the mean and standard deviation of three biological replicates with asterisks indicating statistical significance in an unpaired Student's t-test between the values obtained for the  $\Delta prx1$  null mutant in comparison to the parental strain, wt (\**p* < 0.05, \*\* *p* < 0.01, \*\*\**p* < 0.001).

Both, *CRP1* and *PRX1*, are widely conserved across the *Candida* clade, including several species without any record as commensals or pathogens (Fig. S3). To test whether these two genes are part of the defence against amoeba predation, deletion mutants for *CRP1* and *PRX1* were confronted with *P. aurantium*. Both mutants showed decreased survival in comparison to the wild type after 3 hours of co-incubation (Fig. 8A). As we hypothesized that both mechanisms for stress defence could also contribute to survival when encountering innate immunity, we performed another co-incubation assay with primary macrophages (MDMs) from healthy donors. Both,  $\Delta\Delta crp1$  and

$\Delta/\Delta prx1$  displayed reduced survival when confronted with MDMs (Fig. 8B), indicating that these genes mediating resistance to copper and oxidative stress during predation could also play a role during evasion in the human host.

**Fig. 8: Survival of *C. parapsilosis* mutant strains during amoeba predation (A) and phagocytosis by primary macrophages (B).** Strains of *C. parapsilosis* were incubated with *P. aurantium* for 3 h at a yeast-to-amoeba ratio of 10:1 (A) or with primary macrophages isolated from at least 6 different anonymous donors at a yeast-to-macrophage ratio of 1:1 (B). The number of survivors was determined by plating the cells on YPD media and counting the CFUs. The boxes signify the 25<sup>th</sup> and 75<sup>th</sup> percentile. The median is represented by a short black line within the box for each strain. The whiskers indicate the highest and lowest values from three independent biological and six technical replicates. Asterisks show statistical significance in an unpaired Student's t-test between the values obtained for the null mutants in comparison to the parental strain, wt (\*\*\*, p<0.001).

## Discussion

The arms race between phagocytic predators and their microbial prey is thought to have shaped virulence determinants of bacteria and fungi (Casadevall et al., 2019, Brussow, 2007). Amoebae are predominant environmental micro-predators, but only a few of them have been described to actively feed on fungi (Old & Darbyshire, 1978, Old, 1977, Chakraborty *et al.*, 1983). Such a fungivorous lifestyle was also described for *Protostelium mycophagum*, the type species for the polyphyletic group of protosteloid amoebae that form microscopic, stalked fruiting bodies from single cells and are found on nearly all continents (Spiegel *et al.*, 2017, Kang *et al.*, 2017, Shadwick *et al.*, 2009b, Shadwick *et al.*, 2018). We have recently isolated and characterized a strain of *P. aurantium* (formerly known as *Planoprotostelium aurantium*), which was found to selectively recognize, kill and feed on a wide range of ascomycete and basidiomycete yeasts, including major human pathogens of the *Candida* clade (Radosa et al., 2019). While *C. parapsilosis* acted as a preferred food source, *C. albicans* was found to be protected from initial recognition by an extensive coat of mannoproteins, and *C. glabrata* showed delayed processing after ingestion. A similar survival strategy seems to rescue *C. glabrata* when encountering macrophages. Here, its ability to persist and even replicate inside the phagocyte has been well documented and characterized to the level of single genes (Seider *et al.*, 2011, Kasper et al., 2015, Kaur *et al.*, 2007). A functional genomic approach identified 23 genes in *C. glabrata* which were critically involved in the survival of macrophage phagocytosis (Seider *et al.*, 2014). When comparing this set of 23 genes to all genes expressed during predation by *P. aurantium*, we found 7 genes to be highly upregulated ( $\log_2FC > 1.5$ ) at both time points. The three most upregulated genes with a  $\log_2FC$  of more than 2 were *GNT1* (CAGL0I09922g) *OST6* (CAGL0G07040g), and *PMT2* (CAGL0J08734g), all involved either in cell wall modification or protein glycosylation.

All these genes share orthologues with the other two *Candida* species, but when confronted with *P. aurantium*, only *PMT2* was upregulated in *C. parapsilosis* and even more so in *C. albicans*. In the latter, the gene encodes an essential protein O-mannosyltransferase, which renders the cell more resistant to antifungals and cell wall perturbing agents (Lengeler *et al.*, 2007, Peltroche-Llacsahuanga *et al.*, 2006). The upregulation of mannan synthesis in *C. albicans* in the presence of the predator seems not to be limited to O-linked mannans, but was also observed for the N-linked type. *MNN2* and *MNN22* are two members of another well-characterized family of N-

mannosyltransferases whose absence severely affects the mannoprotein coat of *C. albicans* (Hall *et al.*, 2013, Hall & Gow, 2013). Both genes showed induction levels comparable to *PMT2*. The pivotal role of the mannan coat of *C. albicans* during an interaction with phagocytes of the innate immunity is well documented, as defective O- and N-linked mannosylation led to an increased uptake and phagosomal maturation, most likely through unmasking of  $\beta$ -glucans and enhanced recognition of *C. albicans* via the Dectin-1 receptor (Bain *et al.*, 2014, McKenzie *et al.*, 2010). The fact that mannan biosynthesis was upregulated in *C. albicans* supports the previous finding that mannosidase treated cells were internalized more frequently by *P. aurantium* (Radosa *et al.*, 2019).

The different interaction patterns of the three yeasts were partially reflected throughout the transcriptome of their orthologous genes. The general response to the predator comprised only 79 orthologues. Of these 48 were commonly induced, among them the orthologues of CDC54, CDC46, and MCM3, indicating that all three yeast species were metabolically active in the M/G1 phase of the cell cycle (Cote *et al.*, 2009). Genes involved in fatty acid catabolism were generally induced while their biosynthesis was rather repressed. In contrast, amino acid biosynthesis was commonly upregulated, presumably in response to the nutrient-deprived growth medium used during the confrontation.

Of over 1500 orthologous genes that were differentially regulated in either *C. albicans* or *C. parapsilosis*, only 251 were common DEOs for both species. Within this gene set, the impact on copper homeostatic genes was preeminent especially for *C. parapsilosis* and the null mutant for *CRP1*, the gene with the highest induction, pointed towards a vital role of copper during predation by *P. aurantium*. Intoxication by copper is especially effective in highly acidic environments as occurring during early maturation of the phagolysosome. This strategy was also found to be effective in the bacteriovorous amoeba *Dictyostelium discoideum* and has most likely contributed to the spread of copper resistance islands among bacterial pathogens (Hao *et al.*, 2016). From this perspective, it cannot be surprising that highly tuned copper homeostatic systems were elucidated in the major environmentally acquired fungal pathogens *A. fumigatus* and *Cryptococcus neoformans* (Ding *et al.*, 2013, Wiemann *et al.*, 2017). Both fungi also exploit similar escape strategies when confronted with amoebae or innate immune phagocytes (Hillmann *et al.*, 2015, Novohradská *et al.*, 2017, Steenbergen *et al.*, 2001).

A recent screening approach identified SUR7 as a Cu-protective protein which reduces membrane permeability to Cu in *C. albicans* (Douglas & Konopka, 2019). Although downregulation of *SUR7* was observed at both time points after confrontation with the amoeba, its putative orthologue (CPAR2\_602600) showed higher expression in *C. parapsilosis* after one hour of co-incubation with *P. aurantium*. Also, for *C. glabrata* which seems to lack a *CRP1* orthologue, *SUR7* (CAGL0L01551g) was highly induced at both time-points.

At least some of the toxic effects of Cu are inflicted via Fenton-type chemistry with ROS, which were actively produced in feeding *P. aurantium*. Their impact on the yeast will likely be further aggravated by the downregulation of nearly all SODs, as seen for *C. parapsilosis* during confrontation with the predator. In contrast, expression of the one-cysteine peroxiredoxin *PRX1* was increased in *C. parapsilosis*. Higher expression of the orthologous gene from *C. albicans* was also found during co-incubation with macrophages (Lorenz *et al.*, 2004). We found that an essential cellular function of *PRX1* is tightly linked to a lack of methionine. Intriguingly, among the only 48 commonly upregulated genes in all three *Candida* species, 5 are involved in the metabolism of sulfur-containing amino acids (ECM17, MET15, MET16, MET3, SAM2). For all five genes, the induction was lowest for *C. glabrata*. Amino acid deprivation, and more specifically, a limitation in methionine, also occurs in the phagolysosome of neutrophilic granulocytes (Rubin-Bejerano *et al.*, 2003, Miramón *et al.*, 2012). Its sensitivity to ROS is phenotypically well established for baker's yeast, as mutants lacking either SOD1 or its chaperone CCS1 were unable to grow in normoxic environments due to a methionine auxotrophic phenotype (Chang & Kosman, 1990, Culotta *et al.*, 1997).

In conclusion, our results show that the fungivorous feeding of the predator *P. aurantium* affects essential biosynthetic pathways by targeting the fungal Cu and redox homeostasis. With regard to the millions of years of coevolution of amoebae and fungi, it is well conceivable that basic molecular tool-kits for resistance against environmental phagocytes were later expanded for survival in other hosts.

### Material and Methods

#### Strains and growth conditions

*Protostelium aurantium* var. *fungivorum* has been isolated in Jena, Germany, as described in (Hillmann et al., 2018). Isolated amoebae were further grown in standard size Petri dishes (94x16 mm, Greiner Bio-One, Austria) in PBS (80 g l<sup>-1</sup> NaCl, 2 g l<sup>-1</sup> KCl, 26.8 g l<sup>-1</sup> Na<sub>2</sub>HPO<sub>4</sub> x 7 H<sub>2</sub>O, 2.4 g l<sup>-1</sup> KH<sub>2</sub>PO<sub>4</sub>, pH 6.6) with *Rhodotorula mucilaginosa* as a food source at 22°C, if not stated differently. All yeast strains are listed in Table S3. If not indicated otherwise, all fungi were grown in YPD medium at 30°C, supplemented with 1.5 % [w/v] agar for growth on solid media. Mutant strains of *C. parapsilosis* were grown on the SD-agar (0.4 % [w/v] yeast nitrogen base with ammonium sulfate, 2 % [w/v] glucose, 1.5 % [w/v] agar), supplemented with 10 % [v/v] of a selective drop-out solution excluding leucine or histidine. Complemented strains were grown on YPD agar supplemented with 100 µg/ml nourseothricin (clonNAT, Werner BioAgents, Jena, Germany).

#### RNA isolations from yeast cells and co-cultures with *P. aurantium*

Frozen cell pellets from yeast cultures or co-incubations with *P. aurantium* were resuspended in TES buffer (10 mM Tris-HCl, pH 7.5, 10 mM EDTA, 0.5% [w/v] SDS) and transferred into a chilled tube containing zirconia beads (ZYMO Research, Irvine, CA, USA). Primary extractions of RNA were performed with acidic phenol:chloroform (5:1) shaking at 1500 rpm at 65°C for 30 min in a thermoblock. Afterwards, samples were frozen at -80°C for 30 min, centrifuged at 10.000 g for 15 min for phase separation. Samples underwent two more extractions using phenol:chloroform (5:1) and chloroform:isoamyl alcohol (24:1). The RNA was equilibrated with 10% [w/v] of 3 M sodium acetate (pH 5.2) and precipitated in ice-cold ethanol. After centrifugation, pellets were washed in 70 % [v/v] ethanol, air dried and resuspended in nuclease-free water. RNA samples were stored at -80°C.

#### RNA isolations from yeast cells after confrontation with monocyte-derived macrophages (MDMs)

Adherent macrophages with attached and ingested yeast cells were washed and subsequently lysed by adding RLT lysis buffer containing β-mercaptoethanol (Qiagen, Hilden, Germany) and shock-freezing the plate in liquid nitrogen. Cells were detached

by scraping and transferred into screw cap tube, sedimented by centrifugation and washed once with RLT buffer to remove most of the host RNA. Yeast pellets were shock-frozen again in liquid nitrogen and stored at -80°C. For RNA isolation, pellets were resuspended in 400 µl of AE buffer (50 mM Na-acetate pH 5.3 and 10 mM EDTA) and 40 µl of 10% [w/v] SDS. After mixing for 30 sec, cells were extracted with phenol: chloroform: isoamyl alcohol [25:24:1] for 5 min at 65°C and then frozen at -80°C. Phase separations, precipitation and resuspension of the purified RNA were performed as above.

### **RNA sequencing and analysis of expression data**

The preparation of cDNA libraries from total RNA and the sequencing was performed at LGC Genomics GmbH (Berlin, Germany). Briefly, the quality of RNA samples was first controlled using 2100 Bioanalyzer (Agilent, CA, USA). Next, samples were enriched for mRNA using oligo-dT binding and magnetic separation using the NEBNext Poly(A) Magnetic Isolation Module (New England Biolabs). Samples were reverse transcribed using the NEBNext RNA First and Second Strand Synthesis Modules (New England Biolabs) and purified. The Encore Rapid DR Multiplex system (Nugen) was used for preparation cDNA-libraries which were amplified in a volume of 100 µl for 15 cycles using MyTaq (Bioline) and standard Illumina primers. From these libraries, 2 x 75 bp (*C. parapsilosis*) or 2x 150 bp (*C. albicans* and *C. glabrata*) paired-end reads were sequenced on an Illumina MiSeq platform. FastQC (Andrew, 2010) and Trimmomatic v0.32 (Bolger *et al.*, 2014) were used for quality control and trimming of library adaptors. Mapping of reads was achieved with TopHat2 v2.1.0 (Kim *et al.*, 2013) against the reference genomes of *C. parapsilosis*, *C. glabrata* and *C. albicans*, in combination with the genome of *P. aurantium*. Differential gene expression between time points was analysed with DEseq2 (Love *et al.*, 2014) and EdgeR (Robinson *et al.*, 2010). A list of all differentially expressed genes is provided as Dataset S1. All sequencing data is available from the GEO repository under the accession number GSE116535. The Venn diagram was computed using the package “VennDiagram” from the statistical programming language R. The genes in all areas of the Venn diagram are listed in supplementary dataset III. The PCA was conducted using the method “prcomp” from the “stats” package of R.

### **Gene ontology analysis**

Gene ontology (GO) clustering analysis was performed on all differentially up- and downregulated genes of three *Candida* species using GO Slim (Mi *et al.*, 2017) -Mapper tool available at the Candida Genome Database (<http://www.candidagenome.org/cgi-bin/GO/goTermMapper>) for biological process, molecular function and cellular component. All data from the Gene Ontology analysis is provided as Dataset S2.

### **Quantitative real-time reverse transcription-PCR (qRT-PCR)**

For all qRT-PCR reactions, RNA concentration was determined via NanoDrop ND1000 Spectrophotometer (NanoDrop Technologies Inc., USA). 1 µg of RNA was treated with DNase using RQ1 RNase-free DNase (Promega, USA) and transcribed into cDNA (RevertAid First Strand cDNA Synthesis Kit, Thermo Scientific). The cDNA was diluted 1:10 and used for qRT-PCR that included SYBR Select Master Mix (Applied Biosystems). The experiments were performed in a thermal cycler (Step One Plus, Applied Biosystems), in three biological and three technical replicates. The expression rates reported here are relative to the expression values of the housekeeping gene *ACT1* of *C. parapsilosis*. All primers are listed in Table S4.

### **Detection of reactive oxygen species**

The production of reactive oxygen species during amoeba predation was measured using dihydroethidium (DHE; Thermofisher, Dreieich, Germany) at a final concentration of 10 µM. Amoebae and yeasts were seeded at the MOI of 10. Increased fluorescence, indicating ROS production, was measured using an Infinite M200 Pro fluorescence plate reader (Tecan, Männedorf, Switzerland) in intervals of 2 min over 30 min period at  $\lambda_{ex}$  522 nm/ $\lambda_{em}$  605 nm. ROS production was further visualized by using DHE staining as mentioned above or CellROX®Deep Red staining (Thermofisher) at a final concentration of 5 µM. Fluorescence images were captured using the Zeiss Axio Observer 7 Spinning Disk Confocal Microscope (Zeiss, Germany) at the  $\lambda_{ex}$  370 nm/ $\lambda_{em}$  420 nm (for non-oxidized DHE),  $\lambda_{ex}$  535 nm/ $\lambda_{em}$  610 nm (for oxidized DHE), and at  $\lambda_{ex}$  640 nm/ $\lambda_{em}$  665 nm for Cell Rox Deep Red staining.

### **Construction of gene deletions and complementations in *C. parapsilosis***

Target genes were deleted from the *leu2/his1*- CLIB2014 parental strain using a fusion PCR method described previously (Noble & Johnson, 2005) and adapted to *C. parapsilosis* (Holland *et al.*, 2014). All primer sequences and target genes are listed in Table S4. Briefly, approximately 500 bp of the upstream and downstream DNA loci of

the coding sequence were amplified by PCR with the primer pairs P1/P3 and P4/P6, respectively. The selectable markers, *C. dubliniensis HIS1* and *C. maltosa LEU2* genes were amplified with the P2/P5 primer pair from the plasmids pSN52 and pSN40, respectively. All PCR products were further purified using Gel/PCR DNA Fragments Extraction Kit (Geneaid Biotech, New Taipei City, Taiwan) and connected via PCR through overlapping sequences of the P2/P3 and P4/P5 primer pairs. The entire deletion cassette was amplified using primers P1 and P6 and transformed into the recipient strain in two rounds of transformation. The first allele was replaced by the *CmLEU2* marker and the second allele with the *CdHIS1* marker. Site-specific integration of the selection marker was checked by PCR at both ends of the deletion constructs. Loss of expression was also confirmed by qRT-PCR targeting the respective ORF (Supplementary Fig. S4A-D).

To generate reintegrant strains, the neutral locus NEUT5L was targeted as described in (Gerami-Nejad *et al.*, 2013). The promoter-OR-terminator regions were amplified from the CLIB214 parental strain using specific rec\_F/R primers listed in Table S4. The dominant nourseothricin resistance marker *NAT1*, and a modified sequence of *C. parapsilosis* NEUT5L locus, were amplified from plasmid pDEST\_TDH3\_NAT\_CpNEUT5L\_NheI using Clon\_F/Clon\_R primers. The 5' tails of *gene name\_rec\_F/gene name\_rec\_R* primers contained flanking regions complementary to the sequence of Clon\_F/Clon\_R primers to allow fusion via circular polymerase extension cloning (CPEC cloning). The completely assembled plasmids (Supplementary Fig. S4E) were directly used for transformation of *E. coli* DH5 $\alpha$  without further purification. After purification from *E. coli* up to 3  $\mu$ g of plasmid were enzymatically digested with *StuI* or *HpaI* and *EcoRI* to confirm their correct size. The modified sequence of *C. parapsilosis* NEUT5L locus contains a specific restriction site for *StuI* which linearised the plasmid and enables the integration of the vector into the NEUT5L locus of *C. parapsilosis* via duplication. Integration of the vector into the genome of the parental strain was confirmed by PCR.

### **Chemical transformation of *C. parapsilosis***

Overnight culture of *C. parapsilosis leu2/his1-* were diluted to an OD<sub>600</sub> of 0.2 in YPD media and grown at 30°C/180 rpm to an OD<sub>600</sub> of 1. The culture was harvested by centrifugation at 4000 g for 5 min and the pellet was suspended in 3 ml of ice-cold water. After collecting the cells, the pellet was resuspended in 1 ml of TE with LiAc

(0.1 M Lithium acetate, 10 mM Tris-HCl, 1 mM EDTA, pH 7.5), followed by centrifugation for 30 s at 14,000 g. Cells were then suspended in 200  $\mu$ l of the ice-cold TE-LiAc buffer. For transformation 10  $\mu$ l of boiled herring sperm DNA (2 mg/ml), 20  $\mu$ l of transforming DNA were added to 100  $\mu$ l of competent cells. The mixture was incubated at 30°C without shaking for 30 min followed by the addition of 700  $\mu$ l of PLATE solution (0.1 M Lithium acetate, 10 mM Tris-HCl, 1 mM EDTA, pH = 7.5 and 40 % PEG 3350). Afterwards, the samples were incubated overnight at 30°C. The next day, samples were heat-shocked at 44°C for 15 min, centrifuged and washed twice with YPD medium. Following incubation in 100  $\mu$ l of YPD for 2 hours (180 rpm, 30°C), samples were plated on SD agar plates, supplemented with essential amino acids, and histidine or leucine to obtain heterozygous mutant strains. To select for homozygous mutant histidine and leucine were omitted from the medium. Selective plates were incubated for two days at 30°C. To select for reintegrants, cells were plated on YPD agar with 100  $\mu$ g ml<sup>-1</sup> of nourseothricin.

### **Sensitivity assays**

Yeasts were grown overnight in YPD at 30°C/180 rpm, harvested by centrifugation at 10,000 g for 1 min and washed twice with PBS. For droplet assays, cells were diluted to the concentration of 5x10<sup>7</sup> ml<sup>-1</sup> and 5  $\mu$ l of serial 10-fold dilutions were dropped on agar plates. To determine the MIC<sub>50</sub> of Cu, 2.5x10<sup>4</sup> cells were seeded in a 96 well plate with malt extract broth buffered to pH 3 and CuSO<sub>4</sub>. For oxidative stress sensitivity assays, 11 selective drop-out solutions, each missing one component, were added to SD base (0.4 % yeast nitrogen base with ammonium sulfate, 2 % glucose) with or without 2 mM of *t*-BOOH (Luperox® TBH70X, Sigma-Aldrich, USA) and approx. 3x10<sup>2</sup> cells were seeded in 48 well plates. All plates were incubated at 30°C for two days. Growth in well plates was evaluated by measuring the optical density (OD<sub>600</sub>) in a plate reader (Infinite M200 Pro, Tecan, Männedorf, Switzerland). Data represent the average of 3 biological replicates.

### **Isolation of monocyte-derive macrophages (MDMs)**

Human peripheral blood mononuclear cells (PBMCs) were isolated by density centrifugation. PBMCs from buffy coats donated by healthy volunteers were separated through Lymphocytes Separation Media (Capricorn Scientific, Ebersdorfergrund, Germany) in Leucosep™ centrifuge tubes (Greiner Bio-One). Magnetically labelled

CD14 positive monocytes were selected by automated cell sorting (autoMACs; Miltenyi Biotec, Bergisch-Gladbach, Germany). To differentiate monocytes into MDMs,  $1.7 \times 10^7$  cells were seeded into 175 cm<sup>2</sup> cell culture flasks in RPMI 1640 media with L-glutamine (Thermo Fisher Scientific) containing 10 % heat-inactivated fetal bovine serum (FBS; Bio&SELL, Feucht, Germany) and 50 ng ml<sup>-1</sup> recombinant human M-CSF (ImmunoTools, Friesoythe, Germany) and incubated for five days at 37 °C and 5 % CO<sub>2</sub> until the medium was exchanged. Stimulation with human M-CSF favours the differentiation to M2-type macrophages. After two additional days, adherent MDMs were detached with 50 mM EDTA in PBS and seeded in 6-well plates (for expression analysis) or in 96-well plates (for killing assay) to a final concentration of  $1 \times 10^6$  or  $4 \times 10^4$  MDMs/well, respectively in RPMI complete and incubated overnight. Macrophage infection experiments were performed in serum-free RPMI medium.

### **Ethics statement**

Blood donations for subsequent isolation of PBMCs were obtained from healthy donors after written informed consent. This is in accordance with the Declaration of Helsinki, all protocols were approved by the Ethics Committee of the University Hospital Jena (permission number 2207-01/08).

### **Co-incubation of *C. parapsilosis* with monocyte-derived macrophages (MDMs)**

Overnight cultures of yeast cells were harvested by centrifugation at 5 000 rpm/4°C for 5 min and cells were washed three times in ice-cold H<sub>2</sub>O. Cells were counted in a Neubauer-improved cell counting chamber and added to macrophages in 96-well plates at an MOI of 1 (killing assays) or in 6-well plates at an MOI of 10 (isolation of total RNA) with RPMI medium. Media control wells for each time point were included, where the yeast cells were incubated in RPMI alone without the macrophages. Plates were incubated at 37°C in atmosphere 5% CO<sub>2</sub>.

### ***P. aurantium* and macrophage killing assays**

Yeast strains were grown overnight in YPD medium at 30°C/180 rpm, harvested by centrifugation and counted in CASY® TT Cell Counter (OLS Bio, Bremen, Germany). Amoebae were grown to confluency in PB, harvested by scraping and counted. Yeast cells were co-incubated with amoebae or macrophages in 96-well plates at MOIs of 10 and 1, respectively, and incubated at 22°C or 37°C/5% CO<sub>2</sub>, respectively, for 3 hours. Yeast cells surviving the amoeba predation were collected by vigorous pipetting and

plated on YPD agar. Cells surviving the macrophage killing were first collected from the supernatant, then, intracellular survivors were obtained after lysis of macrophages with 0.5% Triton-X-100 for 15 min. The number of survived yeast cells was calculated as a percentage of CFUs compared to the inoculum. Data are based on three biological and six technical replicates (*P. aurantium*) and six different anonymous donors with 6 technical replicates (macrophages), respectively.

### **Acknowledgements**

This work was supported by grants of the European Social Fund ESF “Europe for Thuringia” (2015FGR0097 to FH and 2016FGR0053 to JL) and a grant from the German Research Foundation (DFG, HI 1574/2-1). SR was supported by a fellowship of the DFG funded excellence graduate school “Jena School of Microbial Communication”—JSMC. This work was also supported by the DFG CRC/Transregio 124 “Pathogenic fungi and their human host: Networks of interaction” subproject INF (TW). MS was supported within the DFG priority program SPP ‘Intracellular compartments as places of host-pathogen interactions’. AG was funded by GINOP-2.3.2-15-2016-00035, by GINOP-2.3.3-15-2016-00006 and by NKFIH K123952.

### **Author contributions**

SR performed most experimental work with input from JLS, RT, and MS. FH, AG, SB and GP supervised the experimental work. Bioinformatic processing and analysis of RNA-Seq data was performed by JL and TW. SR and FH wrote the paper. All authors analysed the data and commented on the manuscript.

## 2.5 Manuscript V: Sprenger *et al.*, prepared for submission to FEMS Yeast Research

### **A *TRP1*-marker-based system for gene complementation, overexpression, reporter gene expression and gene modification in *Candida glabrata***

Marcel Sprenger, Sascha Brunke, Bernhard Hube, and Lydia Kasper

#### Summary:

The molecular Koch's postulates define criteria that must be satisfied to show that a certain gene has a role during pathogenesis. This includes reintroduction of the gene of interest into the mutated organism. However, gene complementation strategies are only rarely used in the haploid yeast *C. glabrata* so far. Here we developed a new gene complementation strategy, expressing the selection marker *TRP1* at its native locus. In addition, we used our strategy to overexpress fluorescence markers, the antigen ovalbumin, or to overexpress and modify genes associated with the vitamin biotin in *C. glabrata*. The *TRP1* locus in *C. glabrata* is a suitable locus to reintegrate gene of interest, either with their native DNA sequence, with specific sequence variations or with alternative promoters, to investigate the role and function of these genes for fungal pathobiology.

#### Own contribution:

Marcel Sprenger planned, performed and evaluated all experiments, and interpreted the data. The co-authors assisted in the conceptualization of the study and editing of the initial manuscript. Marcel Sprenger wrote the manuscript and generated all figures.

#### Estimated authors' contributions:

<b>Marcel Sprenger</b>	<b>66%</b>
Sascha Brunke	12%
Bernhard Hube	4%
Lydia Kasper	18%

**Abstract**

Although less prevalent than its relative *Candida albicans*, *Candida glabrata* is a successful human-pathogenic yeast, causing life threatening candidiasis. It is thus vital to understand the pathogenicity mechanisms and the contributing genes of *C. glabrata*. However, gene complementation as a tool to restore the function of a previously deleted gene is not standardized in *C. glabrata* and less frequently used as compared to *C. albicans*.

In this study, we established a gene complementation strategy using genomic integration at the *TRP1* locus. We prove that our approach can not only be used for integration of complementation cassettes but also for overexpression of fluorescence markers, the antigen ovalbumin or the putative biotin transporter gene *VHT1*. On the example of urea amidolyase Dur1,2 we show that the complementation cassettes can also be used to study the effects of sequence-modifications in genes. With this approach, we found that changes in the lysine-residue within the biotinylation motif of Dur1,2 impaired the usage of urea by *C. glabrata*. Taken together, the *TRP1*-based gene complementation approach is a valuable tool for investigating novel gene functions and for elucidating their role in pathobiology of *C. glabrata*.

**Key words**

***Candida glabrata*, *TRP1*, gene complementation, overexpression, green fluorescent protein**

## **Introduction**

The opportunistic pathogen *Candida glabrata* is a constitutively haploid fungus. It belongs to the Nakaseomyces clade (Kurtzman & Robnett, 2003) and is evolutionarily related to the baker's yeast *Saccharomyces cerevisiae* (Gabaldón & Carrete, 2016). *C. glabrata* is normally associated with the mammalian host and is the second most prevalent *Candida* species to cause life-threatening candidiasis, after *Candida albicans* (Diekema *et al.*, 2012). It is therefore necessary to understand and characterize mechanisms and genes contributing to the pathogenicity of this fungus.

The molecular Koch's postulates define criteria that must be satisfied to show that a certain gene has a role during pathogenesis (Falkow, 1988). One of these criteria states that gene reintegration into a mutated organism (complementation) should restore the pathogenic potential of the organism. Thus, complementation is an important step in elucidating gene functions and to exclude potential pleiotropic effects that originated from genetic manipulation. However, to date gene complementation strategies in *C. glabrata* are less well developed than *e.g.* in *C. albicans*, less frequently used, and each have certain disadvantages. The first strategy used for *C. glabrata* is based on extrachromosomal episomal replicative vectors (Kitada *et al.*, 1996, Frieman *et al.*, 2002, Zordan *et al.*, 2013), which contain the autonomously replicating sequence (ARS) and a centromere (CEN) together with the gene of interest (GOI). An example is the centromere-based plasmid pCgACT which contains the nutritional marker *TRP1* to restore prototrophy of a *trp1*Δ deletion mutant (Miyazaki *et al.*, 2011, Hosogaya *et al.*, 2013, Noble *et al.*, 2013). A strong disadvantage of episomal vectors is, however, the unforeseeable multimerizations or recombinations with the genome, causing unwanted genetic alterations (Pla *et al.*, 1996). Additionally, plasmid loss (for example in environments where tryptophan is readily available) or copy number variations could increase population heterogeneity.

A second strategy for the generation of *C. glabrata* complementation strains relies on genomic integration, either by reintroducing the original GOI together with specific

selection markers at its native locus (Yáñez-Carrillo *et al.*, 2015) or by replacing the *URA3* gene by the GOI and the dominant *NAT1* marker (Nevitt & Thiele, 2011). Both these strategies have the potential to restore the gene of interest to a wild type-like state. The *NAT1* selection marker is, however, widely used for gene deletions in *C. glabrata* (Schwarz Müller *et al.*, 2014) and therefore often not available anymore for later gene complementation, and changes in *URA3* expression levels might influence virulence phenotypes (Brand *et al.*, 2004).

Gene complementation in the diploid *C. albicans* often uses the Clp10 strategy (Murad *et al.*, 2000), whereby the selection marker *URA3* is ectopically expressed at one of alleles of the neutral *RPS1* locus. In contrast to *C. albicans*, the haploid genome of *C. glabrata* makes it more difficult to find suitable loci, since single-allele knock-outs and dosage effects of ectopic expression of nutritional selection markers cannot be compensated by an alternative allele, with unknown influences on the phenotype.

In this study we describe a novel gene complementation strategy for *C. glabrata* based on transformation with and stable genomic integration of a complementation cassette into the *TRP1* locus. We show that reintegration of *TRP1* at this native chromosomal location can restore tryptophan auxotrophy to wild type-like levels. This strategy can not only be used for gene complementation but also for reporter gene expression, gene overexpression, heterologous expression, or expression of genetically modified gene variants in the haploid yeast *C. glabrata*.

We validate the functionality of our complementation system by heterologous expression of fluorescence reporter genes or ovalbumin (OVA), by inducing point mutations in the urea amidolyase gene *Dur1,2*, and by overexpressing the biotin acquisition gene *VHT1* in *C. glabrata*. Artificial OVA expression by pathogens is frequently used as a tool to investigate the cross-reactivity between effector and memory T cells in response to the microbe (Ishizuka *et al.*, 2009, Krummey *et al.*, 2014, Harms *et al.*, 2018). Vitamins are involved in a broad range of cellular processes (Dakshinamurti, 2005, Combs, 2017). Biotin (vitamin H or B<sub>7</sub>) is covalently linked to

several proteins, including enzymes involved in carboxylation reactions (Zempleni *et al.*, 2008). All target proteins possess a conserved lysine residue (Lane *et al.*, 1964), which is biotinylated by the biotin ligase Bpl1 *via* an amide bond (Sternicki *et al.*, 2017). Yeasts belonging to the *Candida* and *Saccharomyces* genus are biotin auxotrophs (McVeigh, 1951, Littman & Miwatani, 1963) due to intrinsic loss of biosynthetic genes (Fitzpatrick *et al.*, 2010, Madsen *et al.*, 2015) and have to take up biotin from the environment. *C. glabrata* and *C. albicans* strictly rely on the putative biotin importer Vht1 for biotin acquisition (Sprenger *et al.*, 2020).

## **Materials and methods**

### **Ethics statement**

Human blood was taken from healthy volunteers with written, informed consent. The blood donation protocol and use of blood for this study were approved by the institutional ethics committee of the university hospital Jena (Ethik-Kommission des Universitätsklinikums Jena, Permission No. 2207–01/08).

### **Strains and growth conditions**

All strains used in this study are listed in **Table S1**. *Escherichia coli* was cultured in liquid lysogeny broth (LB) at 37°C with shaking at 180 rpm and with 50 µg/mL ampicillin for plasmid propagation. *Candida* strains were cultured in liquid Yeast Peptone Dextrose (YPD) broth (2% glucose, 2% peptone, 1% yeast extract) at 30°C (*C. albicans*) or 37°C (*C. glabrata*), with shaking at 180 rpm for 14-16 h. For growth on solid medium, 2% agar was added. Routinely, stationary phase yeast cells from pre-cultures were washed three times in PBS, and the cell number was adjusted in PBS or culture medium.

For growth analyses in liquid media, twenty microliters of a yeast cell suspension ( $5 \times 10^6$  cells/mL) were added to 180 µL media in a 96-well plate (Tissue Culture Test

Plate, TPP Techno Plastic Products AG). In some experiments minimal medium (0.19% yeast nitrogen base (YNB) without biotin, amino acids, ammonium sulfate [Formedium]; 2% glucose) with varying biotin concentrations and different nitrogen sources (0.5% ammonium sulfate, 0.5% urea) was used. The growth was monitored by measuring the absorbance at 600 nm every 30 min for 100 cycles at 30°C or 37°C using a microplate reader (Plate Reader infinite M200 PRO, Tecan Group GmbH) with orbital shaking (30 sec, amplitude: 6 mm, wait: 10 sec) before each measurement and multiple reads per well. All experiments were done in technical duplicates and, at least, biological triplicates. Growth of *Candida* on solid agar was tested by spotting serial dilutions ( $1 \times 10^6$  to  $1 \times 10^1$ ) of yeast cells on YNB plates (0.19 % YNB without amino acids and biotin; 2% glucose and either 0.5% ammonium sulfate or 0.5% urea; 2% oxoid agar).

### **Construction of *VHT1* overexpression, OVA overexpression and fluorescently labelled strains**

The prototrophic *trp1* $\Delta$  + *TRP1* strain was generated by reintroducing *TRP1* into the native *TRP1* locus, amplified from pTRP1 and replacing the FRT sequence in the *trp1* $\Delta$  strain. The *C. glabrata vhr1* $\Delta$  mutant was generated, as previously described (Sprenger *et al.*, 2020), in a *trp1* $\Delta$  strain background, with reintroduction of *TRP1* into the native *TRP1* locus. The overexpression constructs of the biotin transporter gene *VHT1*, the fluorescence markers yeGFP and mCherry, or ovalbumin (OVA) were integrated into the *TRP1* locus by selecting for tryptophan prototrophy. Briefly, plasmids pTRP1-*TEF1*prom-yEGFP, pTRP1-*PDC1*prom-yEGFP, pTRP1-*LYS21* prom-yEGFP, pTRP1-*TEF1*prom-mCherry, and pTRP1-*TEF1*prom-OVA listed in **Table S2**, were generated by PCR, via amplification of the coding sequences of yEGFP (from pCN-PDC1-GFP (Zordan *et al.*, 2013)), mCherry (from pYC56 (Yáñez-Carrillo *et al.*, 2015)) and OVA (codon-optimized) together with the specific promoter and terminator sequences (*HIS3* terminator for yEGFP and *CTA1* terminator for mCherry) with primers, listed in **Table**

**S3**, with 15 bp overlap to the pTRP1 sequence. The generation of pTRP1 has been previously described in detail (Sprenger *et al.*, 2020). The plasmids pTRP1-*TEF1*prom-*VHT1*, pTRP1-*PDC1*prom-*VHT1*, and pTRP1-*LYS21*prom-*VHT1* were generated by PCR, amplifying the coding sequences of *VHT1* together with the native terminator sequence with primers overlapping 15 bp to the pTRP1 sequence.

All constructs were cloned by In-Fusion HD cloning system into *Xba*I-digested pTRP1, and the resulting plasmids were confirmed by PCR and sequencing. The cassettes were amplified by PCR, purified and used to transform a *trp1*Δ strain background to generate tryptophan prototrophic strains using the modified heat-shock method ((Sanglard *et al.*, 1996) with heat shock: 15 min at 45 °C). Resulting clones were selected on solid minimal medium. The correct integration into the *TRP1* locus was verified by PCR, and positive clones were analyzed for yEGFP and mCherry fluorescence by microscopy and FACS (only yEGFP).

### Construction of *DUR1,2* deletion mutants

The *C. glabrata dur1,2*Δ mutant (CAGL0M05533gΔ) was generated in the *trp1*Δ parental strain using the deletion cassette amplified from an existing deletion mutant (Schwarz Müller *et al.*, 2014). Deletion constructs were amplified using P1 and P4 primers (**Table S2**) and purified with QIAquick® PCR purification kit (Qiagen). The transformation was done as described above.

For interspecies comparison, a *C. albicans dur1,2*Δ/Δ (C1\_04660WΔ/Δ) mutant was generated by a standard gene disruption method (Wilson *et al.*, 1999) using lithium acetate transformation (Walther & Wendland, 2003). Briefly, the Arg-, His-, and Ura-auxotrophic parental strain BWP17 was sequentially transformed with 10 μg of PCR-amplified and purified *HIS1* and *ARG4* deletion cassettes, which were flanked by 100 bp of the target homology region, resulting in disruption of the open reading frames of both alleles of C1\_04660W. The correct deletion of *DUR1,2* in *C. glabrata* and *C. albicans* was confirmed by PCR and Southern blot.

### Construction of *DUR1,2* complementation strains

Plasmids pTRP1-*DUR1,2* and pTRP1-*DUR1,2*<sup>K1798R</sup> were generated by In-Fusion HD cloning of PCR-amplified *DUR1,2* wild-type allele (one fragment) together with the up- and downstream intergenic regions with primers with 15 bp overlap to the pTRP1 sequence. The mutated version was created by In-Fusion HD cloning using primers with the codon for arginine instead of lysine (two fragments). Constructs were cloned into *Xba*I-digested pTRP1 and resulting plasmids were confirmed by sequencing. Cassettes containing only *TRP1* or *TRP1-DUR1,2*<sup>wt</sup> and *TRP1-DUR1,2*<sup>K→R</sup> were amplified by PCR, purified, and used to transform a *trp1Δdur1,2Δ* mutant background strain to generate tryptophan prototrophic mutants and complemented strains, respectively. Resulting clones were selected for on solid minimal medium.

For the generation of Clp10-*DUR1,2*<sup>WT</sup> or Clp10-*DUR1,2*<sup>K1779R</sup>, the coding sequences of *DUR1,2* with either the wild-type allele together with the native up- and downstream intergenic regions were amplified. The mutated version was created by In-Fusion HD cloning using primers with the codon for arginine instead of lysine (two fragments). The wild-type allele (one fragment) and the mutated allele (two fragments) were cloned into Clp10 using *Xho*I. Constructed plasmids were verified by sequencing. Homozygous uridine-auxotrophic deletion mutants were transformed with the *Stu*I-linearized empty Clp10 plasmid (Murad *et al.*, 2000) to generate prototrophic mutants or with *Stu*I-linearized Clp10-*DUR1,2*<sup>WT</sup> or Clp10-*DUR1,2*<sup>K1779R</sup> plasmids to generate complemented strains with the native or mutated biotinylation motif. The correct integration of *C. glabrata* and *C. albicans* complementation cassettes was confirmed by PCR and Southern blot.

### Genomic DNA isolation and Southern blot

Yeast cells were harvested, resuspended in 1 mL lysis buffer (1 M sorbitol; 100 mM sodium citrate, pH 5.8; 50 mM EDTA, pH 8.0; 0.6 mg/mL lyticase and 2.5% β-

mercaptoethanol) and incubated at 37°C for 45 min. Afterwards the cells pellet was resuspended in 800 µL proteinase buffer (10 mM Tris-HCl, pH 7.5; 50 mM EDTA, pH 7.5; 0.5% SDS; 1 mg/mL proteinase K) and incubated at 60°C for 30 min. The cell debris was precipitated by adding 800 µL phenol/chloroform/isoamylalcohol (25:24:1), mixed with vortex device for 4 min and centrifuged (20,000g, 5 min, RT). The hydrophilic phase was transferred into a new microcentrifuge tube containing 750 µL isopropanol. The precipitated DNA was centrifuged (20,000g, 5 min, RT), washed with 600 µL 70% ethanol and air-dried. The transparent DNA pellet was reconstituted in 200 µL ddH<sub>2</sub>O containing 10 mg/mL RNase A. The DNA quantity was evaluated using a NanoDrop Spectrophotometer (ND-100, Peqlab). The DNA was stored at 4 °C (short term) or -20 °C (long term). Dilutions of DNA were made freshly.

Thirty µg DNA were digested with *Hind*III (NEB) according to the manufacturer's recommendations. The digested DNA and the DNA Molecular Weight Marker III, DIG-labeled (50 pg per lane, Roche) was separated in a 1% agarose gel. The DNA was pretreated in acid to ensure efficient transfer. The agarose gel was rinsed 10 min in depurination solution (0.25 M HCl) and shortly in water. The gel was denatured two times for 15 min in denaturing solution (0.5 M NaOH, 1.5 M NaCl) and washed briefly in water. Finally, the gel was rinsed in neutralization buffer (1 M Tris-HCl pH 7.5; 1.5 M NaCl) two times for 15 min and equilibrated for at least 10 min in 20× SSC (3 M NaCl, 0.3 M sodium citrate; pH 7.0).

The nylon membrane (positively charged, Roche) was rinsed 2 min in water and 15 min in 20× SSC to activate the membrane, before the DNA was vacuum blotted 1.5 h at 50-100 mbar (Biometra). Before DNA crosslinking, the membrane was rinsed 30 sec in 0.4 M NaOH, 30 sec in 0.2 M Tris-HCl pH 7.5 and dried 10-15 min on a piece of Whatman™ filter paper. The DNA was crosslinked to the membrane by UV light (120 mJ/cm<sup>2</sup>) for at least 60 sec and the membrane was rinsed with 2× SSC. Further steps were performed according the DIG nonradioactive nucleic acid labeling and detection

system (Roche), using the PCR DIG Probe Synthesis Kit, DIG Easy Hyb™, Anti-Digoxigenin-AP, Fab fragments, and CDP-Star.

### **Fungal RNA isolation and reverse transcription-quantitative PCR (qRT-PCR)**

For preparation of RNA from *in vitro* cultures of *Candida*, stationary phase yeast cells were washed three times in PBS, and  $2 \times 10^7$  *Candida* cells per mL were inoculated into minimal medium with different biotin concentrations. At indicated time points, cells were harvested and centrifuged (4,000g, 10 min and 4°C). The cell pellet was washed with ice cold water, centrifuged again, and immediately frozen in liquid nitrogen. The isolation of the fungal RNA was performed as previously described (Lüttich *et al.*, 2012). The quantity of the RNA was determined using the NanoDrop Spectrophotometer ND-1000 (NRW International GmbH). DNase-treated RNA (600 ng) was transcribed into cDNA using 0.5 µg oligo-dT<sub>12-18</sub>, 100 U Superscript™ III Reverse Transcriptase and 20 U RNaseOUT™ Recombinant RNase Inhibitor (all: Thermo Fischer Scientific) in a total volume of 35 µL for 2 h at 42 °C, followed by heat-inactivation for 15 min at 70°C. The cDNA was diluted 1:20 in DEPC-treated water and used for quantitative PCR with EvaGreen® QPCR Mix II (Bio&SELL) performed in a CFX96 thermocycler (Bio-Rad). Primers (**Table S3**) were used at a final concentration of 500 nM. Target gene expression was calculated using the  $\Delta\Delta C_t$  method (Pfaffl, 2001), with normalization to the housekeeping genes *ACT1* and *EFB1*.

### **Protein isolation and Western blot**

For preparation of whole protein extracts, stationary phase cells were washed three times in PBS, diluted to OD<sub>600</sub> 0.2 into minimal medium and incubated at 37°C at 180 rpm overnight. The cells were harvested and mechanically lysed in PBS-KMT (PBS + 3 mM KCl, 2.5 mM MgCl<sub>2</sub>, 0.1% Triton-X-100) + protease inhibitor cocktail (Roche) with acid-washed glass beads by bead beating in a Precellys 24 homogenizer (Peqlab; 6.500 rpm, 2 cycles, each 30 sec, 15 sec pause). The lysate was centrifuged

(14,000 rpm, 4°C for 5 min) and the protein concentration of the supernatant was determined by Pierce™ BCA Protein Assay Kit (Thermo Fisher Scientific). Two aliquots of twenty µg protein of each sample were denatured in one-fourth volume of 4× Lämmli buffer (125 mM Tris-HCl pH 6.8, 50% glycerol, 4% SDS, 0.02% bromophenol blue, 1:10 β-mercaptoethanol) at 95°C for 5 min and separated by denaturing SDS-PAGE with Rotiphorese® Gel 30 (final 12% acrylamide mix (Roth)). Proteins were electro-transferred to nitrocellulose membranes (Whatman) in blotting buffer (25 mM Tris, 192 mM glycine, 10% methanol and 0.1% SDS) and free binding sites were blocked with 5% milk powder in TBS (0.5 M Tris, 1.5 M NaCl, pH 7.6) + 0.05% Tween®-20 (TBS-T) for 3 hr at room temperature. One membrane was incubated with monoclonal mouse anti-chicken egg albumin antibody (Sigma), diluted 1:2000 in TBS-T containing 2% milk powder. The other membrane was incubated with rat anti-α-tubulin antibody (AbD Serotec), diluted 1:1000 in TBS-T containing 2% BSA. Both were incubated at 4°C overnight and gentle shaking. The membranes were rinsed three times in TBS-T, incubated with goat anti-mouse IgG-HRP (1:1000 in 2% milk powder) or goat anti-rat IgG-HRP (1:2000 in 2% BSA) (both Santa Cruz Biotech) to detect ovalbumin and α-tubulin, respectively. Finally, the membranes were rinsed three times in TBS-T and two times in TBS, followed by chemiluminescence detection using Pierce™ ECL Plus Western Blotting Substrate (Thermo Fisher Scientific) according to the manufactures' instructions.

### **Experiments with human monocyte-derived macrophages (hMDMs)**

Primary macrophages were differentiated from CD14-positive monocytes as previously described (Sprenger *et al.*, 2020), seeded in 24-well plates ( $2 \times 10^5$  hMDMs/well) in RPMI with 50 ng/mL M-CSF, and incubated overnight. Prior to macrophage infection, the medium was exchanged to serum- and biotin-free RPMI with L-glutamine (Thermo Fisher Scientific) to exclude biotin uptake by *Candida* prior to phagocytosis. The fungal survival within macrophages was evaluated after 3 h of coinubation with *C. glabrata* at

a multiplicity of infection (MOI) of 1, by plating of appropriate dilutions on YPD agar as previously described (Sprenger *et al.*, 2020). Macrophages ( $1.5 \times 10^5$  hMDMs/well) were allowed to adhere onto coverslips in a 24-well plate overnight in RPMI containing 50 ng/mL M-CSF and 10 % FBS, and then infected with *C. glabrata* at an MOI of 2 for the indicated time points. Phagocytosis was synchronized on ice for 30 min followed by two washing steps with pre-warmed medium to remove unbound *Candida* cells.

### **Fluorescence analysis by flow cytometry and microscopy**

Stationary phase cells were diluted 1:20 into fresh YPD medium and incubated at 37 °C for 2 h and 180 rpm. Then, cells were harvested and washed once with PBS, fixed with 500  $\mu$ L Roti<sup>®</sup>-Histofix 4% for 20 min and washed again with PBS. The median fluorescence intensity (MFI) of *C. glabrata* yeast cells was evaluated with BD FACS Verse<sup>®</sup> (BD Biosciences, Franklin Lakes (USA)) counting 50,000 events. Data analysis was performed using the FlowJO<sup>™</sup> 10.2 software (FlowJO LLC, Ashland (USA)). The gating strategy was based on blotting forward (FSC) and side scatter (SSC) to exclude cellular debris.

The staining of phagocytosed yeast cells was adapted from (Kasper *et al.*, 2018). Infected macrophages were fixed with Roti<sup>®</sup>-Histofix 4% and stained with 50  $\mu$ g/mL Concanavalin A conjugated with Alexa Fluor<sup>™</sup> 647 (ConA-AF647; Thermo Fisher Scientific) at 37°C for 30 min to visualize external *Candida* cells. Coverslips were mounted with ProLong<sup>™</sup> Gold Antifade Mountant with DAPI and fluorescence images were recorded using the Zeiss AXIO Observer.Z1 (Carl Zeiss Microscopy).

### ***In silico* analysis and statistics**

Information about gene orthologs was obtained from the *Candida* Genome Database (CGD) (Skrzypek *et al.*, 2017) and the *Saccharomyces* Genome Database (SGD) (Cherry *et al.*, 2012). Data are reported as scatterplot with mean  $\pm$  SD, line charts with mean  $\pm$  SD, or bar charts showing mean + SD. Data were analyzed using

GraphPad Prism 5 (GraphPad Software, San Diego, USA). For statistical analysis of matched observations in macrophage experiments, a repeated measures ANOVA with Bonferroni's multiple comparison test was performed. Statistically significant results are marked with a single asterisk meaning  $p \leq 0.05$ , double asterisks meaning  $p \leq 0.01$ .

## **Results and discussion**

### **Complementation of tryptophan auxotrophy in *C. glabrata* by genomic reintegration**

Gene complementation in the best-studied diploid *Candida* species, *C. albicans*, is often achieved by genomic integration targeting specific promotor regions (*HIS1* (Davis *et al.*, 2002) and *ENO1* (Staab *et al.*, 2003)) or neutral ORFs (*ADH1* (Hünninger *et al.*, 2014), *RPS1*, (Murad *et al.*, 2000), and *ACT1* (Morschhäuser *et al.*, 1998, Xu *et al.*, 2014)). However, similar approaches in the haploid genome of *C. glabrata* would lead to an additional knock-out of the targeted gene. To define a suitable locus for gene integration, we therefore first carefully reviewed the literature to exclude unwanted side-effects upon genetic modification, especially during infection experiments. We chose the tryptophan biosynthesis gene *TRP1* as a target locus for integration, as previous data has shown that genetic manipulation in this locus has no influence on fungal fitness in a systemic *C. glabrata* infection model (Jacobsen *et al.*, 2010) and on the interaction with macrophages (Schwarz Müller *et al.*, 2014, Seider *et al.*, 2014). In addition, the *TRP1* gene is, besides *HIS3*, *LEU2*, and *URA3* widely used as selection marker in different plasmid vectors in *S. cerevisiae* and *C. glabrata*.

As a basis for complementation constructs, we created a pTRP1 plasmid vector based on the plasmid pUC19, which harbors the *TRP1* gene as the selection marker together with its up- and downstream regions for homologous recombination at the native *TRP1* locus. The remaining part of the multiple cloning site of the pUC19 backbone downstream of the *TRP1* terminator allows easy insertion of any GOI (**Figure 1A**). A *trp1*Δ mutant, which can be used as the parental strain for integration of pTRP1, has been previously created with the *SAT1* flipper protocol (Jacobsen *et al.*, 2010), where only one recombination site (FRT) of the flip-recombinase (FLP) remains at the *TRP1* locus (**Figure 1B**). To generate a *TRP1* complementation strain in a strain background that harbors no additional gene deletions, the *TRP1* construct was PCR-amplified from

pTRP1 and transformed into *trp1* $\Delta$ . We used this PCR-amplified complementation cassette instead of the whole plasmid to rule out the unspecific genomic integration of additional vector DNA. Correct integration into the *TRP1* locus was then verified by Southern blotting (**Figure 1C**). Phenotypically, the growth of the complemented strain (*trp1* $\Delta$  + *TRP1*) was restored in minimal medium lacking tryptophan (**Figure 1D**). We can therefore conclude that the *TRP1* locus is suitable for expression of target genes, which is similar to the Clp10 strategy in *C. albicans* (Murad *et al.*, 2000), but uses the native chromosomal location of the *TRP1* locus.

To apply our approach for the analysis of gene functions of a *C. glabrata* GOI, a mutant strain lacking the GOI has to be generated in *trp1* $\Delta$  strain background. This mutant will then be transformed with the above-described *TRP1* cassette for restoring *TRP1* prototrophy, or with the *TRP1* cassette containing the GOI together with promoter and terminator region, to restore *TRP1* prototrophy and function of the GOI. This method then allows the direct comparison of three prototrophic strains – the *trp1* $\Delta$  + *TRP1* wild type strain (**Figure 1**), the *trp1* $\Delta$ GOI $\Delta$  + *TRP1* mutant strain and the *trp1* $\Delta$ GOI $\Delta$  + *TRP1*+GOI complemented strain. This strategy has successfully been applied for complementation of *C. glabrata* with the biotin-metabolic genes *VHR1* and *VHT1*, for which recovery of wild type phenotypes after complementation was proven (Sprenger *et al.*, 2020).

Of note, our strategy of restoring the tryptophan prototrophy of a *trp1*-auxotrophic parental strain can be used to complement genes in a published triple auxotrophic *his3* $\Delta$  *leu2* $\Delta$  *trp1* $\Delta$  *C. glabrata* mutant library remaining leucine and histidine auxotrophy (Schwarz Müller *et al.*, 2014). A good alternative strategy might be the integration of complementation cassettes into intergenic regions, which is already established in *C. albicans* (Gerami-Nejad *et al.*, 2013) and in *C. glabrata* (Ueno *et al.*, 2011). However, genomic integration in these regions can raise the problem of inefficient transcriptional activity due to a silenced chromatin structure (Rando & Winston, 2012, Gartenberg & Smith, 2016).

### **Heterologous expression of yEGFP, mCherry, and ovalbumin in *C. glabrata***

In order to determine whether the *TRP1* locus is suitable for heterologous expression of fluorescent markers and ovalbumin, an antigen used for immunological studies, we used the In-Fusion HD cloning system to fuse different promoters with these GOIs and into the *Xba*I-digested pTRP1 vector (**Figure 2A**). This technique allows the combination of promoter, protein-encoding, and terminator sequences by one cloning step. Several well-investigated promoters (Zordan *et al.*, 2013) were fused with yEGFP (yeast-enhanced green fluorescent protein (Cormack *et al.*, 1997)) to achieve constitutive expression under *in vitro* conditions (*TEF1*prom and *PDC1*prom), but also induced expression upon phagocytosis by macrophages (*LYS21*prom). The correct integration into the *TRP1* locus into the *trp1*Δ strain was verified by PCR and positive clones were analyzed for yEGFP fluorescence by microscopy and FACS.

The expression of yEGFP under control of the *TEF1* promoter led to the highest median fluorescence intensity among all tested promoters in culture medium (**Figure 2B-C**). This construct was expressed by *C. glabrata* cells internalized by macrophages, but also non-internalized cells (**Figure 2D**). The *PDC1*-controlled yEGFP expression showed fluorescence levels similar to *TEF1* in culture medium, which were also similar between phagocytosed and non-phagocytosed yeast cells (Figure 2D). Comparing logarithmically growing to stationary cells, yEGFP fluorescence with *TEF1* and *PDC1* promoters was higher in logarithmic cells (**Figure 2B**). When the expression was controlled by the *LYS21* promoter, the fluorescence signal was higher in phagocytosed vs extracellular *C. glabrata* cells (**Figure 2D**, as expected from a previous study (Zordan *et al.*, 2013)). In contrast to the other promoters, the expression of yEGFP remained low in the logarithmic growth phase when controlled by the *LYS21* promoter (**Figure 2B**).

In addition to yEGFP, the *TEF1* promoter was fused with mCherry (red fluorescent protein), cloned into the *Xba*I-digested pTRP1 and transformed into the *trp1*Δ strain background. The expression of mCherry controlled by the strong constitutive promoter

*TEF1* again led to a strong fluorescence signal of logarithmically growing cells (**Figure 2E**).

The expression of fluorescent markers under control of constitutive or inducible promoters is not only useful for generating fluorescently labeled fungal wild type or mutant strains that can be traced during infection, it also generates reporter strains that can be used to identify promotor-inducing conditions during infection (Miramón *et al.*, 2012). Similarly, the efficiency of transcription and translation based on promoters of interest can be quantified, even by measuring the fluorescence intensity on a single cell level. The method presented here can be expanded by using more than one fluorophores which can be integrated into other genomic regions, like the *HIS3* or *LEU2* locus of *his3Δ* or *leu2Δ* single mutants or the triple auxotrophic *his3Δ leu2Δ trp1Δ* mutant (Jacobsen *et al.*, 2010, Schwarzmüller *et al.*, 2014).

The heterologous expression of ovalbumin (OVA) in pathogens can be used to induce OVA-specific immune responses for investigation of the immune recognition of and T cell activation by the pathogen (Ishizuka *et al.*, 2009, Krummey *et al.*, 2014, Harms *et al.*, 2018). To generate an OVA-expressing *C. glabrata* strain, we fused a codon-optimized OVA gene with the *TEF1* promotor and cloned it into the *XbaI*-digested *pTRP1*. The expression of OVA in *C. glabrata* was verified by Western blot (**Figure 2F**). The heterologously expressed OVA in *C. glabrata* was smaller in size than native ovalbumin from egg white (42.8 kDa) and was detected as two bands. A previous study in *Pichia pastoris* demonstrated that mono- and diglycosylation of OVA correspond to these two bands. The smaller size is therefore likely due to missing *N*-acetylation and phosphorylation in this yeast expression system (Ito & Matsudomi, 2005).

In summary, we have constructed a set of plasmids for fluorescence reporter-based analysis using *TRP1* integration in *C. glabrata*. We have shown that the fluorescence levels depend on the strength of the promotor and promotor-specific induction conditions. Moreover, we used this system for heterologous expression of the well-characterized model antigen OVA as a basis for measuring the specific immune

response of T cells against *C. glabrata*. Additionally, this system can be used for epitope-tagging of proteins or for competitive infection or interspecies competition models, by combining different fluorescently labeled *C. glabrata* strains in one experiment.

### **Overexpression of the biotin transporter gene *VHT1* modulates intracellular survival within macrophages**

To evaluate the suitability of our *TEF1*, *LYS21* and *PDC1* promoter constructs for overexpression of *C. glabrata*'s own genes, we used the system with the biotin transporter gene *VHT1* of *C. glabrata*. The expression of the biotin transporter gene *VHT1* is normally induced when availability of biotin in the environment is low, and its expression is dependent on the transcriptional regulator Vhr1 (Sprenger *et al.*, 2020). Similar constructs as described for yEGFP were created, and transformed into a *trp1* $\Delta$  strain (wild type) and a *trp1* $\Delta$  *vh1* $\Delta$  strain (mutant). Resulting strains were analyzed for the transcriptional abundance of *VHT1* after inoculation into nutrient-rich medium. The transcript abundance of *VHT1* was strongly increased compared to the wild type when the gene was controlled by *TEF1*prom or *PDC1*prom, both constitutively active promoters, whereas the *LYS21*-controlled *VHT1* expression was only marginally increased (**Figure 3A**). The overexpression of *VHT1* was independent of its native regulator, Vhr1, as the additional deletion of *VHR1* had no impact on the transcript abundance of *VHT1*.

*VHR1* is needed for survival of *C. glabrata* in macrophages. This gene contributes to upregulation of *VHT1* under biotin limitation, it may also have regulatory targets in addition to *VHT1* regulation (Sprenger *et al.*, 2020). To elucidate whether *VHR1*-dependent *VHT1* induction is important during *C. glabrata*-macrophage interaction, we tested whether overexpression of *VHT1* by our system can diminish the survival defect of the *vh1* $\Delta$  mutant. We confronted hMDMs with *VHT1* overexpression strains and evaluated survival of phagocytosed fungal cells. The *vh1* $\Delta$  strain showed an

attenuated intracellular survival within hMDMs as previously described (Sprenger *et al.*, 2020), while both *VHT1*-overexpressing strains showed survival rates comparable to the wild type (**Figure 3B**). These data imply that the overexpression of *VHT1* can indeed compensate the deletion of *VHR1*, whereas the wild type with its functional *Vhr1* does not benefit from higher *VHT1* expression (**Figure 3B**).

### **Mutations in the biotinylation motif of Dur1,2 prevent the utilization of urea**

Biotinylation is a covalent posttranslational modification of lysine residues in target proteins (Lane *et al.*, 1964). Most of these lysine residues lie in highly conserved AMKM sequence motifs of biotin-dependent enzymes (Samols *et al.*, 1988, Chapman-Smith & Cronan, 1999). The enzyme urea amidolyase Dur1,2 is important for utilizing urea as a nitrogen source, and its expression is highly induced by urea (Navarathna *et al.*, 2011). It possesses a conserved biotinylation motif in its carboxylase-acting C-terminal domain in both, *C. glabrata* and *C. albicans* (**Figure 4A**, (Samols *et al.*, 1988, Chapman-Smith & Cronan, 1999)). *DUR1,2* is important for the pathogenicity of *C. albicans* (Ghosh *et al.*, 2009, Navarathna *et al.*, 2012) and *C. glabrata* (Brunke *et al.*, 2015). To study whether biotinylation is important for Dur1,2 functionality, we mutated the lysine codon AAA into the arginine-coding AGA (amino acid position 1798 in *C. glabrata* and 1779 in *C. albicans* (**Figure 4B**)), using our newly developed complementation strategy in *C. glabrata* and the established Clp10 strategy in *C. albicans* (Murad *et al.*, 2000). Growth of the mutant strains in liquid (**Figure 4C, E**) and solid (**Figure 4D, F**) medium showed a growth defect in media with urea as the sole nitrogen source. The K→R mutation strains exhibited similar phenotypes as the *dur1,2* deletion mutants of both species (**Figure 4C-F**). Interestingly, the *Cadur1,2Δ/Δ* mutant and the K→R mutation strain not only showed reduced growth on agar plates containing urea, but also failed to induce colony wrinkling at 37°C (**Figure 4F**). These data suggest that biotinylation of Dur1,2 is indeed essential for urea utilization in *C. glabrata* and *C. albicans*.

In summary, we conclude that the *TRP1* locus is a suitable locus to reintegrate genes of interest, either with their native DNA sequence, with specific sequence variations or with alternative promoters, to investigate the role and function of these genes for fungal (patho)biology.

### ***Acknowledgements***

We gratefully acknowledge Isabell Nold, Patrick Schmerer, Yi Enn Cheong, Aylina Kulle, and Simone Schiele for their technical help with genotypic mutant characterization and cfu counting; Matthias Brock for helpful discussions in the development of the complementation strategy and Annemarie Landmann for his advice on the ovalbumin project. We thank Nadja Jablonowski, Stephanie Wisgott, Daniela Schulz, and Dorothee Eckardt for isolation of PBMCs and excellent technical assistance; Annika König, Daniel Fischer, Fabrice Hille, and Sophie Austermeier for their support during cultivation of hMDMs. Use of the auto-MACS system was kindly provided by the research group Fungal Septomics, ZIK Septomics Jena. This work was supported by the Deutsche Forschungsgemeinschaft SPP 1580 (Hu 528/17–1).

Figures and legends

**FIGURE 1: Construction and verification of *TRP1* complemented strains.**

(A) Overview of the plasmid used for gene complementation in *C. glabrata*. The insertion site allows cloning of GOI sequences with their promoter and terminator

(B) Depiction of the *TRP1* gene locus in the *C. glabrata* ATCC2001 reference genome, the *trp1* deletion mutant (*trp1Δ*) and our complementation strain (*trp1Δ + TRP1*). A

DNA probe was designed for the terminator region to detect gene-specific fragments by Southern blotting. (C) Southern blot of *Hind*III-digested genomic DNA of ATCC2001, *trp1* $\Delta$ , and *trp1* $\Delta$  + *TRP1* (*Cg* wt). The expected sizes from (B) correspond to the visible bands. (D) Growth analysis of *C. glabrata* ATCC2001, *trp1* $\Delta$ , and *trp1* $\Delta$  + *TRP1* in nutrient-rich medium (YPD) and minimal medium (SD) at 37°C for 24 h. Values are absorption at 600 nm and shown as mean  $\pm$  SD of at least three replicates.

**FIGURE 2: Heterologous expression of yEGFP, mCherry, and ovalbumin in *C. glabrata*.** (A) Overview of constructed plasmids for yEGFP, mCherry, and ovalbumin (OVA) expression in *C. glabrata*. Three different promoters were fused with yEGFP, and the constitutive *CgTEF1* promoter was fused either with mCherry or OVA. The constructs were subsequently cloned into the *XbaI*-linearized pTRP1 plasmid. (B-

E) The fluorescence of the different strains was evaluated by (B) flow cytometry of cells grown in culture medium and (C-E) by fluorescence microscopy, during (D) infection of macrophages and (C and E) *in vitro* growth in minimal medium of stationary phase yeast cells (scale bar: 10  $\mu\text{m}$ ). (B) All strains, grown in YPD at 37°C and 180 rpm (stationary phase), were diluted 1:20 in fresh YPD and incubated 2 h under the same growth conditions (exponential phase). Yeast cells of both growth phases were analyzed for green fluorescence (FITC channel) using BD FACS Verse. (D) Primary human macrophages (hMDMs) were infected with yeast cells at an MOI of 5 and incubated for 3 h at 37°C and 5%  $\text{CO}_2$ . Non-phagocytosed yeast cells were counterstained with Alexa Fluor 647-coupled concanavalin A (representative examples shown by arrows). (F) Equal amounts of protein extracts were of the OVA-expressing *C. glabrata* (Cg-OVA), the parental strain (Cg wt) and isolated egg white ovalbumin (OVA) were blotted and probed for OVA. A separate gel with the same amounts was probed for  $\alpha$ -tubulin (loading control). The protein sizes were estimated by using PageRuler Plus prestained (Fisher Scientific).

**FIGURE 3: The overexpression of *VHT1* increases intracellular fitness of *vhrl*Δ.**

(A) *C. glabrata* wt (black letters), mutant (*vhrl*Δ, red letters), and corresponding overexpression strains (+*LYS21*prom-*VHT1*, +*TEF1*prom-*VHT1*, +*PDC1*prom-*VHT1*) were cultivated in YPD for 90 min at 37 °C and 180 rpm. Target gene expression was analyzed by qRT-PCR and normalized to *ACT1* and *EFB1*. Expression is shown relative to the parental strain. Data are shown as mean ± SD of two independent experiments. (B) *C. glabrata* wt (black letters), mutant (*vhrl*Δ, red letters), and corresponding overexpression strains (+p*LYS21*-*VHT1*, +p*TEF1*-*VHT1*) were pre-cultured in YPD + 2 mg/L biotin before confrontation with hMDMs. Survival of *C. glabrata* strains after 3 h co-incubation with hMDMs at an MOI of 1, shown as % of survival (mean ± SD). Each single dot represents one technical replicate/blood donor (at least eight donors in two independent experiments). For statistical analysis, a repeated measures ANOVA with Bonferroni's multiple comparison test was performed comparing all strains (\*  $p \leq 0.05$ , \*\*  $p \leq 0.01$ ).

**FIGURE 4: Biotinylation of Dur1,2 is essential for urea utilization.** (A) Dur1,2 possess a highly conserved biotinylation motif (AMKT) in *C. glabrata* and *C. albicans*. (B) Upper part: DNA sequence which is transcribed into the lysine (K) residue essential for biotinylation and biotin structure coupled to lysine. Lower part: The adenine of the triplet codon was mutated to guanine to induce an amino acid exchange to arginine.

## Manuscript V

---

(C-F) Growth analysis of (C-D) *C. glabrata* wt, *Cgdur1,2Δ*, + *CgDUR1,2<sup>WT</sup>*, and *CgDUR1,2<sup>K1798R</sup>* and (E-F) *C. albicans* wt, *Cadur1,2Δ/Δ*, + *CaDUR1,2<sup>WT</sup>*, and *CaDUR1,2<sup>K1779R</sup>* in (C, E) liquid and on (D, F) solid minimal medium at 30°C (E) or 37°C (C, D, and F) containing either 0.5% ammonium sulfate or 0.5% urea as sole nitrogen source. Values are represented as mean ± SD of at least three replicates and representative picture are shown.

### 3 Additional results on manuscript II

The following results are related to **manuscript II**.

#### 3.1 The conservation of the biotin biosynthesis gene cluster and the regulated biotin transport among pathogenic *Candida* species

A common ancestor of *Candida* and *Saccharomyces* species has lost the biotin biosynthetic pathway, and parts of the biosynthetic pathway were rebuilt through horizontal gene transfer from different proteobacteria and neofunctionalization [317]. Some *S. cerevisiae* strains possess the biosynthesis genes *BIO1* and *BIO6* enabling the *de novo* synthesis of biotin ([318], **Figure 3A**). Most strikingly is the comparison to, mainly in the environment found, fungal pathogens, like *Aspergillus* and *Histoplasma*, which possesses a complete biosynthetic pathway to produce biotin *de novo* [299]. Interestingly, different *Candida* species contain a different set of genes in the pathway of biotin synthesis as indicated in **manuscript II, Figure S1**. The biosynthesis starting from KAPA is present in *C. albicans* and *C. tropicalis*, whereas *C. dubliniensis* and *C. auris* progressively minimized the pathway and only the *BIO2* remains in the genome. Interestingly, the closest relative of *C. albicans*, *C. dubliniensis* possesses no orthologues of *BIO3-5* and was only able to use DTB (**manuscript II, Figure S1**). *C. glabrata* and *C. parapsilosis* have lost the whole biosynthetic pathway and probably rely only on biotin uptake from the environment (**Figure 3B**). **Manuscript II** showed that orthologs of the biotin transporter *CaVht1* and the biotin regulator *CaVhr1* are present in *C. glabrata* and *C. albicans*. *In silico* analyses revealed that orthologs of these genes can be found in as well in other medically important *Candida* species (**Table 3**).

## Additional results

**Figure 3. The biotin biosynthetic gene cluster in medically important *Candida* species and *S. cerevisiae*.** (A) Biotin biosynthetic pathway. (B) [317] showed and *in vitro* growth analyses suggested that *C. albicans*, *C. tropicalis*, and *S. cerevisiae* are equipped with *BIO2-5*, whereas *C. dubliniensis* and *C. auris* can exclusively use DTB and *C. glabrata* and *C. parapsilosis* are not able to use biotin precursors. // *BIO2* in *S. cerevisiae* is not located in the cluster with *BIO3-5*.

**Table 3: Putative orthologs of CaVht1 and CaVhr1 in other medically important *Candida* species.** The percentage of identical amino acids between *Candida* species and *S. cerevisiae* was analyzed with CDG [31] or CloneManager 9 (with asterisks).

<i>C. albicans</i>	CaVht1 orf19.2397	Identities	CaVhr1 orf19.7468	Identities

<i>S. cerevisiae</i>	YGR065C	19%*	YIL056W	21.7%

### 3.2 The transcriptional regulation of *CgVHT1* and *CgBPL1* depends on nutrient sources, but not *CgVHR2*

The availability of different nutrients affects the transcription of *C. albicans* metabolic genes to improve metabolization of these nutrients, or to shut down other, unneeded metabolic pathways [281, 319]. To analyze how the expression of biotin-related genes is affected by different nutrient conditions, the transcription of the biotin transporter gene *CgVHT1* and the biotin protein ligase *CgBPL1* in response to different carbon- and nitrogen sources in combination with variations in biotin levels was analyzed.

The expression of *CgVHT1* and *CgBPL1* was strongly induced during logarithmic growth under biotin limitation in the presence of glucose (**manuscript II** and [320]). When comparing the expression of both genes between logarithmic and stationary *C. glabrata* cultures in nutrient-rich YPD medium, transcript levels were reduced during logarithmic compared to stationary growth. This suggests that progressive biotin depletion or accumulated metabolites caused increasing expression of biotin-responsive genes upon prolonged (stationary) growth (**Figure 4A**). Overall, the level of regulation was similar between *CgVHT1* and *CgBPL1*, suggesting similar regulation mechanisms of these genes (**Figure 4B**). While the expression of *CgVHT1* and *CgBPL1* was strongly induced in media lacking biotin and containing glucose as carbon source and ammonium sulfate as nitrogen source, media with non-fermentable carbon sources like glycerol and amino acids only marginally induced *CgVHT1* and *CgBPL1* expression (**Figure 4B**). Furthermore, the addition of amino acids to glucose-containing media reduced the transcript abundance of *CgVHT1* and *CgBPL1* by app. 50% (**Figure 4B**). This indicates that amino acid-dependent processes can overcome the need for *VHT1* under biotin limitation (see also **manuscript II**) and that potentially other regulators in addition to *CgVhr1* are involved in the regulation of these genes.

## Additional results

Upregulation of *CgVHT1* and *CgBPL1* under biotin limitation was strongly dependent on *CgVhr1* at early time points (90 min) (**manuscript II**). *CgVHT1* expression, however, gets induced to wild type (wt)-like levels at later time points (180 min) in the absence of *VHR1* (**Figure 4C**), suggesting a role of *CgVhr1* for an initial upregulation of *CgVHT1*. However, this also suggests that additional regulators exist, which are involved in *CgVHT1* regulation at later time points.

**Figure 4: Growth phase and nutrient sources dependent expression of *CgVHT1* and *CgBPL1*.** Stationary *C. glabrata* cells were incubated in (A) fresh YPD, (B) minimal medium containing 2% glucose and 0.5% ammonium sulfate (AS), 1% casamino acids (AA) or 3% glycerol, or (C) minimal medium containing 2% glucose and 0.5% ammonium sulfate (AS) for (A-B) 90 min or (C) 180 min at 37°C and 180 rpm with or without biotin. Target gene expression was analyzed by qRT-PCR and normalized to *CgACT1*, *CgEFB1* and *CgEFT2*. Values are represented as mean + SD of three independent experiments, whereby n-fold expression for each gene is shown relative to (A) stationary phase culture or (B-C) culture with glucose and ammonium sulfate and 2 µg/L biotin. For statistical analysis, a Two-way ANOVA with Bonferroni post-tests was used (\*\* $p \leq 0.01$ , \*\*\* $p \leq 0.001$ ; comparing different nutrient sources). (D) Stationary *C. glabrata* cells were incubated in minimal medium containing 2% glucose and 0.5% ammonium sulfate for 90 min at 37°C and 180 rpm with indicated biotin concentrations. Target gene expression was analyzed by qRT-PCR and normalized to *CgACT1*, *CgEFB1* and *CgEFT2*. Values are represented as mean + SD of three independent experiments, whereby n-fold expression for each gene is shown relative to glucose and ammonium sulfate with 2 µg/L biotin. (E) *C. glabrata* wild type (wt), mutant (*CgVhr2Δ*), or complemented strain (*CgVhr2Δ* + *CgVHR2*) were confronted with human blood monocyte-derived macrophages (hMDMs). Survival of *C. glabrata* strains after 3 h, (% survival of inoculum) is shown. Values are represented as scatterplots with mean ± SD and each single dot corresponds to one blood donor (total of eleven different donors in at least three independent experiments). For statistical analysis, a Repeated Measures ANOVA with Bonferroni's multiple comparison test was performed (\*\* $p \leq 0.01$  comparing wt and deletion mutant; ##  $p \leq 0.01$  comparing deletion mutant to the complemented strain).

*S. cerevisiae* possesses the putative transcription factor Vhr2 (YER064C) with high similarities to Vhr1 in terms of the protein sequence as well as DNA binding specificity [321]. The *VHR2* gene arose from whole genome duplication in the ancestor of *S. cerevisiae*, belongs to the basic leucine zipper domain (bZIP) transcription factor family and is also present in *C. glabrata* (CAGL0J03014g), but not in *C. albicans* [31, 322]. To analyze whether *CgVhr2* is an additional *CgVHT1* regulator, a deletion strain of CAGL0J03014g (*Cgvhr2* $\Delta$ ) and a complemented strain (*Cgvhr2* $\Delta$  + *CgVHR2*) with its native promoter were constructed. These strains were analyzed for transcriptional inducibility of *CgVHT1* and *CgBPL1* under biotin limitation and for survival within primary human monocyte-derived macrophages (hMDMs). *CgVHR2* was not involved in the transcriptional control of *CgVHT1* and *CgBPL1* (**Figure 4D**), but was necessary for survival of *C. glabrata* inside macrophages (**Figure 4E**). These data suggest that *CgVHR2* has yet unknown regulatory functions in *C. glabrata* that are independent of biotin transport (**Figure 4E**).

In summary, these data show that the regulation of biotin-related genes in *C. glabrata* is influenced by nutritional conditions. It also suggests that additional transcriptional regulators, in addition to Vhr1, affect *VHT1* and *BPL1* expression in order to fine-tune the biotin levels of *C. glabrata* in response to environmental stimuli.

### **3.3 Major biotin-dependent carboxylases possess a biotinylation motif, and pyruvate-carboxylase genes are regulated by biotin**

The depletion of biotin increases the expression of the biotin transporter gene *VHT1* and biotin protein ligase gene *BPL1* to sustain sufficient biotin import and attach biotin to biotin dependent proteins to ensure functioning of biotin-dependent processes (**manuscript II**). These are essential for key metabolic pathways, like fatty acid metabolism, gluconeogenesis and amino acid metabolism, requiring most highly biotinylated pyruvate carboxylase Pyc1/2 and acetyl carboxylase Acc1 (**Figure 5B**)[323, 324]. Correspondingly, several studies in *S. cerevisiae* show that Pyc1/2- and Acc1-deficient strains are severely attenuated in general growth [325-328]. Biotinylation is a covalent posttranslational modification of lysine residues in proteins being essential for carboxylation reactions [329]. The specific biotinylated lysine residue in pyruvate carboxylases Pyc1/2, acetyl-CoA carboxylase Acc1 and urea amidolyase Dur1,2 of *S. cerevisiae* is located in a highly conserved AMKM motif [330, 331]. Previous studies showed that site-directed mutagenesis of this lysine residue affects biotinylation [330] and the first methionine residue is critical for carboxylase activity [332].

## Additional results

By using *in silico* analyses biotin-dependent carboxylases were found in *C. albicans* and *C. glabrata* possessing this motif with slight sequence modifications (**Figure 5A**). Alanine in the biotinylation motif of Acc1 was substituted by valine (AMKM → VMKM), and the last methionine in the biotinylation motif of Dur1,2 was replaced by threonine (AMKM → AMKT) in both *Candida* spp. and by alanine in *S. cerevisiae*. The impact of these amino acid substitutions on biotinylation efficiency and enzymatic activity of the respective carboxylase is unknown. Still, the first methionine, required for enzymatic activity, is present in all of these biotinylation motifs. The necessity of the lysine residue in the biotinylation motif of Dur1,2 is demonstrated in **manuscript V**.

**Figure 5: Protein biotinylation in *C. albicans* and *C. glabrata*.** (A) Biotin-dependent carboxylases possess a highly conserved biotinylation motif (AMKM, with single amino acid divergence) in *C. glabrata*, *C. albicans* and *S. cerevisiae*. (B) Western blot of biotinylated proteins of *C. albicans* (SC5314; left) and *C. glabrata* (ATCC2001; right). Both strains were cultivated in biotin-free SD medium at 180 rpm and 30°C or 37°C, respectively. The yeast cell suspension was harvested after 4 and 24 h by centrifugation. The 0 h time point (stationary phase culture, YPD) was used as control.

Biotinylated proteins are recognized by high affinity biotin-binding proteins like avidin and streptavidin [333], and are detectable in Western blots with avidin/streptavidin conjugated to horseradish peroxidase (HRP). To analyze the biotinylated protein pattern during biotin depletion, Western blots of whole cell extracts of *C. glabrata* and *C. albicans* after 4 and 24 h were performed. The most prominent and stable biotinylated protein had a size of approximately 130 kDa, which, according to size prediction ((**Figure 5A**) and [31]), correlates to a pyruvate carboxylase (**Figure 5B**). As predicted by the *in silico* analyses (**Figure 5A**), *C. glabrata* extracts showed two protein bands, corresponding to two pyruvate carboxylase isoforms (Pyc1 and Pyc2), similar to *S. cerevisiae* [325]. The larger band, likely corresponding to CgPyc1 (129.9 kDa),

remained more biotinylated after 24 h of biotin depletion. Comparing both *Candida* species, *in silico* analyses suggest that *C. albicans* reduced the number of carboxylases and relies on one pyruvate carboxylase, encoded by *CaPYC2* (Figure 5A). A biotinylated protein with a molecular size of approximately 250 kDa, correlating to the predicted size of the acetyl-CoA carboxylase Acc1, was present in the stationary phase culture of both species, but it diminished during cultivation under biotin limitation (Figure 5B).

**Figure 6: Expression of biotin-dependent carboxylase genes ACC1 and PYC1/2 in *C. albicans* and *C. glabrata*.** (A) *C. glabrata* wt, mutant (*Cgvh1*Δ), and complemented strain (*Cgvh1*Δ+*CgVHR1*) and (B) *C. albicans* wt, mutant (*CaVhr1*Δ/Δ), and complemented strain (*CaVhr1*Δ/Δ+*CaVHR1*) were pre-cultivated in YPD and then incubated in minimal medium for 180 min at 37°C and 180 rpm. Target gene expression was analyzed by qRT-PCR and normalized to *CgACT1*, *CgEFT2*, *CgEFB1*, or *CaTDH3* and *CaEFB1*. Values are represented as mean + SD of three independent experiments, whereby n-fold expression for each gene is shown relative to the wt in 2 µg/L biotin. For statistical analysis, a Two-way ANOVA with Bonferroni post-tests was used (\* $p \leq 0.05$ , \*\* $p \leq 0.01$ , \*\*\*  $p \leq 0.001$ ; comparing 2 µg/L biotin and w/o biotin).

Studies in *S. cerevisiae* hinted at the pyruvate carboxylases of importance in, both, biotin sensing and inducing a biotin-starvation response (upregulation of Vhr1-dependent genes) [334], but it remained unknown how biotin availability affects the

## Additional results

---

expression of biotin acceptor genes in *Candida* species. Therefore, the transcript levels of the corresponding *PYC* and *ACC* genes in *C. glabrata* and *C. albicans* were analyzed. The expression of the both *ACC1* genes, in *C. glabrata* and *C. albicans*, was only marginally regulated by biotin, whereas the transcript abundance of *CgPYC1* and *CaPYC2* increased upon biotin limitation (**Figure 6A-B**). Taken together, the upregulation of *CgPYC1* and *CaPYC2* together with the mostly stable biotinylation upon biotin limitation indicate the importance of these enzymes for cellular metabolism.

### **3.4 The usage of alternative biotin-sources is Vht1-dependent**

In association with the mammalian host, free biotin could be restricted to invading microbes as mammalian cells are also auxotrophic for biotin and need to recycle biotin by proteolytic digestion of biotinylated proteins, releasing biocytin [335]. This intermediate is degraded to lysine and biotin by biotinidase activity (**Figure 7A**)[335]. During host invasion and damage of various cell types, alternative host-derived biotin sources like biotinylated proteins or biocytin could be available. Therefore, growth analyses with these potential host-derived biotin sources were performed. Analogous to the experiments in **manuscript II**, biotin-starved *Candida* cells were used.

*C. albicans* and *C. glabrata* wild type cells were able to use these alternative biotin sources for robust growth suggesting that both fungi are enzymatically equipped to further process these sources as shown in **manuscript II (Figure S1)**. *VHT1* but not *VHR1* deletion mutants of both species, however, were defective in growth with biotinylated BSA and biocytin (**Figure 7B-C**), suggesting that Vht1 may import these host biotin sources. Previous studies, however, showed that uptake of labeled biotin cannot be inhibited by biocytin, indicating that Vht1 is high selective for biotin [336]. These data suggest that extracellular enzymatic processing of biotinylated substrates and biocytin to biotin might be required, followed by biotin uptake depending on the biotin transporter Vht1 (**manuscript II, Figure 3**).

**Figure 7. The usage of alternative biotin sources is Vht1-dependent.**

(A) Biotin is cycled within the cell during an uncoupled (free) and coupled state mediated by enzymatic reactions. The biotin-protein ligase 1 (Bp1) covalently links biotin to acceptor proteins like apocarboxylases, generating functional active holocarboxylases. Protein turnover by proteases releases biocytin (biotinyl-L-lysine), which is further metabolized to lysine and biotin by biotinidase activity. (B-C) Yeast growth of biotin pre-starved wt, mutants (*vhr1* $\Delta$ , *vht1* $\Delta$ ), or complemented strains (*vhr1* $\Delta$  + *VHR1*, *vht1* $\Delta$  + *VHT1*) of (B) *C. glabrata* (37°C) or (C) *C. albicans* (30°C) in minimal medium containing 2  $\mu$ g/L biotinylated BSA, 2  $\mu$ g/L or 2 mg/L biocytin. Values are represented as mean  $\pm$  SD of at least three replicates.

### 3.5 Biotin promotes amino acid-induced growth by increasing environmental pH and ammonia release

Certain conditions can bypass the need for biotin. *C. glabrata* is able to grow in media with casamino acids (CAA) as a sole carbon- and nitrogen source in the absence of biotin dependent on *CgVHR1* (manuscript II, Figure S3). Still, growth is significantly enhanced under such conditions, when biotin is present (Figure 8A), suggesting that amino acids can only partially bypass the requirement for biotin. In medium with CAA

## Additional results

---

as a sole carbon- and nitrogen source, *C. albicans* is known to induce filamentation associated with an increase in environmental pH [283]. This *C. albicans*-driven alkalization is caused by ammonia release due to the catabolism of amino acids [283]. As biotin promotes filamentation in *C. albicans* [337, 338], we analyzed the impact of biotin on filamentation under alkalization-inducing conditions.

In medium with an initial pH of 4.5, colony wrinkling, indicating filamentation of the *C. albicans* wild type, was only visible when sufficient amounts of biotin (2 µg/L) were added (**Figure 8B**). Noteworthy, the initial increase to a neutral pH (pH 6.5) abolished this phenotype and the *C. albicans* wild type showed a fuzzy-wrinkled colony morphology independent of biotin addition, suggesting that a neutral pH bypasses the requirement of biotin-promoted alkalization for filamentation (**Figure 8B**).

*C. glabrata* requires *CgVHR1* for growth under conditions that combine low biotin with limitations of optimal C- and N-sources, like the growth with amino acids [338]. To find out whether *CaVHR1* and other *C. albicans* biotin-metabolic genes have an impact on the above-described colony wrinkling, we investigated the colony morphology of biotin-metabolic mutants when growing on agar containing CAA adjusted to an initial pH of 4.5. The degree of colony wrinkling was reduced in the *CaVHR1* deletion mutant and remained unaffected by addition of either higher amounts of biotin or biotin precursors (**Figure 8C**). The deletion of the partial biotin biosynthesis pathway genes *BIO2-5* demolished the ability of *C. albicans* to grow with the biotin precursors KAPA and DTB [338]. This result was further supported by the fact that the *Cbio2-5Δ/Δ* mutant did not show colony wrinkling on agar with KAPA or DTB as biotin precursors. The *Cavht1Δ/Δ* mutant showed only growth and colony wrinkling with KAPA and high amounts of biotin (**Figure 8C**). This is in line with the fact that high external biotin was needed to support growth in liquid medium in the absence of *VHT1* (**manuscript II**). Similar to this observation, the growth defect of *Cavht1Δ/Δ* was also rescued by addition of KAPA, but not DTB (**Figure 8D**). This indicates that *CaVHT1*, similar to its *S. cerevisiae* ortholog, is also required for DTB uptake [339], whereas KAPA usage does not require *VHT1*.

Environmental alkalization by *C. albicans* is associated with ammonia release and a rise in environmental pH [283]. Therefore, the impact on ammonia release and environmental pH changes during *C. albicans* and *C. glabrata* growth was visualized with phenol red and measured spectrometrically, respectively. In all experiments, the initial pH was adjusted to 4.5 (yellow color). In the presence of biotin, *C. albicans* and *C. glabrata* wild type growth caused increased pH values, as indicated by an orange to red color (**Figure 9A**) and ammonia release (**Figure 9B**). Of note, *C. glabrata* increased the environmental pH much slower and released ammonia to a lower extent than *C. albicans* (**Figure 9A-B**).

**Figure 8: Growth and colony morphology is dependent on biotin availability.** (A) Growth of *C. glabrata* wt, *Cg vhr1*Δ and *Cg vhr1*Δ + *Cg VHR1* in liquid YNB-CAA medium without or with 2 μg/L biotin at 37°C and 180 rpm measured every 8 h. (B) The initial pH and the presence of 2 μg/L biotin impaired the colony morphology of  $1 \times 10^5$  *C. albicans* wt cells grown on YNB-CAA at 37°C for 48 h. (C) *C. albicans* wt, mutants (*Cavhr1*Δ/Δ, *Cavht1*Δ/Δ, *Cabio2-5*Δ/Δ), and complemented strains (*Cavhr1*Δ/Δ + *CaVHR1* or *Cavht1*Δ/Δ + *CaVHT1*) were spotted on YNB-CAA (initial pH 4.5) in separate wells of a 12-well plate and incubated at 37 °C for 48 h. The colony morphology was documented with binocular microscope (Zeiss), scale bar: 1 mm. (D) Yeast growth of biotin pre-starved *C. albicans* wt, *Cavhr1*Δ/Δ, *Cavhr1*Δ/Δ + *CaVHR1*, *Cavht1*Δ/Δ or *Cavht1*Δ/Δ + *CaVHT1* at 30°C in minimal medium containing 2 μg/L KAPA or DTB. Values (in A and D) are represented as mean ± SD of at least three replicates.

As expected from our growth and filamentation analyses (**Figure 8A-C**), alkalinization, as seen by the rise in medium pH, and the release of ammonia was enhanced in the presence of biotin. The deletion of *CaVHR1*, but not *CgVHR1*, caused a reduced

## Additional results

medium pH change and ammonia release (**Figure 9B-C**). As expected from previous data (**manuscript II**), the biotin transporter mutants (*vht1Δ*) of both species were unable to grow with intermediate biotin concentrations. This deficiency correlated with the reduced ammonia secretion (**Figure 9C-D**). Collectively, these data suggest that *VHR1* plays a role in the utilization of amino acids in both *Candida* species, and influences the induction of proper *C. albicans* filaments under this specific condition.

**Figure 9: *Candida*-driven alkalization and ammonia release is enhanced by biotin and *VHR1*.** (A) Alkalization of YNB-CAA-Allantoin agar by wt, mutants (*vhr1Δ*, *vht1Δ*), or complemented strains (*vhr1Δ* + *VHR1*, *vht1Δ* + *VHT1*) of *C. albicans* (above) and *C. glabrata* (below) after 72 h incubation at 37°C. HK indicated heat-killed *Candida* cells (70°C, 30 min). The pH was visualized by 20 mg/L phenolred. A pH-increase causes a color change from yellow (initial pH 4.5) over orange to red. Volatile ammonia released by (B) wt cells of *C. albicans* and *C. glabrata* grown 72 h on YNB-CAA-allantoin agar and (C-D) wt, mutants (*vhr1Δ*, *vht1Δ*), or complemented strains (*vhr1Δ* + *VHR1*, *vht1Δ* + *VHT1*) of (C) *C. albicans* and (D) *C. glabrata* grown 48 h on YNB-CAA-allantoin agar. Values (in B-D) are represented as mean ± SD of at least three replicates. For statistical analysis, a Two-way ANOVA with Bonferroni post-tests was used (\* $p \leq 0.05$ , \*\* $p \leq 0.01$ , \*\*\* $p \leq 0.001$ ; comparing wt and mutant strains).

### 3.6 Biotin availability during infection has no influence on the interaction between *C. glabrata* and *C. albicans* and macrophages

Biotin uptake is essential to maintain cellular homeostasis of *Candida* spp. but also of the mammalian host. The host can experience biotin limitation due to specific diets and also during infection by biotin-consuming pathogens. This can have an influence of activities of immune cells. For example, it was shown that human dendritic cells and CD4<sup>+</sup> T lymphocytes react to biotin limitation with an enhanced pro-inflammatory response [340, 341], whereas monocytic myeloid cells react *vice versa* [342].

The impact of biotin on the ability of macrophages to phagocytose and kill ingested *Candida* cells as well as the *Candida*-induced cytolysis and pro-inflammatory response was so far unknown. To test different macrophage polarization states, primary M-CSF-treated macrophages (hMDMs) were stimulated for 24 h with the Th1 cytokine IFN- $\gamma$  or the Th2 cytokine IL-4 to favor a pro- or anti-inflammatory macrophage polarization phenotype [343]. Macrophages were then infected with *C. albicans* or *C. glabrata* wild type cells and co-incubated for 1 and 3 h in biotin-depleted or biotin-rich medium to determine phagocytosis and survival rates, respectively. Phagocytosis was nearly unaffected by biotin (**Figure 10A**). Exclusively, the phagocytosis of *C. albicans* by anti-inflammatory macrophages was marginally reduced (**Figure 10A**). While fungal biotin conditions before macrophage confrontation had an impact on *C. glabrata* and *C. albicans* survival (**manuscript II**), the survival of both *Candida* spp. was not affected by the availability of biotin during the infection. Interestingly, the stimulation with IFN- $\gamma$  increased phagocytosis-mediated killing of *C. glabrata*, whereas *C. albicans* killing efficiency was unaffected by macrophage stimulation (**Figure 10B**).

In order to determine the impact of biotin on fungus-driven cytolysis and release of pro-inflammatory mediators (IL-1 $\beta$ , TNF $\alpha$ , IL-6 and IL-8), unstimulated macrophages (M-CSF-treated) were infected with *C. albicans* and *C. glabrata* wild type cells and co-incubated for 24 h in presence or absence of biotin. In accordance with previous studies [178, 211, 344], *C. albicans* induced a strong cytokine release by and damage of macrophages (app. 70% cytotoxicity), whereas *C. glabrata* induced no visible macrophage damage and low IL-1 $\beta$  secretion (**Figure 10C-D**). However, the release of IL-6 and TNF- $\alpha$  was comparable between both fungal species, and only the secretion of IL-1 $\beta$  and the chemokine IL-8 were attenuated in *C. glabrata* infected macrophages (**Figure 10D**). Biotin had no effect on the secretion of the tested pro-inflammatory cytokines and there were only marginal survival differences for *C. glabrata* between the two macrophage polarization states.

## Additional results

**Figure 10: Interaction of *C. albicans* and *C. glabrata* with macrophages depending on biotin availability.** *C. glabrata* or *C. albicans* wt cells were confronted with human blood monocyte-derived macrophages (hMDMs) pre-cultivated either IFN- $\gamma$  and M-CSF or IL-4 and M-CSF without (-) or with (++) 200  $\mu$ g/L biotin. (A) Uptake of yeast cells (% phagocytosis) was quantified by differential staining after 1 h of co-incubation (MOI 2). (B) Fungal survival after 3 h, (% survival of inoculum). (C) Cytolysis (% cytotoxicity; 100% refers to full lysis) of and (D) release of pro-inflammatory cytokines and chemokines by unstimulated macrophages after infection with *C. albicans* and *C. glabrata* after 24 h of co-incubation (MOI 5). Positive (LPS; 1  $\mu$ g/mL) and negative control (MC, medium control) were included. Values are represented as scatterplots (mean  $\pm$  SD). Each single dot represents one technical replicate/blood donor (at least three donors in two independent experiments).

These data suggest that external biotin levels during interaction of *Candida* cells with macrophages have no influence on host activities like phagocytosis, fungal killing, susceptibility to fungus-driven cell lysis and release of pro-inflammatory mediators. This is in contrast to the fungal internal biotin pool, which is essential for survival and proliferation within macrophages (**manuscript II**).

### 3.7 Biotin impacts on CaVHT1-dependent macrophage lysis and pro-inflammatory cytokine secretion

The uptake of biotin by the putative biotin transporter Vht1 is essential for *C. albicans* and *C. glabrata* to proliferate in environments with limited biotin, likely encountered in host niches like the macrophage phagosome. Deletion of *VHT1* attenuated fungal

proliferation within macrophages (both species), survival and macrophage lysis (*C. albicans*) (**manuscript II**).

To see whether biotin availability during *C. albicans*-macrophage interaction influences the infection outcome of a strain that strongly depends on biotin, we monitored inflammasome activation, macrophage cytotoxicity and cytokine release after infection with the *CaVHT1* deletion strain. To exclude variations in the fungal biotin pool, all strains were biotin pre-starved. This pre-starvation significantly lowered the intracellular survival of *Cavht1* $\Delta/\Delta$  (**manuscript II**).

*C. albicans* is, unlike *C. glabrata*, a potent activator of the NLRP3 inflammasome in macrophages [345]. To study the influence of *CaVHT1* on inflammasome activation, IL-1 $\beta$  secretion by LPS-primed primary hMDMs after infection with biotin-starved *C. albicans* wt, deletion and complemented strains was measured 5 h p.i. The *Caece1* $\Delta/\Delta$  mutant, known to trigger less IL-1 $\beta$  secretion in hMDMs, was included as control [218, 346]. The *Cavht1* $\Delta/\Delta$  mutant was completely unable to induce secretion of IL-1 $\beta$  when interacting with macrophages in biotin-free culture medium (**Figure 11A**), while the addition of 2 mg/L biotin restored a wt-like IL-1 $\beta$  secretion. This biotin concentration was sufficient to promote wt-like growth of *Cavht1* $\Delta/\Delta$  (**manuscript II**).

In order to determine whether the reduced intracellular survival and inflammasome activation of the biotin transporter mutant *Cavht1* $\Delta/\Delta$  is associated with an altered late cytolysis and progressive pro-inflammatory host response, the release of LDH and the secretion of IL-1 $\beta$ , IL-6, IL-8 and TNF- $\alpha$  was quantified after 24 h of co-incubation. As described in **manuscript II**, the *VHT1* deletion mutant was severely attenuated in damage. The addition of biotin (2 mg/L) partly rescued the damage potential of this mutant (**Figure 11B**). In accordance to that, the secretion of the cytokines IL-1 $\beta$ , IL-6 and TNF- $\alpha$  and chemokine IL-8 was strongly reduced in *Cavht1* $\Delta/\Delta$ -infected macrophages in a biotin-limited environment and reached wt level in biotin-enriched medium (**Figure 11D-F**).

## Additional results

**Figure 11: Impact of *VHT1* on interaction of *C. albicans* with macrophages dependent on biotin availability.** Biotin-prestarved *C. albicans* wt, mutants (*Cavht1*Δ/Δ, *Caec1*Δ/Δ), or complemented strains (*Cavht1*Δ/Δ + *CaVHT1*) were confronted with human blood monocyte-derived macrophages (hMDMs) in the absence (w/o) or presence of 2 mg/L biotin (w/). (A) The early IL-1β release was quantified 5 h p.i. with *C. albicans* (MOI 5) of LPS-primed hMDMs (2 h pre-incubation with 50 ng/mL LPS). (B) Cytolysis (% cytotoxicity; 100% refers to full lysis) of and (D-F) release of pro-inflammatory cytokines and chemokines by hMDMs after infection with *C. albicans* 24 h p.i. (MOI 5). Positive (LPS; 1 μg/mL and negative control (MC, medium control) were included. Values are represented as scatterplots (mean ± SD). Each single dot represents one technical replicate/blood donor (at least five donors in two independent experiments). For statistical analysis, a repeated measures ANOVA with Bonferroni's multiple comparison test was performed (\*  $p \leq 0.05$ , \*\*  $p \leq 0.01$ , \*\*\*  $p \leq 0.001$  comparing wt and deletion mutant).

These data imply that *Vht1*-dependent proliferation of *C. albicans* in biotin-scarce environments mediates cytolysis of macrophages and activation of a pro-inflammatory response. This requirement for *VHT1* can only be overcome when high amounts of biotin are available continuously.

## 4 Discussion

Pathogenic *Candida* species have evolved sophisticated immune evasion strategies to thrive within macrophages, by surviving antimicrobial activities, adapting to nutrient scarceness, and persisting within or escaping from these cells. The adaptation to the nutritional environment within the phagosome of macrophages needs rapid transcriptional responses. Such responses are common among facultative intracellular pathogens, but need to be fine-tuned dependent on cellular localization of the pathogen, extrinsic nutrient availability, and intrinsic nutrient requirements. In **manuscript I**, these adaptation mechanisms were summarized and discussed, comparing *Candida* species with bacterial and other fungal pathogens. Fungal pathogens often show common responses leading to repression of energy-consuming processes and activation of alternative carbon- and nitrogen assimilation pathways, whereas pathogenic bacteria rely on species-specific responses dependent on intrinsic nutritional requirements and their intracellular localization.

The ability of pathogenic *Candida* species to acquire and metabolize macro- and micronutrients is essential for survival in the hostile phagosomal environment [251, 253-255, 258, 314]. In general, *Candida* species have a remarkable metabolic flexibility that allows them to switch between metabolization of different nutrients, depending on their availability in different host niches [319]. However, this metabolic flexibility mainly accounts for macronutrients. The requirement of essential micronutrients such as vitamins or trace metals, that are often co-factors of important metabolic enzymes, cannot be bypassed. The strong impact of the essential vitamin biotin (vitamin H) on survival inside macrophages and virulence of *C. glabrata* and *C. albicans* was demonstrated in **manuscript II**. Furthermore, the importance of copper and redox homeostasis for *C. parapsilosis* during contact with macrophages and predatory amoebae was stressed in **manuscript IV**. To extend the genetic toolbox for research on *C. glabrata* and *C. parapsilosis*, to get further insights into gene functions and to identify new virulence genes as well as targets of antifungal substances, RNA-interference for *C. glabrata* (**manuscript III**), and gene complementation strategies for *C. glabrata* (**manuscript V**) and *C. parapsilosis* (**manuscript IV**) were developed.

### 4.1 Establishment of new genetic manipulation tools to study biology and virulence of *C. glabrata* and *C. parapsilosis*

Gene deletion is a broadly employed and long used approach to study the function of potential virulence-associated genes in the major *Candida* species *C. albicans* [99]. However, due to the increasing prevalence of other *Candida* spp., the understanding of pathogenicity mechanisms of these NAC species like *C. glabrata* or *C. parapsilosis* has recently come into focus.

The approaches used so far for the creation of deletion mutants in these two NAC species resemble the strategies used in *C. albicans*, relying on selective markers like *NAT1*, *HIS3* or *URA3* [347, 348]. To describe molecular mechanisms of pathogenesis and gene functions, the molecular Koch's postulates [108] should be fulfilled, which comprise the reintroduction of the deleted gene to regain wild type phenotypes and thus exclude pleiotropic effects associated with the gene deletion process. In *C. albicans*, genomic integration is a commonly used tool for reintroducing a certain gene into a knock-out strain. However, in *C. glabrata* and *C. parapsilosis* this approaches are less commonly used. We established a genomic reintegration strategy in *C. glabrata* that can be used to complement deletion mutants with their original gene, either expressed by the native or any conditional promotor (**manuscript V**). In addition, this strategy can be used to reintroduce modified versions of a gene, to investigate not only the gene function itself, but also specific nucleotide exchanges (respectively amino acid exchanges in the corresponding protein) and changes in gene expression pattern. Moreover, the new complementation strategy was applied for labeling of *C. glabrata* with two well-known fluorophores  $\gamma$ EGFP and mCherry as well as the antigen ovalbumin (**manuscript V, Figure 2**). Fluorescent markers can be useful to tag different mutant strains and perform fluorescence-based experiments and intraspecies or interspecies competition assays, a strategy broadly used for *C. albicans* [349, 350]. By using additional selection markers, like *HIS3*, *LEU2* or *HygB* [351], our new protocol could also be extended to generate double fluorescently labeled strains for monitoring protein-protein interactions *in vivo*.

The newly developed *C. glabrata* complementation strategy relies on integration into the *TRP1* locus, a gene coding for an enzyme involved in the tryptophan biosynthesis [352]. Complementation with *TRP1* in a non-native locus could raises the problem of inefficient transcription and growth defects in tryptophan-poor niches. This possibility was excluded by choosing the native gene locus of the selection marker (**manuscript V**). In addition, deletion of *TRP1* had no influence on the systemic *C. glabrata* infection [68] and this locus was shown to be suitable for a sufficiently high expression level of other genes (**manuscript V**). Nevertheless, a minor risk remains that a certain gene in

the *TRP1* locus is transcribed differently due to the local chromatin structure. Alternatively, gene complementation may be also done in neutral loci, like *NEUT5L* in *C. albicans* [353]. The *NEUT5L* was also suitable to generate complemented strains in *C. parapsilosis* (**manuscript IV** and [354]). Such a neutral locus has also been used in *C. glabrata* on chromosome F [276].

The creation of gene deletions can fail in case of essential genes. Studying such genes is of high importance as these might encode virulence factors and/or potential targets for novel antifungals [103, 355]. For that reason alternative techniques are required, which use knock-down approaches such as targeted transcriptional repression (or induction) of tetracycline promotor-regulated genes (GRACE; gene replacement and conditional expression) or RNA-mediated downregulation [103]. Both methods are also suitable to perform large-scale identification of essential and virulence-associated genes [103] and (**manuscript III**). The established RNA interference (RNAi) strategy for *C. glabrata* has the advantage that no external substances like tetracyclin have to be added to achieve transcriptional gene repression. As members of the *Saccharomyces* complex, including *C. glabrata*, do not possess the mechanism of RNA-based gene silencing, Dicer (*DCR1*) and Argonaute (*AGO1*) were heterologously expressed in *C. glabrata*. In contrast, some pathogenic *Candida* species including *C. albicans* intrinsically possess the RNAi pathway [356]. A disadvantage (or desired advantage in the case of essential genes) of the RNAi technology in the investigation of gene function is that complete gene repression is often not possible and compensation of translation efficiency could overlay differences in transcription [357]. Certainly, the quantitative downregulation efficiency could be affected by the type of RNAi (**manuscript III, Figure 1**) or by using either antisense or hairpin constructs. Thus, different strategies may have to be compared for each gene.

Together, the techniques established in this work add important new genetic tools to investigate the function of novel genes and their role in pathobiology of the second and third-to-fourth most prevalent *Candida* species *C. glabrata* and *C. parapsilosis*.

#### **4.2 Metal and redox homeostasis are essential for intraphagosomal survival**

Besides macronutrients, micronutrients like trace metals and vitamins are essential in fine-tuning and maintaining metabolic fluxes – as cofactors of important metabolic enzymes. Concerning the acquisition of trace metals, one important group of micronutrients, two sides of a coin have to be considered. When low amounts of essential trace metals are present, microbes need high-affinity transport systems for the uptake of these metals from the environment. On the other hand, high metal

## Discussion

---

concentrations are toxic mainly due to the Fenton reaction and ROS production [358]. Metal intoxication by zinc and copper is also one mechanism used by phagocytic cells to kill ingested microbes [233, 359]. It has already been demonstrated that not only the uptake of metals, but also the homeostasis, either the acquisition or detoxification, of trace metals, and their complex regulatory processes, are indispensable for bacterial and fungal pathogens [270, 360].

In **manuscript IV**, it was demonstrated that predation by fungivorous amoebae increases the expression of genes necessary to cope with high copper concentrations in *C. parapsilosis*. The deletion of the copper exporter Crp1, involved in fungal copper resistance, made phagocytosed *C. parapsilosis* cells more susceptible to the antimicrobial activity of predatory amoebae and, to a lower extent, of macrophages (**manuscript IV, Figure 8**). This indicated that *C. parapsilosis* is exposed to copper poisoning in amoebae, whereas the phenotype in macrophages is more ambiguous. In fact, the stable expression of *CpCRP1* within macrophages, compared to the increased expression of the copper transporter *CpCTR1* may indicate that *C. parapsilosis* is rather exposed to copper limitation in macrophages (**manuscript IV, Figure 4**). This reveals differences in the two different phagocyte infection models used in that study. Further survival assays with a *CpCTR1* deletion mutant may address the question of copper restriction or intoxication by amoebae or macrophages.

Copper poisoning in macrophages has been described for other fungal species. In *C. albicans*, *CaSur7* mediates high copper resistance and promotes intraphagosomal growth *in vitro* [236, 237], indicating toxic copper concentrations during *C. albicans*' intraphagosomal stay. Further studies focused on *C. albicans* or *A. fumigatus* infections showed that copper poisoning plays a role during systemic infections [361, 362].

While the pathogen can directly react towards an antimicrobial response, the immune system can also modulate this response. Cytokines like IFN- $\gamma$  can not only influence the macrophage activation status [363] but also the content and pH of the phagosome [137], and even the degree of copper restriction and possibly also intoxication [364]. The copper transporter gene *HcCTR3*, for example, is necessary for replication of *H. capsulatum* in IFN- $\gamma$ -activated but not non-activated macrophages [364]. Recently, similar results were observed for *C. glabrata*, as *CgCTR2* is needed for survival in IFN- $\gamma$  stimulated macrophages [365]. These data open up the interesting perspective that the phagosome content is a consequence of macrophage stimulation. The modulation of macrophage polarization by fungal pathogens [198, 366] may thus be a strategy of these pathogens to alter intraphagosomal nutrition and the toxicity status in favor of the fungus. Alternatively, fungal pathogens may actively modulate the phagosome content,

similar to many bacterial intracellular pathogens, which create a distinct and degradation-permissive pathogen-containing vacuole [367].

Phagocytes can bombard microbes with high phagosomal metal concentrations, but also ROS are produced in high amounts [368]. Therefore, successful intracellular pathogens require efficient oxidative stress detoxification mechanisms [369]. Peroxiredoxins (Prxs) are thiol-specific antioxidant proteins [370]. Deletion of *PRX1*, encoding a Prx, caused attenuated survival of *C. parapsilosis* in amoebae and macrophages (**manuscript IV, Figure 8**), and the increased expression of a homologous gene in *C. albicans* during confrontation with macrophages [175] suggests a similar response pattern. However, the impact on the highly conserved *PRX1* gene in *C. albicans* and *C. glabrata* macrophage interaction remains to be elucidated.

### 4.3 Fungal factors involved in biotin homeostasis

The intrinsic biotin auxotrophy of *Candida* species has long been known [310, 311], but recent studies highlighted infection-relevant roles of biotin by showing that *C. albicans* requires biotin in parenteral nutrition solutions or filament-inducing media to promote proliferation [337, 371, 372].

#### 4.3.1 Biotin uptake and biosynthesis

The necessity of biotin for growth of *C. albicans* and *C. glabrata* was confirmed, and the biotin transporter *VHT1* and the regulator of biotin-metabolic genes *VHR1* were identified as important players of biotin acquisition (**manuscript II**). This acquisition system likely extends to other medically relevant *Candida* species (*C. tropicalis*, *C. parapsilosis*, *C. auris* and *C. dubliniensis*) as these species contain orthologs of *VHR1* and *VHT1* (**Table 3**). A difference between *Candida* species is the presence or absence of the genes *BIO2-5*, which enable the partial synthesis of biotin from precursors (**manuscript II, Figure S1; Figure 3**; [317]). To date, it is unknown whether and how the presence of *BIO2-5* impacts on *C. albicans* colonization or virulence. The partial biosynthetic pathway does not largely affect pathogenicity of *Candida* species, as *C. glabrata* and *C. parapsilosis* (which both lack *BIO2-5*) are still the second and third frequent *Candida* species isolated from patients, while infections with *C. tropicalis* (possessing *BIO2-5*) are less frequent [64]. Also, a loss of *BIO2-5* was dispensable for *C. albicans*' survival and proliferation within macrophages (**manuscript II, Figure S4**). While most *S. cerevisiae* strains contain parts of the biotin biosynthesis cluster (*BIO2-5* genes), prototrophic *S. cerevisiae* strains exist, which additionally possess the genes *BIO1* and *BIO6* and are fully able to synthesize biotin [318]. It is tempting to speculate that there are also clinical *Candida* isolates that are capable of biotin synthesis.

## Discussion

---

The existence of the incomplete biotin biosynthesis gene cluster (*BIO2-5*) may be a benefit for *C. albicans* or *C. tropicalis* during commensalism on mucosal surfaces, promoting acquisition of biotin precursors from microbes living in close proximity. Also 20% of biotin-auxotrophic bacteria of the human microbiome possess similar incomplete biotin biosynthetic gene clusters [373], indicating that this phenomenon is also found in other kingdoms. As mammalian hosts are biotin auxotroph [335] other microbes are likely the only potential source of such precursors for *Candida* species in the host. Conceivably, the *BIO2-5* cluster could also benefit the competition of *Candida* species with other microbes, which have completely lost the ability to synthesize biotin, like bacteria of the Actinobacteria and Firmicutes phylum or other *Candida* species [374]. Ohsugi *et al.* described that members of the Enterobacteriaceae excrete biotin and biotin precursors, which further stresses a role of biotin and biotin intermediates in cross-feeding within microbial communities [373, 375].

To date, the influence of biotin or biotin precursor acquisition on *C. albicans* colonization of the gut, the main reservoir of *C. albicans* [50, 51] has not been elucidated. While many studies about *C. albicans* gut colonization are published, most of these studies used antibiotic-treated mice to accomplish stable gut colonization with *C. albicans* [376]. This could be problematic to interpret the impact of biotin on colonization in a healthy situation as the intact microbiota is essential to producing B-vitamins, especially biotin or biotin precursors, for the host and very likely for *Candida* [374]. Probably, the stable gut colonization with *C. albicans* in antibiotic-treated mice may be depending on biotin of the daily diet. The amount of biotin in the gastrointestinal tract, exemplary documented for chicken in the cecal content, is in the range of nanograms [377], while amounts of its precursors are not investigated. Of note, *Candida* species require only 0.2-2 ng biotin per mL for robust growth *in vitro* (**manuscript II, Figure S3**), suggesting enough biotin for *Candida* cells in the gastrointestinal tract containing a functional microbiota. Moreover, dietary fluctuation, the mode of nutrition (dietary source) and the microbiota composition of the large intestine (bacterial source) potentially impair the biotin content [378].

*CgVHT1* (CAGL0K04609g) and *CaVHT1* (CR\_03270W) were identified as the main factors responsible for biotin uptake in *C. glabrata* and *C. albicans* (**manuscript II, Figure 3**). Both genes show high similarity to the *S. cerevisiae* high affinity biotin transporter gene *VHT1* [379], coding for Vht1, which functions as a biotin-proton symporter with twelve putative transmembrane helices [379]. According to *in silico* analyses, Vht1 in *C. albicans* belongs to the anion: cation symporter (ACS) family as part of the major facilitator superfamily (MFS) [380]. BLASTp analyses revealed that

orthologs of *VHT1* were also found in other *Candida* spp., *Aspergillus* spp. and other fungal species suggesting that biotin uptake is facilitated in a similar way in distantly related fungi [381]. Even mammals use a similar transport system consisting of a sodium-driven symporter (SMVT) or proton-driven symporter (MCT1) with twelve membrane-spanning domains [336]. In contrast, bacteria use an ATP-mediated transport system BioY [336], and some species additionally employ a secondary transporter, YigM [336].

Although our data strongly indicate that Vht1 is the main biotin transporter in *C. glabrata* and *C. albicans*, growth of *vht1*Δ mutants was still possible in presence of high external biotin. This may be due to passive diffusion of highly concentrated biotin into the cells. However, it cannot be excluded that a low affinity biotin transporter or other transporters of the MFS family, which are structurally similar to Vht1, contribute to biotin import [380]. Besides, *C. glabrata* and *C. albicans* genomes contain other genes with sequence similarities to *ScVHT1* (**manuscript II, Figure 2**). These genes did not show any biotin- or *VHR1*-dependent transcriptional regulation, but could still mediate low affinity biotin uptake (**manuscript II, Figure S2**). Creating additional, possibly conditional, knock-outs in a *vht1*Δ mutant background strain might help to understand how this mutant can acquire biotin when present in high amounts.

*C. albicans* and *C. glabrata* can use biotinylated proteins and biocytin as biotin source dependent on *VHT1* (**Figure 7**). Consequently, these *Candida* species must possess a biotin salvage pathway that releases biotin from proteins or amino acids [382]. It remains to be elucidated which protease is required for the cleavage of biotinylated proteins and where this process takes place. Interestingly, the abundance of the GPI-anchored protease Mkc7 is increased in *S. cerevisiae* upon biotin limitation [383]. The involvement of this protease in the usage of biotinylated proteins could be further tested, as orthologous genes are also present in *C. albicans* (*CaSAP99*) and *C. glabrata* (*CgYPS2*). It is also conceivable to assume that small biotinylated peptides, which are released by extracellular fungal proteases like yapsins [72] or Saps [44], are transported into fungal cells, followed by further intracellular processing. Independent on where biotinylated proteins are processed, a result will be the release of biocytin (biotinyl-L-lysine). In mammalian cells, a hydrolytic enzyme, called biotinidase [335], can hydrolyze biotin from biocytin to make this freely available, e.g. for later coupling to other acceptor proteins, or for transfer of biotin to histones [384]. The eukaryotic biotinidase belongs to the nitrilase superfamily, with an amidase activity on non-peptide bonds [384, 385]. Whether *Candida* species or related yeasts possess a biotinidase gene is unknown, but the ability to use biocytin and biotinylated proteins suggests the presence of such enzymatic activity.

### 4.3.2 Regulation of biotin uptake and biosynthesis

The transcriptional regulation of biotin-related genes by Vhr1 revealed species-specific differences (**manuscript II, Figure 4**). *C. glabrata* showed a Vhr1-dependent transcriptional activation of *CgVHT1*, similar to *S. cerevisiae* [386]. In contrast, CaVhr1 activated the expression of the incomplete biosynthetic pathway (*CaBIO3-5*), but not *CaVHT1*. The impact of ScVhr1 on *BIO* gene expression is described in baker's yeast [386, 387]. In line with this, the deletion of *CaVHR1* led to impaired growth with the biotin precursors KAPA and DTB (**Figure 8D**). This Vhr1-mediated activation of partial biotin biosynthesis could become important for acquisition of bacteria-produced biotin precursors (see above) during colonization of *C. albicans* of the mammalian gastrointestinal tract, where *CaVHR1* was shown to be upregulated [388]. BLASTp analyses of the Vhr1 protein sequence exhibited that this putative transcription factor was exclusively found in members of the order Saccharomycetales ([381]; unpublished own observations), which have an enriched repertoire of genes associated with transcription compared to other phyla [389]. This indicates that Saccharomycetales may use a different regulation mechanism probably due to the biotin auxotrophy, which is not present in other environmental fungi.

The *CaVHR1*-independent transcriptional activation *CaVHT1* (**manuscript II, Figure 4**) and the delayed *CgVHR1*-independent upregulation of *CgVHT1* (**Figure 4C**) upon biotin limitation suggested the presence of other, yet unknown, *VHT1* regulators in both species. This was underlined by transcriptional analyses of *CgVHT1* in response to nutrient availability and growth phase (**manuscript II, Figure 3**).

The genome of *S. cerevisiae* possesses a *VHR1* paralog, *VHR2*, which is present in the genome of *C. glabrata*, but not *C. albicans*. Both genes encode factors which share similarities in their DNA-binding motif and are predicted to be involved in amino acid metabolism [321]. Vhr2 was not involved in the transcriptional control of *CgVHT1* and *CgBPL1* (**Figure 4**). However, *CgVHR2* was, similar to *CgVHR1*, necessary for survival after phagocytosis by macrophages. It might be possible that a Vhr1-Vhr2 core response improves fungal survival within macrophages. Future transcriptional profiling of *vhr1Δ* and *vhr2Δ* mutants may verify how and which genes are regulated by both or only one factor. Using a *vhr1Δvhr2Δ* deletion strain may improve the interpretation of transcriptional profiles and survival experiments.

The chromatin-remodeling protein *SNF2* or the iron regulators *AFT1/2* modulate the expression of *VHT1* in baker's yeast [390, 391]. Orthologs of *SNF2* or *AFT1/2* are therefore candidates for additional regulators in *C. glabrata* or *C. albicans*. In *S. cerevisiae*, *VHT1* and most *BIO* genes showed Gcn4-dependent induction in response to amino acid limitation [392]. DNA-binding motifs of Vhr1 and Gcn4 binding

are similar. BLAST analyses exhibited potential binding sites for both regulators in the promoter region of *CgVHT1* (done in this study, not shown). In addition to that, the expression of *CgVHT1* was not upregulated in biotin-poor medium with amino acids as a sole carbon- and nitrogen source - conditions at which Gcn4 is degraded [393]. Together, these data suggest that Gcn4 may be an additional regulator of *CgVHT1*. Therefore, it was intended to delete *CgGCN4* in order to analyze the effect on *CgVHT1* expression. Unfortunately, this approach failed several times, possibly due to essential gene functions of *CgGCN4*.

In order to identify more regulators involved in the response to biotin limitation, screening of transcription factor knock-out libraries in *C. glabrata* [347] and *C. albicans* [245] for failed *VHT1* induction upon biotin limitation could be realized in future.

#### 4.3.3 Influence of biotin and *VHR1* on cellular processes

*C. glabrata* and *C. albicans* are able to grow with amino acids despite biotin limitation, while growth in media with glucose and ammonium was not possible without biotin. Interestingly, deletion of *CgVHR1* showed a growth defect in biotin-limited media with amino acids, which did not occur when only biotin limitation or only amino acids as sole carbon- and nitrogen-source were present. These data may indicate a putative function of *CgVHR1* in amino acid usage, while biotin is limited, suggesting Vhr1 as regulating screw between macronutrient availability and biotin acquisition. Data from *S. cerevisiae* suggest that, Vhr1 might indeed regulate Gcn4-related processes like the utilization of amino acids as sole carbon- and nitrogen source [321].

This and a previous study found that biotin promotes filamentous growth of *C. albicans* ([337]; **manuscript II, Figure 1**). This effect is more pronounced when amino acids are the sole carbon- and nitrogen source (**Figure 8B**). Our data suggest that this is due to an enhanced alkalinization and ammonia release in presence of biotin – a process that promotes hypha formation [283]. This process seems to depend on *CaVHR1*, since mutants lacking *CaVHR1* showed less ammonia release and alkalinization (**Figure 8C, 9A,C**), which may be due to a disturbed usage of amino acids, similar to effects seen when *CgVHR1* was deleted. Future studies with amino acids drop out media or transcriptional profiling would be helpful to get insights, which amino acid pathway is affected.

The availability of biotin increases the nutritional flexibility for *C. albicans* and *C. glabrata*, as biotin-dependent enzymes like pyruvate carboxylase (Pyc), acetyl-CoA carboxylase (Acc) and urea amidolyase (Dur1,2) can promote gluconeogenesis, fatty acid synthesis and metabolism of urea. On the other hand, the present work shows that biotin limitation makes the cell more dependent on the presence of certain

## Discussion

---

metabolites that overcome the missing function of biotin-dependent enzymes. The deficiency in acetyl-CoA carboxylase or pyruvate carboxylase activities under biotin deprivation may be bypassed by feeding with the fatty acids or aspartate, respectively [394, 395]. In line with this, casamino acids (mixture of all amino acids except tryptophan; see also above) and aspartate bypassed the need for biotin in *C. glabrata* and *C. albicans* (**manuscript II, Figure S1C, S3B,G**). These data suggest that biotin-auxotrophic *C. albicans* and *C. glabrata* can grow albeit solely in certain biotin-poor niches containing amino acids.

The focus of this thesis was the elucidation of biotin uptake by pathogenic *Candida* species. Further studies may investigate which function of biotin within the fungal cell is essential to withstand macrophage killing and initiate proliferation. An important player may be the biotin-protein ligase 1 (Bpl1), coupling biotin to biotin-dependent enzymes. This factor is essential in *S. cerevisiae* [395] and shows Vhr1- and biotin-dependent regulation in *C. glabrata* and *C. albicans* (**manuscript II, Figure 4**). A conditional knock-down, probably by the established RNAi in *C. glabrata*, could be used to investigate its role during interaction with macrophages. The last parts of the biotin cycle in the cell are biotinylated enzymes as mentioned above. Protein biotinylation in *C. glabrata* and *C. albicans* decreased upon biotin limitation, but less in the pyruvate carboxylase, confirming the importance of pyruvate carboxylation for the cell (**Figure 5B**).

Besides the role of biotin in carboxylase reactions, recent studies found that non-carboxylase proteins and histones are targets of biotinylation. This posttranslational modification was already observed in *C. albicans* [396] and studies in mammalian cells revealed the impact of biotinylated histones in cell proliferation, gene silencing and cellular response to DNA damage [397]. The impact of biotinylated non-carboxylase proteins and histones on fungal biology and virulence needs to be determined. Likely the biotinylation of histones could be detrimental after engulfment by phagocytes.

### 4.4 Biotin homeostasis in fungal virulence

The shift from commensalism to pathogenicity requires the adaptation to new host environments with altering nutrient compositions [319, 398]. The necessity of biotin differs quite a lot for different pathogens; many pathogenic bacteria possess the advantageous ability to synthesize this vitamin *de novo*, being independent of the external supply during infection [293, 299, 399], whereas *Candida* species have to struggle for sufficient biotin uptake to grow properly. Phagocytic cells use direct (active sequestration of nutrients) or indirect (no influx of nutrients) nutrient limitation mechanisms to starve ingested microbes and potentially kill them [400]. Hence,

enduring nutrient limitations within phagocytic cells is essential for pathogenic microbes to survive and proliferate. At the beginning of this thesis it was unknown, whether biotin limitation is one stressor *C. albicans* and *C. glabrata* encounter within the phagosome or other host niches.

#### 4.4.1 Fungal biotin homeostasis is required for adaptation to macrophages

The two unlike *Candida* species, *C. albicans* and *C. glabrata*, evolved different strategies to evade immune cell-mediated killing [401]. *C. albicans* favors an aggressive route by rapidly forming hyphae, inducing an inflammatory response and escape, while *C. glabrata* keeps the inflammatory response low, replicates as yeast and persists inside macrophages for days [178]. However, the phagocytosis of *C. albicans* and *C. glabrata* yeast cells induces a similar initial transcriptional response, enabling fungal survival and proliferation within the harmful phagosome [72, 175]. This indicates that both species have similar metabolic adaptation strategies.

While biotin limitation prior to infection reduced survival and proliferation of *C. glabrata* and *C. albicans* wild type cells in macrophages (**manuscript II, Figure 5**), external biotin levels during the interaction had no impact on the interaction of the two *Candida* species with macrophages or the secretion of pro-inflammatory cytokines by these immune cells (**Figure 9**). This indicates that external biotin levels had no detectable or visible impact on macrophage activities in the experimental setting used. This is in contrast to other immune cells which showed an altered pro-inflammatory response depending on biotin availability [340-342].

While *VHT1* was necessary for biotin-dependent growth *in vitro* and proliferation within macrophages, *Vhr1*, as transcriptional regulator of biotin-related genes, was essential for survival and the initial proliferation of both *Candida* species (**manuscript II**). The importance of *VHR1* for the interaction with macrophages is supported by the strong upregulation of this gene upon phagocytosis (**manuscript II, Figure 5G-H**). When the intracellular biotin pool of *C. albicans* and *C. glabrata* was lowered by cultivation in biotin-free medium prior to infection, the intracellular survival of wild type cells and *VHR1* deletion mutant cells was similar (**manuscript II, Figure S5**). This implies that *Vhr1* functions for survival are only important when the fungus has access to a sufficiently high internal biotin pool. Possibly, *Vhr1* functions in the reorganization of stored biotin. Alternatively, potential *Vhr1*-dependent amino acid-related processes may affect initial survival and proliferation (**manuscript II, Figure S3B; Figure 8A,C**; see above 4.3.3). The upregulation of amino acid permease genes upon phagocytosis

## Discussion

---

implies that amino acids are indeed available to internalized *Candida* cells [72, 175] and the impact of efficient amino acid metabolism on survival and proliferation of described for *C. albicans* has been extensively studied [253, 256, 285]. Nevertheless, the reduced survival and initially delayed proliferation of *VHR1* deletion mutant cells in *C. albicans* did not cause a reduced cytolysis or cytokine response (**manuscript II, Figure 6F and data not shown**). This could be due to the delayed transcriptional regulation of Vhr1 targets by other factors (see *CgVHT1* expression) or compensation by other factors. To get further insights into the potential targets of Vhr1, comparative transcriptional profiling during growth with amino acids as sole carbon- and nitrogen sources and during phagocytosis could be performed in future.

One critical question for all studies on facultative intracellular pathogens is related to the access of nutrients after phagocytosis: Which nutrients are available within the phagosome, and which of these are used by the pathogen? Inherent or acquired auxotrophies in pathogens might be a useful tool to define metabolite availabilities in different host niches [263], and to study how pathogens acquire and exploit essential micronutrients during infection. This has been described nicely for *Pseudomonas aeruginosa* [402]. Previous work with biotin-auxotrophic *M. tuberculosis* and *F. tularensis* mutants [403-406], and this thesis suggest that the intracellular compartment of those pathogens is biotin-depleted. This was mainly concluded from the transcriptional increase in biotin-related genes in both *Candida* species upon phagocytosis, which is underlined by previous large-scale transcriptional profiling of *C. albicans* (e.g. upregulation of *BIO2*, *VHR1*, *BIO5*, and *BPL1*) [175] and *C. glabrata* (e.g. upregulation of *BPL1* and *VHT1*) [72]. Taken together, a rich biotin storage and a functional biotin acquisition pathway (Vhr1-Vht1) increased fungal fitness inside macrophages (**manuscript II, Figure 5-6**), suggesting that a functional biotin homeostasis is even more beneficial for the fungus within a biotin-depleted phagosome. Similarly, other vitamins may be limited in the phagosome. The fungus *H. capsulatum*, for example, needs riboflavin biosynthesis for proliferation within macrophages and virulence *in vivo* [305]. All in all, the depletion of essential vitamins can be assumed as new form of nutritional immunity [265]. It is so far unknown, however, whether this process is active or passive.

As discussed above, the scarcity of biotin in host niches like the phagosome may be bypassed by amino acids (**manuscript II, Figure S3; Figure 8**). In addition, proliferation of *C. albicans* (as hypha) and *C. glabrata* (as yeast) followed by bursting of, possibly, first the phagosomal and second the cytosolic membrane could allow fungal access to host-derived biotin or other alternative biotin sources (biotinylated proteins or biocytin), which can be used in a Vht1-dependent manner (**manuscript II,**

**Figure S1; Figure 7).** Such host-derived biotin sources may explain why a *CaVHR1* deletion mutant had initial survival and proliferation defects, but caused wild type-like-like late macrophage damage, while a *CaVHT1* deletion mutant was attenuated in both, proliferation and host cell damage. To further elucidate whether *Candida* can indeed use host-derived biotin sources during infection, feeding macrophages with radiolabeled biotin could be performed. This method is commonly used for other nutrient sources like amino acids (stable isotope labeling with amino acids; SILAC [407]). In case *Candida* cells can use host-derived biotin, radiolabeled biotin should appear inside of *Candida* cells.

Besides the effects of *Vht1* on fungal proliferation and macrophage damage, the *C. albicans*-induced inflammatory response was also diminished. The inflammasome, an important inflammatory pathway, lead to secretion by IL-1 $\beta$  secretion [408] and is activated by *C. albicans* and not by *C. glabrata* [345]. Early secretion of IL-1 $\beta$  by macrophages was highly attenuated after challenge with a biotin-starved *Cavht1 $\Delta/\Delta$*  mutant (**Figure 11A**). Of note, this phenomenon was only observed in biotin-free infection medium, whereas the presence of 2 mg/L biotin during infection, which is sufficient to support growth of this mutant in culture medium (**manuscript II, Figure 3**), led to wild type-like IL-1 $\beta$  release (**Figure 11A**). Similarly, the biotin-starved *Cavht1 $\Delta/\Delta$*  mutant caused reduced macrophage damage and release of pro-inflammatory cytokines at later time points (**Figure 11B-F**). This indicates that *CaVHT1*-dependent proliferation within macrophages is essential for the early and late inflammatory response, linked to macrophage lysis. The activation of the inflammasome in macrophages finally leads to a programmed cell death, caused by pyroptosis [408], which increases fungal survival [409]. Thus, the reduced survival of the biotin-starved *Cavht1 $\Delta/\Delta$*  mutant (**manuscript II, Figure S5B**) may be linked to reduced inflammasome activation (**Figure 11A**). Either the pre-feeding or the presence of high amounts biotin during infection can increase survival and inflammasome activation (**manuscript II, Figure 6C; Figure 11A**). Probably biotin can be taken up with one yeast cell during phagocytosis and promoting intraphagosomal growth of the *Cavht1 $\Delta/\Delta$*  mutant and progressive cytolysis. A large scale screening of macrophage inflammasome activation upon challenge with different *C. albicans* strains suggests that *CaVHT1* is involved inflammasome activation by *C. albicans* [409]. Several studies showed that *C. albicans* filamentation and cell wall remodeling activated the inflammasome in macrophages [345, 410, 411], which, both, might be lacking in the biotin-starved *Cavht1 $\Delta/\Delta$*  mutant. The lack of filamentation of the *Cavht1 $\Delta/\Delta$*  mutant in biotin-limited environments supports this view and may explain the attenuated induction of IL-1 $\beta$  caused by this mutant.

### 4.4.2 VHT1-mediated biotin acquisition promotes fungal fitness in the murine host and virulence

*C. glabrata* and *C. albicans* are able to disseminate to almost all organs during systemic infection but cause different infection outcomes in commonly used mouse models. *C. albicans* induces a fast and progressive immune reaction and mice die from dysregulated inflammatory response, immunopathology and sepsis [412]. In contrast, *C. glabrata* persists over weeks in various mouse tissues [68, 413-415], induces only a transient pro-inflammatory cytokine response within colonized host tissues and causes a minor influx of immune cells [66, 68, 413, 415, 416].

In stark contrast to these differences *in vivo*, *C. albicans*, like *C. glabrata*, requires an external biotin supply for robust growth facilitated by the putative high affinity biotin transporter Vht1 (**manuscript II**). The attenuated virulence of a *C. albicans vht1Δ/Δ* mutant during systemic challenge therefore strongly suggests that biotin acquisition is necessary for *C. albicans* virulence. Importantly, the reduced burdens in *C. glabrata vht1Δ* mutant-infected brains and *C. albicans vht1Δ/Δ* mutant-infected kidneys and brains implied a biotin-dependent proliferation in those organs (**manuscript II, Figure 7**). Importantly, kidney and temporarily the brain are target organs in which *C. albicans* filaments, but not in liver and spleen [66, 143, 147, 417-420]. The morphological plasticity of *C. albicans* is necessary for virulence and mutants that cannot change between yeast and hyphal morphology are often attenuated [33]. As known from the *in vitro* and macrophage studies, *VHT1* deletion leads to a reduction in hyphal growth when biotin is limiting (**manuscript II, Figure 3, 6**). The lack of hyphae, thus, may be one reason for reduced virulence of the *Cavht1Δ/Δ* mutant. Histological analyses would be required to elucidate the fungal morphology of the *Cavht1Δ/Δ* mutant in these organs. Moreover, previous observations showed also that *C. glabrata* is able to temporarily proliferate in the brain (**manuscript II, Figure 7**; [66, 68, 421]), the organ with a *VHT1*-dependent colonization effect.

The bioavailability and the accessibility of biotin during infection of mouse organs with *C. albicans* and *C. glabrata* remain unclear. However, several studies showed that the blood is richest in biotin, followed by the liver and kidney tissues, and lowest biotin amounts are found in brain and spleen (**Table 4**).

Another explanation for the reduced cfus of a *VHT1* deletion mutant in the brain may, however, also be a differential organ tropism of this mutant. So far, the exact location of brain-colonizing *C. glabrata* and how it crosses the blood brain barrier (BBB) is unknown. *C. albicans* and *Cryptococcus neoformans* are able to cross the BBB *in vivo* and *in vitro* [422-424]. *C. glabrata* may use pathways for BBB passage similar to those

described for *Cr. neoformans* - transcytosis across endothelial cells [425], or paracellular passage [423, 426]. Alternatively, the use of migrating macrophages as “Trojan horse” has been reported for *Cr. neoformans* [427]. Interestingly, fungal inositol transporters are required for the transmigration of *Cr. neoformans* across the BBB, suggesting alterations of the fungal metabolism during passages [428]. However, in contrast to biotin (**Table 4**), inositol is highly abundant in brain tissue [429, 430], which could be an attractant for disseminating cryptococcal cells. To distinguish between Vht1-dependent organ trafficking and subsequent proliferation, quantification of initial brain and kidney colonization by the *vht1Δ* mutants at early section time points (6 and 12 h) may be necessary. Sensing the vitamin status in certain niches may influence not only organ tropism but also virulence traits, as e.g. nicotinic acid can modulate adhesion of *C. glabrata* [309], differentiation of *Legionella pneumophila* [431], and virulence gene expression in *Bordetella pertussis* [432]. It would be highly interesting to elucidate whether biotin availability can directly modulate the expression of virulence-associated genes. In the case of *C. albicans* it seems clear that the presence of biotin promotes filamentation in *C. albicans*, an important virulence trait and associated with the expression of several further virulence factors [32].

**Table 4: Documented amounts of biotin in various host tissues.**

organ	host	Concentration	reference
brain	rat	0.046 µg/g	[434]
		0.073 µg/g	[435]
blood	rat	13.34 µg/L	[434]
cerebrospinal fluid (CSF)	rabbit	1.95 µg/L	[435]
	Rat	0.44 µg/g	[434]
liver	Pig	0.51* – 0.83# µg/g	[436]
	chicken	2.02* – 5.59# µg/g	[436]
kidney	Rat	0.3 µg/g	[434]

\* biotin-depleted, # biotin-supplemented, 4.09316 nmol/g  $\pm$  1 µg/g. *Candida* species require only 0.2-2 µg/L (app. 0.0002-0.002 µg/g) biotin for robust growth *in vitro*.

The importance of biotin for *C. albicans* and *C. glabrata* shown in this thesis resembles the results of studies with the bacterial pathogens *M. tuberculosis* and *F. tularensis*, which provided evidence that biotin is required for intraphagosomal fitness and virulence [403, 404, 406]. Nevertheless, inhibition of biotin synthesis in other fungal and bacterial pathogens was not accompanied with attenuated virulence [305, 433], due to

## Discussion

---

the presence of biotin transporter genes and high plasma biotin level in mice [433]. This could also explain why the *CaVHT1* deletion mutant was not completely avirulent during systemic candidiasis, depicted by a delayed infection progression in at least some mice (**manuscript II, Figure 7B**).

It was surprising that, despite a strict requirement for high external biotin, *vht1* $\Delta$  mutants of both *Candida* species colonized liver and spleen similarly to the wild type (**manuscript II, Figure S6**). Possibly, both species have access to excessive biotin in these organs, or fungal proliferation *per se* is restricted in these tissues, making Vht1-dependent biotin acquisition dispensable. Of note, *C. albicans*' filamentation, as indicator of proliferation, is actively inhibited by specialized phagocytes in the liver [174], which likely support the growth inhibition in this organ. Histological sections from different *C. glabrata*-infected mouse organs showed accumulated yeast cells (each > 5 yeast cells) [68], which can be explained by either proliferation of few yeast cells in the tissue or by bursting of a group of initially administrated yeast cells from the blood stream into the tissue. Further approaches are required to distinguish between injected mother cells and daughter cells, and to learn about the level of organ-specific proliferation in the host. For such experiments, fluorescently labeled yeast cells, similarly to those used in **manuscript II**, or fluorometric cell cycle assays would be useful to track cell division [437, 438].

Similar to the organ cfu kinetics during persistence of *in vivo*, the viability and resulting cfu count of *C. glabrata* under nutrient-limited conditions (staying in PBS) lowered continuously. Also, a macrophage persistence model showed only weak intracellular proliferation of *C. glabrata* over the duration of one week, and a continuous decline in fungal burden due to fungal killing [Fischer *et al.*, unpublished data]. Consequently, weak or no fungal proliferation together with fungal clearance by decreased viability or host-mediated mechanisms lead to the diminished fungal burden over time. Indeed, growth is not always required in the lifestyle of pathogens. Cellular quiescence represents a strategy to slow down or arrest microbial growth favoring persistence for days or months up to years [439], leading to chronic infections [440]. Those microbial populations are better tolerated by the immune system and resist antimicrobial therapies [440], which could be a characteristic for the chronic phase of *C. glabrata* infections [68].

In conclusion, *C. glabrata* and *C. albicans*, different in their infection strategies, employ a similar biotin uptake system, which is essential for the interaction with macrophages and during systemic infections. The usage of the biotin transporter mutant allows investigating in which niches biotin may be limited and where biotin is important for

fungal proliferation. Thus, the uptake of biotin by pathogenic *Candida* species represents a metabolic adaptation strategy during infection.

#### 4.5 Outlook

It needs to be clarified whether the role of biotin on the interaction of *Candida* cells with macrophages is indeed linked to the phenotypes observed *in vivo*. During systemic infection with *C. albicans*, inflammatory monocytes and macrophages expand, especially in spleen and liver and promote fungal clearance [147]. Apart from the histological association of *C. glabrata* with and the attraction of monocytic cells *ex vivo* [68, 194], the role of monocytic cells for the dissemination and the persistence or clearance of *C. glabrata* during systemic infection is unknown. However, the importance of macrophages for protection from fungal infection seems to hold true for different pathogens besides *C. albicans*. Macrophage depletion curtailed *Blastomyces dermatitidis* infection [441], and monocytes are used as “Trojan horse” for dissemination and BBB translocation by *Cr. neoformans* [427, 442]. Macrophage depletion experiments [443] together with immunohistochemical analyses could be used to further characterize the interaction of *C. glabrata* with monocytic cells *in vivo*. Furthermore, the mechanism of brain colonization by *C. glabrata*, probably by crossing the BBB, could be further investigated using a microfluidic chip model to mimic the blood circulation, the endothelial barrier and the barrier supporting brain parenchyma, mainly astrocytes and microglial cells.

The *C. glabrata* mouse model used does not lead to killing of the host, while human patients can die from systemic *C. glabrata* infections. Consequently, we do not know whether *VHT1* and biotin acquisition are required for *C. glabrata* virulence, similar to *C. albicans*. The prevalence of *C. glabrata* infections is increased in elderly people, which is often associated with a senescent immune system and metabolic disorders [64, 65]. Therefore, a novel systemic candidiasis infection model with aged mice could be developed, which mimics more the human situation.

This thesis revealed many aspects of the biotin metabolism in two highly prevalent *Candida* species, but the exact role of the biotin biosynthesis cluster in the viability and pathogenicity or commensalism of *C. albicans* (and also *C. tropicalis*) remains unclear. The reintegrating of the biotin prototrophy in *C. albicans*, by using *BIO1* and *BIO6* from prototrophic *S. cerevisiae* strains [318], could be a useful tool to study the effect on colonization and virulence to answer another key question: whether a biotin auxotrophy is a fitness cost, which makes *Candida* cells dependent on the microbiota and the host?

## 6 Appendix

### 6.1 Additional experimental procedures

The following sections contain a more detailed description of the mutagenesis in *C. albicans* and *C. glabrata* and methods referring to the additional data.

#### 6.1.1 Additional *in silico* tools

To design primer sequences and develop cloning strategies the software CloneManager 9 was used. Chemical structures and formulas were constructed with ChemBioDraw Ultra13.0. All figures were created with Adobe Illustrator CS5.1, Microsoft PowerPoint or GraphPad 5. The expression data were analyzed with Bio-Rad CFX Manager.

#### 6.1.2 Additional strains, plasmids and oligonucleotides

Additional strains (**Table 5**), oligonucleotides (**Table 6**), and plasmids (**Table 7**) are not mentioned in **manuscript II** and **V** and referred to the additional data.

**Table 5. Strains.**

### 6.1.3 Isolation of genomic DNA

Dependent on the follow-up experiments, genomic DNA was either isolated with a quick isolation protocol for standard PCR or the lyticase protocol for high-molecular DNA preparation used for Southern blotting. For both protocols, a liquid culture of *Candida* cells was grown overnight at 30°C (*C. albicans*) or 37°C (*C. glabrata*) in YPD or SD medium. Cells were harvested by centrifugation (4,000g; 2 min, RT).

#### Quick DNA isolation

The cells were disrupted by two freeze and thaw steps (2 min at -80°C and 1 min at 95°C) in 250 µL Harju buffer (2% Triton™ X-100, 1% SDS, 100 mM NaCl, 10 mM Tris-HCl pH 8.0, 1 mM EDTA) followed by vortexing. The cell debris was precipitated by adding 250 µL chloroform and centrifugation (20,000g; 5 min, RT). Following, the hydrophilic phase was transferred into a new microcentrifuge tube containing 500 µL ice-cold 100% ethanol. The DNA was precipitated by centrifugation (20,000g; 5 min, RT), washed once with 70% ethanol and air-dried. The transparent DNA pellet was reconstituted in 100-200 µL ddH<sub>2</sub>O.

#### Isolation of high-molecular DNA

The cells were washed with 1 mL ddH<sub>2</sub>O, transferred in 2 mL screw tubes and centrifuged (20,000g; 1 min, RT). The cells were resuspended in 1 mL lysis buffer (1 M sorbitol; 100 mM sodium citrate, pH 5.8; 50 mM EDTA, pH 8.0; 0.6 mg/mL lyticase and 2.5% β-mercaptoethanol) and incubated at 37°C for 45 min. Afterwards the cells were centrifuged, resuspended in 800 µL proteinase buffer (10 mM Tris-HCl, pH 7.5; 50 mM EDTA, pH 7.5; 0.5% SDS; 1 mg/mL proteinase K) and incubated at 60°C for 30 min. The cell debris was precipitated by adding 800 µL phenol/chloroform/isoamylalcohol (25:24:1), mixed with vortex device for 4 min and centrifuged (20,000g; 5 min, RT). The hydrophilic phase was transferred into a new microcentrifuge tube containing 750 µL isopropanol. The precipitated DNA was centrifuged (20,000g; 5 min, RT), washed with 600 µL 70% ethanol and air-dried. The transparent DNA pellet was reconstituted in 200 µL ddH<sub>2</sub>O containing 10 mg/mL RNase A.

The DNA quantity was evaluated using a NanoDrop Spectrophotometer (ND-100, Peqlab). The DNA was stored at 4°C (short term) or -20°C (long term). Dilutions of DNA were made freshly.

### 6.1.4 Polymerase Chain Reaction (PCR) and gel electrophoresis

#### **Taq-PCR**

This PCR was used for all standard reactions (genotyping of mutants), which do not require proof-reading activity (**Table 8**).

## Additional experimental procedures

**Table 8: Components and conditions of Taq-PCR.**

Component	per reaction	PCR program:		
nuclease-free water	14.3 $\mu$ L	Initial denaturation	95°C	30 sec
10× ThermoPol® Puffer	2 $\mu$ L	Denaturation	95°C	30 sec
10 mM dNTPs	0.5 $\mu$ L	Annealing	xx°C <sup>1</sup>	30 sec
10 $\mu$ M forward Primer	0.5 $\mu$ L	Extension	68°C	xx sec <sup>2</sup>
10 $\mu$ M reverse Primer	0.5 $\mu$ L	Final extension	68°C	10 min
Taq DNA Polymerase	0.2 $\mu$ L	hold	4°C	$\infty$
template DNA	100 ng (1 $\mu$ L)			

} 30×

<sup>1</sup> The annealing temperature was calculated with  $T_m$  calculator v 1.12.0 from NEB.

<sup>2</sup> The extension time was dependent on fragment length; 1,000 bp = 60 sec.

### Colony PCR

The colony PCR was performed to directly check *E. coli* transformants for correct plasmid constructs. Instead of 1  $\mu$ L of DNA, a small amount of colony material was inoculated into one 20  $\mu$ L reaction. The initial denaturation step was extended to 5 min.

### High fidelity PCR

This PCR was used for the synthesis of all cloning and transformation constructs (Table 9).

**Table 9: Components and conditions of High fidelity PCR.**

Component	per reaction	PCR program:		
nuclease-free water	32.5 $\mu$ L	Initial denaturation	98°C	30 sec
5× Phusion HF	10 $\mu$ L	Denaturation	98°C	10 sec
10 mM dNTPs	1 $\mu$ L	Annealing	xx°C <sup>1</sup>	20 sec
10 $\mu$ M forward Primer	2.5 $\mu$ L	Extension	72°C	xx sec <sup>2</sup>
10 $\mu$ M reverse Primer	2.5 $\mu$ L	Final extension	72°C	10 min
Phusion® DNA Polymerase	0.5 $\mu$ L	hold	4°C	$\infty$
template DNA	100 ng (1 $\mu$ L)			

} 35×

<sup>1</sup> The annealing temperature was calculated with  $T_m$  calculator v 1.12.0 from NEB.

<sup>2</sup> The extension time was dependent on fragment length; 1,000 bp = 30 sec.

### Probe PCR

The synthesis of Southern blot probes required the incorporation of digoxigenin (DIG)-labeled dNTPs into the PCR product to detect gene-specific fragments in the Southern blot. All components are part of the PCR DIG Probe Synthesis Kit (Roche, Table 10). The high fidelity PCR program (Table 9) was used.

**Table 10: Components of the PCR synthesizing Southern blot probes.**

Component	labeling reaction	control reaction
nuclease-free water	34.25 $\mu$ L	34.25 $\mu$ L
PCR Buffer with MgCl <sub>2</sub> (3)	5 $\mu$ L	5 $\mu$ L
PCR DIG mix labeled (2)	2.5 $\mu$ L	-
PCR DIG mix unlabeled (4)	2.5 $\mu$ L	5 $\mu$ L
10 $\mu$ M forward Primer	2.5 $\mu$ L	2.5 $\mu$ L
10 $\mu$ M reverse Primer	2.5 $\mu$ L	2.5 $\mu$ L
Expand High Fidelity DNA Polymerase (1)	0.75 $\mu$ L	0.75 $\mu$ L
template DNA	100 ng (1 $\mu$ L)	100 ng (1 $\mu$ L)

The synthesized fragments were mixed with 1 $\times$  loading dye, separated by size in 1% agarose gels in 1 $\times$  TAE buffer (40 mM Tris, 20 mM acetic acid, 1 mM EDTA) for 40-60 min at 90-130 V and for size comparison 0.6  $\mu$ g GeneRuler™ 1 kb DNA Ladder, ready-to-use (Thermo Fisher) was carried along. DNA fragments were stained in an ethidium bromide bath (0.15% staining solution, Fisher BioReagents) and visualized under UV light using an INFINITY3026 Imager with a camera and InfinityCapt V14.2 software.

### 6.1.5 Transformation of *E. coli* and isolation of plasmid DNA

One aliquot (app. 50  $\mu$ L) of chemically competent *E. coli* cells (Stellar™ cells or DH5 $\alpha$ ) was thawed on ice. One hundred ng pure plasmid DNA or 5 to 10  $\mu$ L ligation mixture was added to the cells and chilled on ice for additional 15 min. The uptake of DNA was facilitated by the heat shock method (42°C, 90 sec) and incubation in ice-cold water for 1 min. To express the antibiotic resistance gene, 450  $\mu$ L LB or SOC medium was added and the cell suspension was incubated for 1 h at 37°C and 180 rpm. Different dilutions (1:10 and 1:100) were plated on LB agar (with 50  $\mu$ g/mL ampicillin; LB-Amp) and incubated over night at 37°C. Grown colonies were checked for positive constructed plasmids *via* colony-PCR, streaked on fresh LB-Amp agar and grown o/n 37°C. For plasmid isolation, positive clones were incubated in LB-Amp medium at 37°C and 180 rpm, dependent on the required amount of plasmid DNA, 5 or 25 mL cultures were used. The cultures were harvested by centrifugation, washed with water and the cell pellet was resuspended in 350  $\mu$ L P1 buffer (50 mM Tris-HCl pH 8.0, 10 mM EDTA and freshly added 100  $\mu$ g/mL RNase A). The bacterial lysis was executed by adding 350  $\mu$ L P2 buffer (200 mM NaOH, 1% SDS) and inverting the cell suspension. After 5 minutes, the lysis was neutralized by adding 350  $\mu$ L P3 buffer (3 M potassium acetate pH 5.5). The precipitated cell debris and chromosomal DNA was removed by centrifugation (20,000g; 5 min, RT). One milliliter supernatant was transferred in a new tube containing 500  $\mu$ L isopropanol and mixed by vortexing followed by centrifugation (full spin, 10 min, RT). The precipitated plasmid DNA was washed once with 500  $\mu$ L 70% ethanol, air-dried and reconstituted in 30-100  $\mu$ L ddH<sub>2</sub>O.

### 6.1.6 Southern blot

High-molecular genomic DNA was digested with the appropriate restriction enzyme for 2 h to 16 h in the thermo-cycler. The reaction buffer and time, as well as inactivation procedure were selected according to the manufacturer's recommendations. The digested DNA was separated in a 1% agarose gel for 16 h with a current potential of 27 V. For size comparison, the DNA Molecular Weight Marker III, DIG-labeled (50 pg per lane, Roche) was carried along. A small gel was loaded and stained with ethidium bromide (0.15% staining solution, Fisher BioReagents) to check for successful digestion. The DNA was pretreated in acid to ensure efficient transfer. The agarose gel was rinsed 10 min in Depurination solution (0.25 M HCl) and shortly in water. The gel was denatured two times for 15 min in Denaturing solution (0.5 M NaOH, 1.5 M NaCl) and washed briefly in water. Finally, the gel was rinsed in Neutralization buffer (1 M Tris-HCl pH 7.5; 1.5 M NaCl) two times for 15 min and equilibrated for at least 10 min in 20× SSC (3.0 M NaCl, 0.3 M Sodium Citrate, adjust pH to 7.0).

**Figure 12: Setup of vacuum blotting to transfer DNA from agarose gel to positively-charged nylon membrane.**

The nylon membrane (positively charged, Roche) was rinsed 2 min in water and 15 min in 20× SSC to activate the membrane, before the DNA was blotted 1.5 h at 50-100 mbar (**Figure 12**). In between fresh 20× SSC was added to the agarose gel preventing dehydration. Before DNA crosslinking, the membrane was rinsed 30 sec in 0.4 M NaOH, 30 sec in 0.2 M Tris-HCl pH 7.5 and dried 10-15 min on a piece of Whatman™ filter paper. The DNA was crosslinked to the membrane by UV light (120 mJ/cm<sup>2</sup>) for at least 60 sec and the membrane was rinsed with 2× SSC. The membrane was incubated for at least 45 min at 40-44°C in 20 mL pre-warmed DIG Easy Hyb™ under rotation in hybridization flasks (Biometra). The optimal hybridization temperature is dependent on GC content and length of the probe. The probe was denatured at 99°C for 5 min, cooled on ice and 5-20 μL, depending on strength of PCR product, were added to the pre-hybridization solution. The probe was hybridized overnight at 40-44°C under rotation.

The membrane was washed two times in low stringency buffer (2× SSC, 0.1% SDS) for 5 min and two times in pre-warmed high stringency buffer (0.1× SSC, 0.1% SDS, 68°C or 0.5× SSC, 0.1% SDS, 65°C) for 15 min. Afterwards, the membrane was rinsed twice with maleic acid buffer (0.1 M maleic acid, 0.15 M NaCl, pH 7.5 with 0.3% Tween®20) and once with maleic acid buffer without Tween®20 for 5 min each. Unspecific binding sites on the membrane were blocked with 1% blocking solution (Roche) in 1× maleic

acid buffer for 30 min at RT. Then, anti-Digoxigenin-AP, Fab fragments (Roche, 1:10,000 diluted) were added and incubated for 1 h at RT under rotation. Afterwards, the membrane was rinsed twice with maleic acid buffer (0.1 M maleic acid, 0.15 M NaCl, pH 7.5 with 0.3% Tween<sup>®</sup>20) and twice with maleic acid buffer without Tween<sup>®</sup>20 for 15 min each. The membrane was equilibrated for 5 min in alkaline phosphatase buffer (0.1 M Tris-HCl, 0.1 M NaCl, pH 9.5) under shaking in a plastic shell. The chemiluminescence reaction was started by adding CDP-*Star*<sup>®</sup> (Roche, 1:100 diluted in alkaline phosphatase buffer) onto the membrane in the plastic foil and incubated 5 min at RT in the dark. The membrane was shortly dried on Whatman<sup>™</sup> filter paper and the chemiluminescence was detected in the Chemoimager with an exposure time of 1 h.

### 6.1.7 Protein isolation and Western blot of biotinylated proteins

For preparation of whole protein extracts, stationary phase cells were washed three times in PBS, diluted to OD<sub>600</sub> 0.2 into minimal medium without biotin and incubated at 30°C (*C. albicans*) or 37°C (*C. glabrata*) at 180 rpm for 4 and 24 h. The cells were harvested and mechanically lysed in PBS-KMT (PBS + 3 mM KCl, 2.5 mM MgCl<sub>2</sub>, 0.1% Triton-X-100) + protease inhibitor cocktail (Roche) with acid-washed glass beads by bead beating in a Precellys 24 homogenizer (Peqlab; 6.500 rpm, 2 cycles, each 30 sec, 30 sec pause). The lysate was centrifuged (14,000 rpm, 4°C for 5 min) and the protein concentration of the supernatant was determined by Pierce<sup>™</sup> BCA Protein Assay Kit (Thermo Fisher Scientific). Fifteen µg protein per condition and strain were denatured in one-fourth volume of 4× Lämmli buffer (125 mM Tris-HCl pH 6.8, 50% glycerol, 4% SDS, 0.02% bromophenol blue, 1:10 β-mercaptoethanol) at 95°C for 5 min and separated by denaturing SDS-PAGE with Rotiphorese<sup>®</sup> Gel 30 (final 8% acrylamide mix (Roth)). Proteins were electro-transferred to nitrocellulose membranes (Whatman) in blotting buffer (25 mM Tris, 192 mM glycine, 10% methanol and 0.1% SDS) and free binding sites were blocked with 5% milk powder in TBS (0.5 M Tris, 1.5 M NaCl, pH 7.6) + 0.05% Tween<sup>®</sup>20 (TBS-T) overnight. The membrane was incubated with Streptavidin-HRP (CST), which was diluted 1:4000 in TBS-T containing 2% BSA (Serva), and incubated for 2 h at room temperature and gentle shaking. The membrane was rinsed three times in TBS-T and two times in TBS, followed by chemiluminescence detection using Pierce<sup>™</sup> ECL Plus Western Blotting Substrate (Thermo Fisher Scientific) according to the manufacturer's instructions.

### 6.1.8 Construction of *Candida* mutant strains

#### 6.1.8.1 Mutagenesis strategy in *C. albicans*

All *C. albicans* mutants were generated in the Arg<sup>-</sup>, His<sup>-</sup>, and Ura<sup>-</sup>-auxotrophic parental strain background BWP17 using a PCR-based gene disruption strategy [444]. The detailed description of the construction of the *CaVHR1* and *CaBIO2-5* deletion mutants in *C. albicans* is enclosed in the Master thesis of Teresa Sofie Hartung [445]. The construction of the *CaVHT1* (CR\_03270WΔ/Δ) and *CaDUR1,2* (C1\_04660WΔ/Δ) deletion mutants is exemplarily depicted for *CaVHT1* (**Figure 13**) and described in **manuscript II** and **manuscript V**, respectively.

## Additional experimental procedures

**Figure 13: Gene mutagenesis and complementation in *C. albicans*, exemplary shown for *CaVHT1*.** (A) Left: Separate amplification of *HIS1* and *ARG4* deletion cassettes with long oligonucleotides from pFA-*HIS1* and pFA-*ARG4* [444], respectively. The gray overlapping sequences of the primers are homologous to the up- and downstream regions of the GOI. Middle: Structure of the GOI (*VHT1*) locus in the diploid parental strain BWP17. (B) Sequential deletion of both gene alleles by two subsequent transformations with *HIS1* and *ARG4* constructs and homologous recombination. (C) After correct gene deletion, the strain was either complemented with *URA3* by using the Clp10 plasmid [110] (non-auxotrophic mutant) or reconstituted with *URA3* and the GOI by cloning the GOI into Clp10. The black arrows indicate the location of primers used to verify the correct insertion in the transformed yeast cell.

The transformation protocol was adapted from [446]. Briefly, *C. albicans* cells from a stationary culture were adjusted to OD<sub>600</sub> 0.2 in 24 mL YPD medium and grown to exponential phase (until OD<sub>600</sub> 0.8 was reached) for 3-4 h at 180 rpm and 30°C. The cell suspension was harvested by centrifugation (5 min; 3,000g) and washed with 10 mL water resuspended in 500 µL TELiAc. In a new microcentrifuge tube, 10 µL of carrier DNA (UltraPure™ Salomon Sperm DNA Solution, Life Technology GmbH, boiled 10 min at 98°C prior to use and stored on ice), 1-10 µg of linearized DNA (plasmid DNA or PCR product) and 100 µL of *Candida* cells in TELiAc (1× TE, pH 7.4;

0.1 M lithium acetate) were mixed. Next, 600  $\mu$ L PEG/LiAc solution (40% PEG3350, 0.1 M lithium acetate, 1x TE) was added and mixed by pipetting gently up and down. The transformation mixture was incubated o/n at 30°C. On the next day, the DNA uptake was facilitated by the heat shock at 44°C for 15 min in the water bath followed by cooling on ice for 1 min. The cells were centrifuged (5 min; 6,000 rpm) and washed once with YPD medium. Finally, the cells were washed and resuspended in 450  $\mu$ L PBS and spread on three SD plates in equal proportions. The agar plates were incubated at 30°C for 2-4 days. Grown colonies were streaked on fresh plates and used for genomic DNA isolation. The correct integration of deletion and complementation cassettes was confirmed by PCR and Southern blot (**Figure 14-15**).

**Figure 14: Verification of *CaVHT1* deletion and complementation by Southern blot.** A *CaVHT1*-specific probe, generated by PCR using primers *Ca19.2397term Sonde fwd* (4/74) and *Ca19.2397term Sonde rev* (4/75) (product size: 199 bp). The high molecular genomic DNA was digested with *PstI*, giving different bands in strains with the native gene (*Ca wt* [BWP17]), heterozygous deletion mutant (*vht1Δ*), homozygous deletion mutant (*vht1Δ/Δ* Clp10) and complemented strains (*vht1Δ/Δ+VHT1*).

**Figure 15: Verification of *CaDUR1,2* deletion and complementation by Southern blot.** A *CaDUR1,2*-specific probe, generated by PCR using primers *CaDUR1,2*prom Probe fwd (5/28) and *CaDUR1,2*prom Probe rev (5/29) (product size: 236 bp). The high molecular genomic DNA was digested with *PsiI*, giving different bands in strains with the native gene (*Ca wt* [BWP17]), heterozygous deletion mutant (*dur1,2Δ*), homozygous deletion mutant (*dur1,2Δ/Δ* Clp10) and complemented strains (*dur1,2Δ/Δ+DUR1,2*; *dur1,2Δ/Δ+DUR1,2<sup>K→R</sup>*).

### 6.1.8.2 Mutagenesis strategy in *C. glabrata*

All *C. glabrata* mutants were generated in the parental strain background ATCC2001. Flanking homologous regions were cloned into pTS50 to construct a gene-specific *CgNAT1* deletion cassette [347]. The detailed description of the construction of the *CgVHR1* and *CgVHT1* deletion mutants is enclosed in the Master thesis of Stefanie Allert [320]. For gene complementation studies, the additional auxotrophic marker *CgTRP1* was chosen and requires a *CgTRP1* deletion background (**manuscript II and V**). Therefore, the deletion cassettes were amplified from existing *CgVHR1* and *CgVHT1* deletion mutants and transformed into *Cgtrp1Δ*, complemented either with *CgTRP1* or with *CgTRP1* together with the gene of interest at the native *CgTRP1* locus. The construction of the complementation plasmids is described in **manuscript II**. The *Cgdur1,2Δ* mutant (CAGL0M05533gΔ) was generated in the same way (described in **manuscript V**), as the *Cgdur1,2Δ* exists an triple-auxotrophic strain background [347].

The transformation protocol was adapted from [446]. Briefly, *C. glabrata* cells from a stationary culture were adjusted to OD<sub>600</sub> 0.2 in 50 mL YPD medium and grown to exponential phase (until OD<sub>600</sub> 0.8 was reached) for 3-4 h at 180 rpm and 37°C. The cell suspension was harvested by centrifugation (5 min; 3,000g). The cell pellet was first washed with 5 mL 1× TE and then with 5 mL TELiAc and finally resuspended in 500 μL TELiAc. Fifty microliter aliquots were either used directly or frozen at -80°C if needed and 5 μL of carrier DNA (UltraPure™ Salomon Sperm DNA Solution, Life Technology GmbH, boiled 10 min at 98°C prior to use and stored on ice) and 4 μg of PCR product were added. The transformation mixture was completed with 300 μL

Plate-Puffer (40% PEG3350 in TELiAc), mixed and incubated at 30°C for 30 min. The DNA uptake was facilitated by heat shock at 45°C for 15 min in the water bath followed by cooling on ice for 1 min. The cells were centrifuged (5 min; 6,000 rpm) and washed once with YPD medium. Dependent on the selection marker, the cells were additionally incubated for 3-4 h at 30°C and 180 rpm in 1 mL YPD to express the *NAT1* resistance gene. Finally, the cells were washed and resuspended in 450 µL PBS and spread on three YPD-NTC (250 µg/mL nourseothricin) or three SD plates dependent on the selection marker. The agar plates were incubated at 37°C for 1-3 days. The growth time is dependent on nutrient-rich (YPD) and nutrient-defined media (SD). Grown colonies were streaked on fresh plates and used for genomic DNA isolation.

**Figure 16: Gene mutagenesis and complementation in *C. glabrata*, exemplary shown for *CgVHR2*.** (A) Structure of the GOI (*VHR2*) and *TRP1* loci in the parental strain *trp1*Δ. (B) Deletion cassette construction by infusion cloning of up- and downstream homologous regions referring to the GOI into the 5' and 3' region of the *NAT1* cassette of pTS50 [347]. Red regions of the primer overlap with the pUC19 backbone and gene regions (green) overlap with the *NAT1* cassette. (C) Mutagenesis in *C. glabrata* is done by homologous recombination. After gene deletion, the strain was either complemented with *TRP1* alone (non-auxotrophic mutant) or reconstituted with *TRP1* and the GOI. The black arrows indicate the location of primers used to verify the correct insertion in the transformed yeast cell.

## Additional experimental procedures

The *CgVHR2* (CAGL0J03014g) deletion mutant was generated by flanking the barcoded *NAT1* cassette of *Cgfre8Δ* [314, 347] with *CgVHR2*-specific 5'- and 3'-flanks (701 bp upstream and 807 bp downstream) and integrating into an *Xba*I-linearized pUC19 vector using the Infusion HD Cloning Kit (Clontech). The plasmid was verified by control digest and sequencing. The deletion construct was amplified by PCR, purified with QIAquick PCR Purification Kit (Qiagen) and used for transformation of the *Cgtrp1Δ* parental strain. The *Cgvhr2Δ Cgtrp1Δ* mutant was verified by PCR.

For gene complementation, the coding sequence of *CgVHR2* together with the up- and downstream intergenic regions was inserted into p*CgTRP1* using the In-Fusion® HD Cloning Kit (Clontech) to generate p*CgTRP1-CgVHR2* and the correct plasmid was confirmed by sequencing. The tryptophan auxotrophy in the *Cgvhr2Δ Cgtrp1Δ* mutant was restored by transformation of PCR-amplified *CgTRP1* or *CgTRP1 + CgVHR2* cassettes to generate a non-auxotrophic mutant or gene complemented strain, respectively. All strains were verified by PCR and further analyzed by Southern blot (Figure 17-20).

**Figure 17: Verification of *CgVHR1* deletion and complementation by Southern blot.** A *CgVHR1*-specific probe, generated by PCR using primers *CgVHR1*-term Sonde new fwd (3/51) and *CgVHR1*-term Sonde new rev (3/52) (product size: 428 bp). The high molecular genomic DNA was digested with *A/Iel*, giving different bands in strains with the native gene (*Cg wt* [ATCC2001]; *trp1Δ*; *trp1Δ+TRP1*), deletion mutant (*vhr1Δ*) and complemented strains (*vhr1Δ+VHR1*).

**Figure 18: Verification of *CgVHT1* deletion and complementation by Southern blot.** A *CgVHT1*-specific probe, generated by PCR using primers *CgVHT1*-prom Sonde fwd (2/15) and *CgVHT1*-prom Sonde rev (2/16) (product size: 398 bp). The high molecular genomic DNA was digested with *PciI*, giving different bands in strains with the native gene (*Cg wt* [ATCC2001]; *trp1Δ*; *trp1Δ+TRP1*), deletion mutant (*vht1Δ*; *trp1Δ vht1Δ*) and complemented strains (*vht1Δ+VHT1*).

**Figure 19: Verification of *CgVHR2* deletion and complementation by Southern blot.** A *CgVHR2*-specific probe, generated by PCR using primers *CgVHR2* prom Sonde fwd (4/31) and *CgVHR2* prom Sonde rev (4/32) (product size: 413 bp). The high molecular genomic DNA was digested with *HindIII*, giving different bands in strains with the native gene (*Cg wt* [*trp1Δ+TRP1*]), deletion mutant (*vhr2Δ*; *trp1Δ vhr2Δ*) and complemented strains (*vhr2Δ+VHR2*).

## Additional experimental procedures

**Figure 20: Verification of *CgDUR1,2* deletion and complementation by Southern blot.** A *CgDUR1,2*-specific probe, generated by PCR using primers *CgDUR1,2*prom Probe fwd (5/48) and *CgDUR1,2*prom Probe rev (5/49) (product size: 276 bp). The high molecular genomic DNA was digested with *KpnI*, giving different bands in strains with the native gene (*Cg wt* [*trp1Δ*+*TRP1*]), deletion mutant (*dur1,2Δ*; *trp1Δ dur1,2Δ*) and complemented strains (*dur1,2Δ*+*DUR1,2*; *dur1,2Δ*+*DUR1,2*<sup>K→R</sup>).

### 6.1.9 Alkalinization assay and ammonia quantification

The alkalinization assay on solid agar was adapted from [283]. Briefly,  $1 \times 10^5$  *Candida* cells were spotted onto agar (0.69% YNB without amino acids, ammonium sulfate and biotin (Formedium); 20 mg/L phenol red; 1% casamino acids; 0.5% allantoin; 2% oxoid agar; initially adjusted to pH 4.5 with HCl) in a 12-well plate and incubated at 37°C for 48-72 h. The quantification of volatile ammonia released from *Candida* cells was adapted from [283, 447]. Briefly, an acidic trap consisting of 100  $\mu$ L of 10% citric acid was placed underneath the colonies in the lid of an inverted 12-well plate. After 24 to 72 h incubation, the acidic trap was removed and the ammonia was quantified by adding 160  $\mu$ L of Nessler's reagent to 40  $\mu$ L diluted sample. Ammonia was calculated with the help of a standard curve of eight dilutions of an ammonium chloride solution (500  $\mu$ g/mL). Heat killed *Candida* cells (70°C, 30 min) were included as negative control.

### 6.1.10 Macrophage experiments

For all macrophages, primary human monocyte-derived macrophages were used and isolated and differentiated like previously described.

#### 6.1.10.1 Phagocytosis assay

Macrophages ( $1.5 \times 10^5$  M $\Phi$ ) were allowed to adhere onto coverslips in a 24-well plate overnight at 37°C and 5% CO<sub>2</sub> in RPMI + 10% FBS and 50 ng/mL rh M-CSF. On the next day, macrophages were washed twice with RPMI and finally 250  $\mu$ L RPMI were added. Stationary phase yeast cells were washed, stained with 0.2 mg/mL FITC for 30 min in carbonate buffer (0.15 M NaCl, 0.1 M Na<sub>2</sub>CO<sub>3</sub>, pH 9.0) and adjusted to  $1.2 \times 10^6$  *Candida*/mL in cold RPMI and the macrophages were infected with 250  $\mu$ L yeast suspension to get an MOI of 2. Phagocytosis was synchronized for 30 min on ice. Afterwards, unbound *Candida* cells were removed by two washing steps with pre-warmed RPMI and finally 500  $\mu$ L RPMI were added and the infected macrophages were incubated at 37°C and 5% CO<sub>2</sub> for 1 h. Phagocytosis was stopped by two washing steps with PBS, adding 300  $\mu$ L Roti®-Histofix 4%, and infected macrophages were stained with 50  $\mu$ g/mL Concanavalin A conjugated with Alexa Fluor™ 647 (ConA-AF647; Thermo Fisher Scientific) at 37°C for 30 min to visualize external *Candida* cells. Coverslips were mounted with Mowiol mounting medium and fluorescence images were recorded using the Zeiss AXIO Observer.Z1 (Carl Zeiss Microscopy).

#### 6.1.10.2 Cytokine and chemokine measurements

Macrophages ( $2 \times 10^5$  M $\Phi$ ) were allowed to adhere in a 24-well plate overnight at 37°C and 5% CO<sub>2</sub> in RPMI + 10% FBS and 50 ng/mL rh M-CSF. On the next day, macrophages were washed twice with RPMI and finally 400  $\mu$ L RPMI were added. Stationary phase yeast cells were washed and adjusted to  $4 \times 10^6$  and  $1 \times 10^7$  *Candida*/mL in cold RPMI and the macrophages were infected with 100  $\mu$ L yeast suspension to get an MOI of 2 or 5, respectively. For comparison, macrophages were stimulated with 1  $\mu$ g/mL LPS (positive control; from *E. coli* O55:B5, Sigma) or only RPMI (medium control). After 24 h incubation at 37°C and 5% CO<sub>2</sub>, infected macrophages were centrifuged (300g, 10 min), the supernatant was collected in micro-centrifuge tubes and stored at -80°C until measurement. The release of IL-1 $\beta$ , IL-6, IL-8, and TNF- $\alpha$  was quantified using commercial eBioscience™ ELISA Ready-SET-Go!™ kits according to the manufacturer's instructions. The supernatants defrosted on ice, were diluted appropriate in 1 $\times$  assay diluent.

## 6.2 Abbreviations

AA	amino acids – not specified
Amp	ampicillin
AS	ammonium sulfate
ATP	adenosine triphosphate
BBB	blood brain barrier
BLAST	basic local alignment search tool
bp	base pair
BSA	bovine serum albumin
bZIP	basic leucine zipper
C-	carbon-
CAA	casamino acids
cfu	colony forming units
CGD	<i>Candida</i> genome database
Clp10	<i>Candida</i> Integration plasmid 10
CLRs	C-type lectin receptors
ConA	Concanavalin A
CUG	stands for the nucleobases: cytosine, uracil, guanine
DAPA	7,8-diaminopelargonic acid
DCs	dendritic cells
DNA	deoxyribonucleic acid
ddH <sub>2</sub> O	double distilled water
DIG	digoxigenin
dNTPs	desoxynucleotide triphosphate
DTB	desthiobiotin
EDTA	ethylenediaminetetraacetic acid
<i>e.g.</i>	latin: <i>exempli gratia</i> , for example
ELISA	enzyme-linked immunosorbent assay
FBS	fetal bovine serum
FITC	fluorescein isothiocyanate
GPI	glycosylphosphatidylinositol
GOI	gene of interest
HK	heat-killed
HIV	human immunodeficiency virus
HRP	horse radish peroxidase
IFN- $\gamma$	interferon gamma
IL-1 $\beta$	interleukin 1 beta
IL-4	interleukin 4
IL-6	interleukin 6
IL-8	interleukin 8
KAPA	8-Amino-7-oxononanoic acid
LB	lysogeny broth
LDH	lactate dehydrogenase
LPS	lipopolysaccharide
M $\Phi$	macrophages
MCT1	monocarboxylate transporter 1
M-CSF	macrophage colony-stimulating factor
MDMs	monocyte-derived macrophages
MPO	myeloperoxidase
MOI	multiplicity of infection
N-	nitrogen-
NAC	non- <i>albicans</i> <i>Candida</i>

## Abbreviations

---

NADPH	Nicotinamide adenine dinucleotide phosphate hydrogen		
NTC	nourseothricin		
NOD	Nucleotide-binding oligomerization domain		
OD	optical density		
ORF	open reading frame		
o/n	overnight		
PAMPs	pathogen associated molecular patterns		
PBS	phosphate buffered saline		
PCR	polymerase chain reaction		
PEG	polyethylene glycol		
pH	latin: <i>potentia hydrogenii</i>		
p.i.	post infection		
PMNs	polymorphonuclear		
PRRs	pattern recognition receptors		
rh	recombinant human		
RIGI	retinoic-acid-inducible gene I		
RLRs	RIGI-like receptors		
RNA	ribonucleic acid		
RNS	reactive nitrogen species		
ROS	reactive oxygen species		
rpm	rotations per minute		
RPMI	Roswell Park Memorial Institute		
RT	room temperature		
Saps	secretory aspartic proteases		
SD	synthetic defined		
SDS	sodium dodecyl sulfate		
SILAC	stable isotope labeling with amino acids		
SMVT	sodium dependent multivitamin transporter		
spp.	species		
SSC	sodium chloride sodium citrate		
<i>Taq</i>	<i>Thermus aquaticus</i>		
TBS(-T)	Tris-buffered saline (with 0.05% Tween <sup>®</sup> 20)		
TE	Tris-EDTA		
TELiAc	Tris-EDTA lithium acetate		
Th1	T helper cells, type 1		
Th17	T helper cells, type 17		
Th2	T helper cells, type 2		
TLRs	toll-like receptors		
T <sub>m</sub>	melting temperature		
TNF- $\alpha$	tumor necrosis factor alpha		
Tris	tris(hydroxymethyl)aminomethane		
WBC	whole blood count		
WGD	whole genome duplication		
Wt	wild type		
w/	with		
w/o	without		
YNB	yeast nitrogen base		
YPD	yeast	peptone	dextrose

### 6.3 List of publications

- 2020      **Fungal biotin homeostasis is essential for immune evasion after macrophage phagocytosis and virulence.**  
**Sprenger M**, Hartung TS, Allert S, Wisgott S, Niemiec JM, Graf K, Jacobsen ID, Kasper L, Hube B. *Cell Microbiol.* 2020 Feb 21:e13197. doi: 10.1111/cmi.13197. [Epub ahead of print]
- Phagocytic predation by the fungivorous amoeba *Protostelium aurantium* targets metal ion and redox homeostasis**  
Radosa S, Sprague JL, Tóth R, Wolf T, **Sprenger M**, Brunke S, Linde J, Panagiotou G, Gácsér A, Hillmann F. *Cell Microbiol.* under revision, bioRxiv preprint doi: <https://doi.org/10.1101/690503>
- 2019      **RNAi as a Tool to Study Virulence in the Pathogenic Yeast *Candida glabrata*.**  
Ishchuk OP, Ahmad KM, Koruza K, Bojanovič K, **Sprenger M**, Kasper L, Brunke S, Hube B, Säll T, Hellmark T, Gullstrand B, Brion C, Freel K, Schacherer J, Regenber B, Knecht W, Piškur J. *Front Microbiol.* 2019 Jul 24;10:1679. doi: 10.3389/fmicb.2019.01679. eCollection 2019.
- 2018      **Metabolic adaptation of intracellular bacteria and fungi to macrophages.**  
**Sprenger M**, Kasper L, Hensel M, Hube B. *Int J Med Microbiol.* 2018 Jan;308(1):215-227. doi: 10.1016/j.ijmm.2017.11.001. Epub 2017 Nov 7.
- 2017      **A functional link between hyphal maintenance and quorum sensing in *Candida albicans*.**  
Polke M, **Sprenger M**, Scherlach K, Albán-Proaño MC, Martin R, Hertweck C, Hube B, Jacobsen ID. *Mol Microbiol.* 2017 Feb;103(4):595-617. doi: 10.1111/mmi.13526. Epub 2016 Oct 11.
- 2016      **Acid Sphingomyelinase Promotes Endothelial Stress Response in Systemic Inflammation and Sepsis.**  
Chung HY, Hupe DC, Otto GP, **Sprenger M**, Bunck AC, Dorer MJ, Bockmeyer CL, Deigner HP, Gräler MH, Claus RA. *Mol Med.* 2016 Sep;22:412-423. doi: 10.2119/molmed.2016.00140. Epub 2016 Jun 15.

### 6.4 Posters and talks

#### Posters

- 2015      The role of biotin in *Candida glabrata* – macrophage interaction and virulence. SPP 1580 National Meeting, April 19 - 22, 2015 in Bonn, Germany

## Publications, talks and poster

---

- The role of biotin in *Candida glabrata* – macrophage interaction and virulence. 49. Wissenschaftliche Jahrestagung der Deutschsprachigen mykologischen Gesellschaft (DMyKG), September 16 - 19, 2015 in Jena, Germany
- 2016      The role of biotin in *Candida glabrata* – macrophage interaction and virulence, Annual Conference 2016 of the Association for General and Applied Microbiology (VAAM). March 13 - 16, 2016 in Jena, Germany
- The role of biotin in *Candida glabrata* – macrophage interaction and virulence, 5<sup>th</sup> Central European Summer Course and and the 2<sup>nd</sup> Rising Stars in Mycology Workshop. July 2 - 8, 2016 in Szeged, Hungary
- 2017      Fungal biotin homeostasis is crucial for intracellular fitness within macrophages. Gordon Research Seminar and Conference, Immunology of Fungal Infections. January 14 - 20, 2017 in Galveston, Texas, USA
- Fungal biotin homeostasis is crucial for intracellular fitness within macrophages. 12th Symposium of the VAAM Special Group Biology and Biotechnology of Fungi. Molecular Biology of Fungi. September 28 - 30, 2017 in Jena, Germany

### Scientific talks

- 2020      Biotin acquisition is crucial for immune evasion, *in vivo* persistence and virulence of *Candida glabrata* and *C. albicans*. Statusworkshop der DGHM-Fachgruppe „Eukaryontische Krankheitserreger“. February 6 - 8, 2020 in Innsbruck, Austria
- 2018      Fungal biotin homeostasis is crucial for intracellular fitness within macrophages. 14<sup>th</sup> ASM Conference on *Candida* and *Candidiasis*. April 15 - 19, 2018 in Providence, Rhode Island, USA
- Fungal biotin homeostasis is crucial for intracellular fitness within macrophages. 52. Wissenschaftliche Tagung der Deutschsprachigen Mykologischen Gesellschaft (DMyKG). September 6 - 8, 2018 in Innsbruck, Austria
- 2015      The role of *Candida albicans EED1* in Quorum sensing. Statusworkshop der DGHM-Fachgruppe „Eukaryontische Krankheitserreger“. February 26 - 27, 2015 in Erlangen, Germany

## 6.5 Supervision and public related activities

- 2016            Practical course “Molecular & Microbial Infection Biology” for Master Biochemistry July 11 - 22, 2016
- 2016 - 2018    Supervision Master Thesis Teresa Sofie Hartung
- 2018            Contribution to the “Forsche-Schüler Tag”, HKI Jena, April 26, 2018
- 2019            Contribution to the Long Night of Science, HKI Jena, November 22, 2019

## 6.6 Travel grant and awards

- Picture award of DMykG (1<sup>st</sup> place), 48. Wissenschaftliche Tagung der Deutschsprachigen Mykologischen Gesellschaft (DMykG) e. V., September 4 - 6, 2014 in Salzburg, Austria.
- Travel grant at Microbiology and Infection - 4<sup>th</sup> Joint Conference of DGHM and VAAM, October 5 – 8, 2014 in Dresden, Germany
- Travels grant at 14<sup>th</sup> ASM Conference on Candida and Candidiasis 2018, April 15 - 19, 2018 in Providence, Rhode Island, USA.
- Picture award of DMykG (2<sup>nd</sup> place), 53. Wissenschaftliche Tagung der Deutschsprachigen Mykologischen Gesellschaft (DMykG) e. V., September 5 - 7, 2019 in Mannheim, Germany.

## Selbstständigkeitserklärung

---

### **Selbstständigkeitserklärung**

Hiermit erkläre ich, dass ich die vorliegende Arbeit selbst verfasst habe und keine anderen als die angegebenen Quellen und Hilfsmittel verwendet habe. Mir ist die geltende Promotionsordnung der Fakultät für Biowissenschaften der Friedrich-Schiller-Universität Jena bekannt. Personen, die mich bei den Experimenten, der Datenanalyse und der Verfassung der Manuskripte unterstützt haben, sind als Ko-Autoren auf den entsprechenden Manuskripten verzeichnet. Personen die mich bei der Verfassung der Dissertation unterstützt haben, sind in der Danksagung der Dissertation vermerkt. Die Hilfe eines Promotionsberaters wurde nicht in Anspruch genommen. Es haben Dritte weder unmittelbar noch mittelbar geldwerte Leistungen für Arbeiten erhalten, die im Zusammenhang mit dem Inhalt der vorgelegten Dissertation stehen. Die vorliegende Arbeit wurde in gleicher oder ähnlicher Form noch bei keiner anderen Hochschule als Dissertation eingereicht und auch nicht als Prüfungsarbeit für eine staatliche oder andere wissenschaftliche Prüfung verwendet.

Jena, den 29.05.2020

Marcel Sprenger
